CONTENTS

The abstracts are numbered by microsymposium and by category. Contributed posters submitted for microsymposia sessions are included with the abstracts for that microsymposium. Other contributed posters are listed under a general category (01-27). Each category has a collection of sub-categories, and while the abstract numbering scheme does not retain these, abstracts on similar topics have been kept together as far as possible, within the constraints of the complexity of the programme and the space limitations in the poster sessions.

KEYNOTE LECTURES

MICROSYMPOSIA

CATEGORIES

KEY TO THE ABSTRACT CODE NUMBERS

The abstract code numbers are constructed as follows:

[1] An initial letter indicating the presentation type:

K = Keynote Lecture
M = Microsymposium Oral Presentation
P = Poster Presentation
C = Open Commission Meeting
JMR = Monteath-Robertson Symposium

[2] Two digits indicating the date in August when the presentation is scheduled.

[3] Two digits equating to a particular session or category.

This code is either the last two digits of the Microsymposium session
OR
The Main Category code.

[4] Three digits indicating the sequence number of:

A talk within a Microsymposium session
OR
A poster within a group of related posters.

For example:

P05.OC.xxx would represent a poster presented on August 5th as part of the Microsymposium 05OC "Physical Properties and Structural Relationships",

while:

P11.05.xxx would represent a poster presented on August 5th in Category 04 "Crystallography of Biological Macromolecules",

and:

M05.DD.xxx would represent a talk delivered on August 5th in the Microsymposium 05DD "Optimisation Methods"

whereas:

C08.JR.xxx would represent a talk delivered on August 8th in the Open Commission Meeting for Journals.

KEYNOTE LECTURES

K05.01.001 CRYSTALLOGRAPHIC ASPECTS OF FERROELECTRIC THIN-FILM MEMORIES. J. F. Scott, School of Physics, University of New South Wales, Sydney 2052, Australia

Ferroelectric thin films are being utilized as capacitors in dynamic random access memories (DRAMs), where their large dielectric permittivities permit a size reduction of x100 compared with silicon dioxide, and as the memory elements themselves in non-volatile RAMs, where the plus and minus polarization states record "1" or "0" in the Boolean algebra of digital computers. This talk reviews subtle aspects of crystal structure in the thin films, and the relationship between electrical performance (leakage current, breakdown fields, switching time) and that structure. Emphasis is placed upon lead zirconate titanate (PZT), barium strontium titanate (BST), and strontium bismuth tantalate-niobate (SBT). Processing of these materials goes through intermediate phases (pyrochlore and defect-fluorite), and EXAFS data from Tsukuba are used to elucidate the latter.

K05.02.001 NUCLEOSOMES. Timothy J. Richmond, ETH Zürich, Institut für Molekularbiologie und Biophysik, ETH-Hönggerberg, CH-8093, Switzerland.

The nucleosome is the universal, repeating element of chromatin and responsible for the two most fundamental levels of DNA organisation within the eukaryotic cell nucleus. The DNA packaging it provides represses gene transcription generally while being intimately involved in gene-specific activation through reversible modification (e.g. acetylation) and major structural alteration (i.e. chromatin remodelling). The nucleosome core particle comprises an octameric protein assembly containing two copies of each of the four core histones, H2A, H2B, H3, and H4, and a roughly equal mass of DNA in 147 bp. Compared to the nucleosome, the core lacks only the relatively short linker DNA connecting nucleosomes and its associated histone H1. The X-ray crystal structure of the nucleosome core particle provides substantial insight into chromatin structure-function relationships, as will be presented. In addition to the protein and DNA components first seen at 2.8 Å resolution1, the atomic structure refined using data to 2.0 Å permits the reliable location of nearly 1,000 water molecules and ions in the electron density map. Comparison of high resolution structures incorporating different DNA sequences reveals the general similarity of DNA conformation imposed by the histone octamer.

K05.03.001 SOLID-STATE REACTIONS. E.V. Boldyreva, Institute of Solid State Chemistry and Mechanochemistry SB RAS, Kutateladze, 18, Novosibirsk, 128, 630128 Russia, email elena@solid.nsk.su.

Several aspects of the interrelations between the structures of crystals and their chemical reactivity are considered and various possibilities of applying crystallography to studying solid-state reactivity are discussed. The main emphasis is made on the following topics:

- solution and solid-state reactions: what is common and what is different;
- the interplay between *intra*- and *inter*molecular interactions in reactions in molecular solids;
- cooperative effects in solid-state reactivity;
- the role of stresses, strain and structural relaxation in solid-state reactions;
- possible applications of variable-temperature and high-pressure crystallography to studying solid-state reactivity;
- inorganic and organic solid-state reactions: what is common and what is different.

K05.04.001 MOLECULAR MECHANISM OF MUSCLE CONTRACTION. K.C. Holmes, Dept. of Biophysics, Max Planck Institute for Medical Research, Jahnstrasse 29, 69120 Heidelberg, Germany

Muscle contains two sets of intedigitating filaments (thick and thin) containing the proteins myosin and actin. The filaments move past each other through the cyclical interaction of the myosin "cross-bridges" with the actin (thin) filaments. Concomitantly, ATP is hydrolyzed. Crystallographic studies have revealed two conformers of the cross bridge, OPEN and CLOSED. Initially, Rayment et al. showed the myosin cross bridge to be pear-shaped, with an elongated head (known as the "motor domain") consisting of a 7-stranded β sheet and a C-terminal neck (or "lever arm"). There is a deep cleft extending from the nucleotide binding site to the actin binding site. The active site, which contains a P-loop and switch 1 and switch 2 regions similar to those found in the G-proteins is relatively OPEN. The C-terminal neck which connects to the thick filament, forms an extended a-helix which binds two calmodulin-like "light chains". The neck is joined onto the motor-domain via a small compact domain called the "converter". EM studies of the actin-myosin complex show that the neck can function as a lever arm. More recent crystallographic studies by Rayment's group using a truncated form of the cross-bridge without the neck but with a number of nucleotide analogues bound in the active site reveal a second conformation of myosin differing in the position of the switch 2 region. This movement closes the active site around the γ-phosphate. It is coupled with a large movement of the converter domain (a 60° rotation). We have also obtained this structure but with ADP.BeF3 in the active site. Carolyn Cohen's group have now shown that this CLOSED conformation can be also be obtained with the neck present. Comparing the two myosin structures shows that the distal end of the neck (as seen from actin in the actin-myosin complex) would move about 11.0nm along the actin filament in response to the opening and closing of the active site. Myosin appears to transport actin by switching between these two states. In the CLOSED form the neck or lever arm is at the beginning of its stroke whereas in the OPEN form it is at the end of the stroke. The transition CLOSED to OPEN enables release of the γ-phsphate which drives the reaction. The preference for OPEN or CLOSED is also controlled actin binding probably via the cleft by a mechanism yet to be discovered.

K06.01.001 THE IMPACT OF POWDER DIFFRACTION ON MATERIALS SCIENCE. D. E. Cox, Physics Department, Brookhaven National Laboratory, Upton, NY 11973, USA.

In the past two decades, materials science has evolved into a scientific discipline in its own right, while still retaining a very close interdisciplinary relationship with the more traditional areas of condensed matter physics and chemistry, engineering, metallurgy, ceramics and, more recently, biological and environmental sciences. Typical stages in materials research are synthesis and processing, characterization of structure and

properties, advanced development aimed at optimization of the desired property, and integration into some sort of product or process. Laboratory powder diffraction techniques play a major role during the synthesis stage, providing vital feedback about the phase equilibria and reaction kinetics, and frequently enabling novel phases to be identified, a procedure which nowadays is greatly facilitated by the availability of extensive data bases and powerful search-and-match software. Powder diffraction is also widely used for the characterization of structures and structure-property relationships, and in many cases during the optimization stage. In this context, high-resolution synchrotron x-ray and neutron techniques enable information about structure and microstructure to be obtained at hitherto unattainable levels of detail, and are playing an increasingly important role in materials research.

Powder diffraction has made a very significant impact in a great many areas of materials science, especially in the more basic aspects of this research. The list includes high Tc superconductors, magnetic materials, ferro- and piezoelectrics, electro-optic materials, battery electrodes, hydrogen storage, ceramics, catalysts and molecular sieves, polymers and biominerals, and two recent additions; colossal magnetoresistive materials and novel thermoelectrics. A few examples will be discussed in detail to illustrate the role played by powder diffraction.

Work supported by the U.S. Department of Energy, Division of Materials Sciences, under contract DE-AC02-98CH10886.

K06.02.001 MEMBRANE PROTEIN STRUCTURE, AN EXCITING FRONTIER. Johann Deisenhofer, Howard Hughes Medical Institute, University of Texas Southwestern Medical Center, Dallas, Texas 75235-9050, USA

New three-dimensional structures of integral membrane proteins have appeared at a very low rate, indicating that this class of proteins has remained a major challenge for structural biologists. Obviously, the biological importance of membrane proteins demands that we do better. I will briefly discuss the main technical obstacles and attempts at finding ways to overcome them. I will also give an overview of recent significant progress.

K06.03.001 X-RAY STANDING WAVE TECHNIQUE - STRUCTURE-SENSITIVE SURFACE SPECTROSCOPY. M.V.Kovalchuk, Institute of Crystallography RAS, Leninsky pr. 59, 117333 Moscow, Russia

When X-ray irradiates condensed matters we register either elastic reflected beam (diffraction) or yield of secondary (non-elastic) radiations (photo- and Auger-electrons, characteristics fluorescence, etc.), these data provide spectral surface information (spectroscopy). X-ray diffraction methods possessing unique structural sensitivity, in standard geometry provide information only for rather large volumes of studied sample and do not permit to check structural position of concrete atoms and individual sublattices. Spectroscopy studies which permit to study composition and electron properties of surface and of thin layers due to small escape depth of secondary radiations yield, never provide information on structural position of the atom, secondary radiation of which we measure. X-ray standing wave method combines these two approach advantages. Spectroscopy methods obtain structural sensitivity and X-ray diffraction methods obtain surface sensitivity with spectral selectivity. Report concerns physical basis of X-ray standing wave method: formation and behavior of interference wave fields in various condensed matters for various geometry of scattering and diffraction. Report describes various ways to generate X-ray standing wave field of practically any period (from tenth parts of angstrom up to thousand of microns) are studied, they are based on application of two- and multi beam diffraction, total external reflection, wave-guide structures, multi layered synthetic microstructures. Possibilities of method are demonstrated by experiments made at both standard X-ray sources and with SR application.

K06.04.001 CRYO-ELECTRON MICROSCOPY OF SINGLE PARTICLES: THE STRUCTURE OF THE *E.COLI* RIBOSOME. M. van Heel[1], H. Stark[2], A. Patwardhan[1], R. Matadeen[1], E.V. Orlova[1], T. Pape[1], B. Gowen[1], M. Rodnina[3], R. Brimacombe[4], W. Wintermeyer[3]. [1] Imperial College, Department of Biochemistry, London SW7 2AY, UK. [2] Institut für Molekularbiologie und Tumorforschung, Emil-Mannkopff. Str. 2, D-35037 Marburg, Germany. [3] Institut für Molekularbiologie, Universität Witten, D-58448 Witten, Germany. [4] Max-Planck-Institut für Molekulare Genetik, D-14195 Berlin, Germany.

Electron microscopy of individual non-crystallized macromolecules (single particles) is a very rapid technique for probing the three-dimensional (3D) structure of biological macromolecules. By exploiting the different orientations of the macromolecules in the embedding medium, one may extract 3D information from the data without ever collecting tilt series in the microscope.

The ribosome can be blocked in different phases of the elongation cycle by antibiotic interaction; tRNAs or elongation factors (EF-Tu, EF-G) can be bound to their respective binding sites on the ribosome. Thus many functional states of the ribosome which are only milliseconds apart from each other within the functional time scale can be studied. Recently, the structures of the *E.coli* 70S ribosome in their pre- and post-translocational states have been solved at a level of ~20Å and the positions of the tRNA molecules have been visualised and clearly identified. The structure of the kirromucin-stalled ribosome has also been determined to a resolution of 18Å and has now been refined to 13Å. The analysis of these structures is necessary in order to gain structural insight into protein synthesis, which is of immense importance for the understanding of ribosomal function at the molecular level.

K07.01.001 POLYMORPHISM: THE SAME YET DIFFERENT. Jack D. Dunitz, Organic Chemistry Laboratory, Swiss Federal Institute of Technology, ETH-Zentrum, CH-8092 Zurich, Switzerland.

Polymorphism is the ability of a compound to crystallise in more than one distinct crystal structure. Once regarded as something of a rarity, it is now known to occur extensively, and possibly even ubiquitously. Polymorphs can differ markedly in physical properties — solubility, colour, hardness, etc. — but they differ only slightly in thermodynamic stability. Relative stabilities involve both enthalpic and entropic contributions to the Gibbs free energy and are thus temperature and pressure dependent. For organic crystals, where intermolecular interactions are weak, lattice energy calculations for "virtual" crystal structures of a given compound suggest that many polymorphs may be possible within a narrow energy window. This is one of the factors that makes crystal structure prediction so precarious. Moreover, the crystallization process is not under thermodynamic control, so the polymorph obtained by crystallization from the melt or from solution is not necessarily the most stable one under the given conditions. Transformation to the stable form may occur spontaneously or may be extremely slow, depending on the presence of seeds or crystal defects. The nucleation step is presumably rate limiting but there is at present no general theory of this process.

K07.02.001 X-RAY IMAGING: FROM AMPLITUDE TO PHASE. W. Thomlinson, European Synchrotron Radiation Facility, BP 220, F-38043 Grenoble, France.

Mammography, like all standard medical x-ray imaging technologies, relies primarily on the amplitude properties of x-rays, and does not depend on the phase. This is unchanged since the discovery by Roentgen that the intensity of an x-ray beam, as measured by the exposure on a film, was related to the relative transmission properties of an object. However, various imaging techniques have emerged which depend on the phase of the x-rays as well as the amplitude. Phase becomes important when the beam is coherent and the imaging system is sensitive to interference phenomena. Significant new advances have been made which now promise phase information in medical imaging.

The development of perfect crystal optics and the increasing availability of synchrotron radiation facilities have contributed to a significant increase in the application of phase based imaging in materials and life sciences. Topography has become a significant research and development tool, phase contrast imaging has been applied in both projection and computed tomography modes, and recent applications have been made in the field of medical imaging. A new application to mammography is based on a combination of phase and amplitude information. It has been called Phase Radiography [1] and Diffraction Enhanced Imaging [2]. These applications are significant in the field of medicine because they are applied to highly absorbing systems such as those presented in mammography.

This talk will present a look at the various amplitude and phase dependent imaging techniques, and conclude with a presentation of recent work on Diffraction Enhanced Imaging applied to mammography.

K07.03.001 DIFFUSE SCATTERING. T.R. Welberry, Research School of Chemistry, A.N.U, Canberra, ACT 0200, Australia

Conventional crystal structure analysis of disordered materials using Bragg diffraction data reveals only average one-body structural information, such as atomic positions, thermal ellipsoids and site occupancies. Diffuse scattering, on the other hand, gives two-body information and is thus potentially a rich source of information on how atoms and molecules interact with each other. However, although the presence of diffuse scattering has been known since the earliest days of X-ray crystallography, extracting such information from it is still a far from routine process and quantitative studies are rare. One of the reasons for this has certainly been, until relatively recently, that the intensity levels of diffuse scattering are typically several orders of magnitude lower than for the Bragg peaks, making measurement both difficult and time-consuming. Modern developments in X-ray sources (synchrotrons) and detectors (linear-detectors, area-detectors, image plates) have enormously increased the capability for measuring such weak data and this aspect of the field of study, though still presenting challenges, is no longer the limiting factor.

The greater challenges occur in the interpretation and analysis of diffuse scattering. Traditional approaches, developed largely in the field of alloys and simple oxides, present insurmountable difficulties when systems become more complex or when the magnitudes of atomic displacements become relatively large. More recently, progress has been made in an alternative approach to understanding the local atomic and molecular arrangements in disordered materials, which overcomes some of these difficulties[1]. The method consists of comparing diffraction patterns calculated from a computer model of the disordered structure with measured X-ray diffuse intensities. The advantage of the method is that it can be applied generally to all systems regardless of their complexity or the size of the atomic displacements that might be present. The computer models are generated using real-space Monte Carlo methods which employ near-neighbour effective interactions. The only requirement is the specification of the model in terms of sufficiently few parameters which nevertheless adequately describe the local physics and chemistry.

[1] T.R.Welberry & Th. Proffen (1998), Acta Cryst., A54, 661-674.

K07.04.001 CHAPERONIN ASSISTED PROTEIN FOLDING; THE FINAL STEP IN GENETIC EXPRESSION. Paul B. Sigler, Zhaohui Xu and Lingling Chen HHMI, Yale University, 260 Whitney Ave., MB&B Dept., New Haven, CT 06511

The transmission of information from the gene to its functional protein product involves two template guided polymerization steps followed by a spontaneous folding/assembly process. To achieve the accuracy and rates required to sustain life, the polymerization steps require proofreading and editing mechanisms to mitigate unavoidably high error rates. The energy for these error-correcting steps is supplied by nucleoside triphosphates.

Molecular chaperonins proofread and edit the final step in gene expression, protein folding. The lethality of defective chaperonin mutants indicates that this ATP-driven process is required in all cells as well as in protein synthesizing inclusions (chloroplasts and mitochondria). X-ray crystallographic structure analysis and functional studies of the bacterial chaperonin GroEL/GroES in various stages of its functional cycle have illuminated a remarkable "two-stroke engine" mechanism by which non-native peptides are entrapped, unfolded, refolded in a shielded environment and finally expelled. It is now clear how large allosteric changes within a obligatory double ring structure [seven subunits (eight in archaea and eukaryotes) per ring] execute cycles of peptide binding/folding/release with the quantized consumption of seven ATP molecules per cycle. The mechanism by which such a wide range of misfolded proteins are serviced by GroEL is revealed by recent work that shows oligopeptide segments with different sequences bound firmly with similar conformations to the same GroEL surfaces.

K08.01.001 CRYSTALLOGRAPHY AND THE LITHIUM-ION BATTERY. Josh Thomas, Inorganic Chemistry, Angstrom Laboratory, Uppsala University, Box 538, SE-751 21 Uppsala, SWEDEN.

One of the great technological success stories of recent years has been the Li-ion (and more recently the Li-ion polymer) battery, which is now capturing an ever-increasing fraction of the low-power battery market, especially in the cellular 'phone and lap-top sectors. By the same account, it can be stated that crystallography has indeed played a major role in this development, providing a solid basis for understanding and informed materials engineering in all parts of the battery. This will be illustrated here through a number examples taken from a current standard battery configuration: < graphite anode | polymer electrolyte | transition-metal oxide cathode >. A hallmark of much of the crystallographic work in the development of *electrode materials* has been the incisive use if *in situ* XRD and ND techniques in which the structural changes associated with lithium-ion insertion and extraction processes underlying electrochemical activity have been followed during cell cycling to acquire an intimitate sense of how best to modify structure to optimize cell performance. Such information has been combine with "battery engineering" type data describing the morphology of the composite electrodes (particle-size distribution, choice of

lithium salt, geometrical factors, etc.) to provide a holistic picture of cell function. At a more fundamental level, single-crystal electron density studies have also provided new insights into the subtle mech-anistic detail of redox processes related to lithium-ion insertion/extraction in transition-metal oxide systems. Perhaps somewhat surprisingly, crystallo-graphy has also been shown to play a most valuable - not to say decisive - role in the understanding of lithium-ion transport mechanisms in the *polymer electrolyte* : an impressive series of essentially X-ray "powder" diffraction studies of the system LiX.PEOn [PEO = poly(ethylene oxide)] has provided critical structural information relating to the local environment around the Li-cation and X-anion in a solid polymer electrolyte context. It is clear that the PEO backbone is able to take up a multitude of local conformations to accommodate both free ions and ion-pairs, as are known to occur in the more ionically conducting amorphous LiX.PEOn systems.

K08.02.001 SMALL RIBOZYME STRUCTURE AND MECHANISM. David B. McKay and Joseph E. Wedekind, Department of Structural Biology, Stanford University, Stanford, CA, 94305-5126, USA.

Several small ribozymes (RNA enzymes) which catalyze cleavage of phosphodiester bonds are known. Earlier crystallographic studies on the hammerhead ribozyme revealed a simple tertiary fold for the molecule, but failed to explain the mechanism of catalysis; significant conformational rearrangements of the observed structure must be required to reach the catalytic transition state [1,2]. More recently, we have solved the structure of a “leadzyme”, a Pb^{2+}-dependent ribozyme derived from *in vitro* selection experiments, at 2.7 Å resolution [3]. The crystallographic asymmetric unit accomodates two leadzyme molecules in different conformations, with different metal binding properties. These structures suggest a model for bond cleavage which incorporates both the metal binding properties and the apparent flexibility of the cleavage site of the leadzyme molecule.

K08.03.001 WATER STRUCTURES IN ICES AND CLATHRATES: THEME AND PRESSURE VARIATIONS. W.F.Kuhs and F. Gotthardt, MKI Universität Göttingen, Goldschmidstr.1, 37077 Göttingen, Germany, and C.Lobban and J.L.Finney, University College of London, Department of Physics and Astronomy, Gower Street, London WC1E 6BT, UK.

Both water ices and clathrate hydrates consist of three-dimensionally connected assemblies of H-bonded water molecules. Beside two distinct amorphous phases of water, at least thirteen different phases of ice and at least eleven different topologies of clathrate hydrates are known; some of these phases were only very recently identified. The richness of the phase diagram is mainly developed along the pressure axis in p-T-space. Detailed in-situ crystallographic studies on most of these phases have certainly confirmed the theme of tetrahedrality in H-bonded networks of water molecules. This theme, however, is modified in a multitude of variations which very nicely clarify the role of non-H-bonded water-water interactions. The variations of H-bond topologies and (partial) proton ordering indicate that there is a very delicate balance between enthalpic and entropic contributions to the free energy, with the appearance of a number of metastable crystalline phases especially in the pressure range between 0.3 and 1 GPa. Understanding this part of the phase diagram is one of the best possible tests for current models of water-water interactions.

K08.04.001 PROTEIN STRUCTURE MODELING IN THE ERA OF STRUCTURAL GENOMICS. John Moult, CARB, University of Maryland Biotechnology Institute, 9600 Gudelsky Drive, Rockville, MD 20850, USA

The prediction of the tertiary structure of protein molecules from amino sequence information has been a goal of computational biology for more than thirty years. Although we are still not able to compete with experiment, the field has advanced to the point where useful models can be obtained for many proteins. Three large scale, community wide experiments - known as CASP - have now been run to assess what can be done, and what the barriers are to doing more. The results of these experiments will be discussed, focusing on what has been learned about the nature of the problem, what the prospects are for finding universal solutions, and what role structure prediction can play in the era of structural genomics.

K09.01.001 SOLID STATE NMR AS A COMPLEMENTARY TECHNIQUE TO X-RAY DIFFRACTION. Colin A. Fyfe, Department of Chemistry, University of British Columbia, Vancouver, BC, Canada

Solid state NMR and x-ray diffraction have a basic complementary relationship: the former is sensitive to short range effects including ordering while the latter is sensitive to long range orderings and periodicities. In addition, the different time scales of the two experiments means that NMR can provide information on a variety of motions in the solid state not detectable by diffraction experiments giving an additional dimension to the 'structure'. In this lecture, we will review some of the relevant background to solid state NMR and then explore its application firstly to the investigation of various motional processes and subsequently in providing additional information in cases where diffraction studies are incomplete, for example where disorder exists. Lastly, we will describe its use in providing local structural information to aid in the refinement of powder data, including the application of the direct method approach.

K09.02.001 CHARGE DENSITY ANALYSIS AND BOND CHARACTERIZATION OF 3d-TRANSITION METAL COMPLEXES. Yu Wang, Department of Chemistry, National Taiwan University, Taipei, Taiwan ROC

Chemical bond, which makes molecules from independent atoms, is a very important concept in understanding the molecular behavior. Bond characterization is therefore becoming ever needed for predicting the physical and chemical properties of the molecule. The combined quantum mechanical calculation and accurate X-ray crystallography studies are extremely useful for characterizing the chemical bond precisely. Charge density analyses have been applied in terms of deformation density distribution, natural bond orbital analysis and the topological analysis on the total electron density. These analyses provide not only the molecular electron density distribution, but also the information such as bond order, bond type and atom domain in molecule. The complexity of the 3d orbital splitting subjected in the ligand field is well known, this makes the bonding characterization of 3d-transition metal complexes interesting and challenging. Charge density analysis on quite a few such complexes will be discussed systematically. Detail characterization of metal-ligand as well as intra-ligand bond will be described. The valence shell charge concentration (VSCC) of the third quantum shell around the metal ion will be demonstrated by the Laplacian topology, which provides the physical basis for the Lewis model and VSEPR. The great recent advance both in experiment and in theory has made the charge density analysis accessible to even more complicated system, for example, the molecule in its excited or metastable states.

K09.03.001 CRYSTALLOGRAPHY AND NONLINEAR OPTICS. Pamela Thomas, Department of Physics, University of Warwick, Coventry CV4 7AL, UK

Many of the most important materials used in the field of nonlinear optics are single crystals, either organic or inorganic. Therefore, the science of Crystallography has a vital contribution to make to this technologically-valuable field. The emphasis of the talk will be on the important role that an understanding of the crystal structures and physical properties plays in underpinning the device technologies based on these materials.

This talk will focus principally on the crystallography of inorganic crystals used for nonlinear optics. Following a brief review of the basic physics of nonlinear optics and the different types of non-centrosymmetric crystal structure that show significant nonlinear optical properties, the main body of the talk will deal with ferroelectric oxides, such as crystals of the $KTiOPO_4$ (KTP) family and $LiNbO_3$ (LN), which are under extensive research for the production of new optical devices in optics laboratories around the world. A review of many investigations of structure-property relationships in the KTP family, including optical and dielectric properties, structural pseudo-symmetry, twinning and disorder, and high- and low-temperature phase transitions, will be given. The technique of "periodic domain inversion" or "periodic-poling", by which a device architecture is created in a ferroelectric crystal by the introduction of an array of periodic inversion domains into the material, will be introduced and discussed with particular reference to LN and KTP. The role of high-resolution x-ray diffraction and x-ray imaging (including phase-contrast imaging) in characterizing periodically-poled arrays of inversion domains of periods 4-40 μm, will be demonstrated and the useful information concerning domain-wall width, for example, that can be extracted *via* such studies will be discussed. The talk will conclude with a look to the future for both Crystallography and crystals in the field of nonlinear optics.

K09.04.001 ACCURACY IN TRANSLATION: tRNA AND AMINO ACID RECOGNITION BY AMINOACYL-tRNA SYNTHETASES. S. Cusack, EMBL Grenoble Outstation, c/o ILL, 156X, 38042 Grenoble, FRANCE.

Similarities and differences in the modes of recognition of tRNAs and amino acids by their cognate aminoacyl-tRNA synthetases will be discussed with reference to crystal structures of substrate complexes of five Thermus thermophilus class II synthetases: seryl-, lysyl-, prolyl-, histidyl- and asparaginyl-tRNA synthetases.

The native ProRSTT structure has been determined at 2.4Å resolution and with proline bound, at 2.9Å resolution. Preliminary data on the complex of ProRSTT with cognate tRNA have been published at 3.5Å resolution [3]. New results on a ternary complex of ProRSTT with tRNApro and a prolyl-adenylate analogue at 2.85Å resolution will be presented. In addition a new structure of HisRSTT has been determined at 2.4Å resolution without any substrate bound whereas previously the structure was known with histidine and histidyl-adenylate bound [1]. The structure of AsnRS with an analogue of asparginyl-adenylate shows how discrimination between aspartic acid and asparagine is achieved [2].

These structures shed further light on (a) specific amino acid recognition (b) conformational changes associated with amino acid binding (c) the mechanism of amino acid activation (d) the mode of anti-codon recognition by the anti-codon binding domain in class IIa synthetases (e.g. ProRS) compared to class IIb synthetases (e.g. LysRS).

K11.01.001 STRUCTURE SOLUTION FROM POWDERS. C. Giacovazzo , A. Altomare, A. Guagliardi, A.G.G. Moliterni and R. Rizzi, Istituto di Ricerca per lo Sviluppo di Metodologie Cristallografiche, CNR, 70125 Bari, Italy, and G. Polidori, Dipartimento di Scienze della Terra, Università di Perugia, 06100 Perugia, Italy.

Crystal structure solution from powders data may play a central role in research and technology because it allows to investigate materials which are not available as a single crystal of adequate size and quality. Owing to the collapse of the three-dimensional lattice onto the 2Θ-axis the ab-initio crystal structure solution is still a challenge. The loss in the experimental information may be overcome by: better design of instruments (e.g., synchrotron radiation, time-of-flight technology at pulsed neutron sources, detectors,) improving the methods for the crystal structure solution (Direct Methods, maximum entropy-likelihood, MonteCarlo, simulated annealing, genetic algorithm, modelling of optimal crystal packing, …). Direct Methods are paying an essential role for enlarging the size of the structures solvable from powder data. The performances of the new version of the package EXPO [1] will be outlined, where use may be made of some prior information.

K11.02.001 STRUCTURAL BASIS OF IMMUNE RECOGNITION. Ian A. Wilson, The Scripps Research Institute, Department of Molecular Biology, La Jolla, CA 92037 U.S.

The immune system combats invading microorganisms, such as viruses and bacteria, by neutralizing them directly or by killing infected cells. Antibodies, in the humoral system, have enormous genetic diversity that can be harnessed for high affinity recognition of a universe of antigens. In the cellular system, T cell receptors (TCR) have similar genetic diversity but bind their antigens with medium to low affinity to allow kinetic control of signaling events. The molecular basis of antigen recognition was initiated over 25 years ago due to the availability of soluble antibodies from multiple myelomas of mouse and human origin. Since then, over 100 structures of antibodies against small haptens, peptides, carbohydrates, and proteins have illustrated how this diversity can be sculpted onto a constant structural framework and has led to an understanding of antibody-antigen interactions, conformational changes in ligand recognition, design of therapeutics, and in the use of antibodies as catalysts. Structural studies of the cellular immune system have been more intractable, however, and only in the past decade or so have the crystal structures of MHC molecules and, more recently, T cell receptors (TCR) become available. Antigens are presented to the TCR as peptide fragments by MHC class I, and class II, or as glycolipids by non-classical MHC molecules, such as CD1. The crystal structures of single peptide-MHC complexes have illustrated how a myriad of peptide antigens can fit into the same MHC binding groove. In the past two years, T cell structure and TCR- MHC-peptide complexes have been made possible through protein engineering in order to express sufficient quantities of soluble material. I shall give an historical perspective on the structural studies of these immune proteins and then focus on our work on antipeptide, antisteroid, antiprotein and catalytic antibodies, various classical and nonclassical MHC molecules,

TCR and TCR-MHC complexes. These immunoprotein systems have contributed a wealth of data to our understanding of ligand-receptor interactions, protein engineering, enzyme catalysis, induced fit, glycoproteins, cell surface receptors and signal transduction.

K11.03.001 CRYSTALLOGRAPHY IN EXTREME CONDITIONS OF PRESSURE AND TEMPERATURE: MYTH OR REALITY? Daniel Häusermann, High Pressure Group, European Synchrotron Radiation Facility, Grenoble, France (now at the Geophysical Laboratory of the Carnegie Institution of Washington)

Considering that 99.9% of the known, non-gaseous, universe is under high pressure and non-ambient temperature, one can wonder why so many crystallographers work at 1 bar… Even in the case of bio-crystallographers, who may argue that 1 bar is the prevalent condition for life, one can advance arguments of pressure sterilization, virus destruction, enzyme deactivation, and maybe even studies of the origin of life using the pressure parameter. So now, can we argue to those convinced, that there is a world of crystallography to explore in conditions of extremes of pressure and temperature ? Looking at the progress made in the last few years, there are plenty of results that show that we are now able to perform complete structural studies of materials in extreme conditions of P and T, and this opens a whole new field of crystallography, and especially of applied crystallography. The availability of intensely bright monochromatic synchrotron radiation and of area detectors now allow the collection of data suitable for structural refinement in conditions fast approaching those prevailing at the center of the Earth. In less extreme conditions, larger samples allow structural studies and characterization of reaction kinetics in materials undergoing chemical synthesis. If to this we also add studies of liquid, and of course of melting, then we see that these new techniques can now be applied to a range of scientific problems spanning most fields of investigation covered today. Finally, one of the main concerns of crystallographers being sample 'quality', we must add that these techniques now also allow the characterization of this quality, as we can measure and even map, stress, strain, texture…

In this lecture we will review the progress which made such measurements possible, give an overview of the recent most exciting results, and demonstrate to the purists that even when we have to relax their 'R-factor' standards to enter the real world, we may still be doing crystallography…

K11.04.001 CRYSTAL STRUCTURE OF A HEPATITIS DELTA VIRUS RIBOZYME: CLUES TO RNA CATALYSIS. A.R. Ferre-D'Amare [1], K. Zhou [2], J.A. Doudna [1,2], [1] Dept. of Molecular Biophysics and Biochemistry, and [2] Howard Hughes Medical Institute, Yale University, New Haven, CT 06520

Hepatitis delta virus (HDV) contains a single-stranded circular RNA genome of 1700 nucleotides, and is coinfectious with Hepatitis B virus. Replication of the HDV genome by a rolling circle mechanism produces linear multimers of both genomic- and anti-genomic RNAs, both of which contain a self-cleaving activity that processes them to unit length. The activity has been mapped to a catalytic RNA, or ribozyme, domain whose function is required for HDV replication in vivo. To understand the catalytic mechanism of the HDV ribozyme, the crystal structure of the genomic sequence was solved at 2.3 Å resolution. The structure revealed a buried active site cleft reminiscent of protein enzymes. Key residues in the vicinity of the labile bond can now be tested for their role in catalysis. The delta ribozyme crystals were obtained by a new approach in which the ribozyme was engineered to bind to the small RNA binding domain of the U1A protein. Preliminary results suggest this may be a generally useful technique for growing high-quality crystals of other RNAs and solving their structures.

K12.01.001 COLOSSAL MAGNETO-RESISTANCE. Paolo G. Radaelli, ISIS Facility, CCLRC, Rutherford Appleton Laboratory, Chilton, Didcot, Oxon, OX11 0QX, UK.

Mn^{+3}/Mn^{+4} mixed-valence oxides (manganites) have been studied for the last fifty years, and represent a cornerstone in our general understanding of transition metal oxides. In the last five years, however, there has been a very significant and rapid surge of interest for these materials, reminiscent of what happened for copper oxides a decade ago. Three main classes of manganites have been intensively studied: the three-dimensional perovskites $A MnO_3$, the layered compounds of the so-called Ruddlesden-Popper series $A_{n+1}Mn_nO_{3n+1}$ and the cubic pyrochlore $Tl_2Mn_2O_7$. This research effort was prompted by the realisation that, in certain temperature ranges, the electrical resistivity of some manganites can be changed by several order of magnitudes in an applied magnetic field, a phenomenon now known as "colossal magneto-resistance" (CMR). CMR is a high-field effect and is therefore widely recognised not to be suitable *per se* for electronics or information-storage applications. Nevertheless, the peculiar electronic structure of CMR manganites can be exploited for devices such as spin valves. In addition to the interest for applications, manganites are studied for their extremely rich physics, which encompasses some of the most interesting phenomena in modern solid-state research: magneto-structural polarons, charge, orbital and magnetic ordering and phase segregation. Crystallographic techniques have given a paramount contribution to manganite research, mainly due to the large electron-lattice coupling. The initial emphasis on correlations between transport and average structural properties (bond lengths, bond angles, etc.) has gradually shifted towards more local structural phenomena, associated with the so-called Jahn-Teller polarons. Charge ordering and some of its more unusual manifestations like "stripes" continue to attract very significant attention. More recently, it has been recognised that the crystal and magnetic structure of some manganites may become intrinsically non-uniform, either dynamically or statically (phase segregation). Consequently, high-resolution diffraction may provide the next breakthrough in our understanding of manganite physics.

K12.02.001 ROLE AND PERSPECTIVES OF *AB-INITIO* MOLECULAR DYNAMICS IN CRYSTALLOGRAPHY. Michele Parrinello, Max-Planck-Institut fur Festkorperforschung, Heisenbergstr. I, D-70569 Stuttgart, Germany

Ab-initio molecular dynamics is a very powerful method for the study of the electronic, structural and dynamical properties of crystals with a very large number of atoms in their unit cell, without the restriction of symmetry or limiting assumptions such as harmonic approximation. If needed, the quantum mechanical behaviour of the nuclei can also be included. The development of ever less expensive and more powerful parallel computers and user-friendly software packages allow mote and more groups to harness the power of this method. We argue that the accuracy and predictive power of *ab-initio* molecular dynamics is such that it can and will be used in the routine refinement of crystal structures. Furthermore, the evolution of a crystal as a function of temperature, pressure and other thermodynamics fields can be investigated. In particular *ab-initio* molecular dynamics has the unique capability of describing the change in chemical bonding that is induced for instance by the application of an external pressure. We will illustrate with a selected number of examples the power of *ab-initio* molecular dynamics, indicate its present limitations and discuss the efforts currently being made to extend its scope.

K12.03.001 THE HIDDEN ORDER OF APERIODIC CRYSTALS. W. Steurer, Laboratory of Crystallography, Swiss Federal Institute of Technology, CH-8092 Zurich, Switzerland.

Aperiodicity and crystalline order - these two terms seem to exclude each other. Ideal translational symmetry is reflected in a reciprocal lattice with peaks (Bragg reflections) at the lattice nodes. Thus, a diffraction pattern with sharp Bragg reflections and no disorder diffuse scattering is characteristic for a perfect crystal such as silicon, for instance. Three reciprocal basis vectors are needed to index its diffraction pattern. Materials with an essentially discrete diffraction pattern which can be indexed with integers with more than three reciprocal basis vectors are called aperiodic crystals. They combine crystalline order in the n-dimensional parameter space with aperiodicity in the 3D physical space.

K12.04.001 STRUCTURAL GENOMICS OF A HYPERTHERMOPHILE: A FEASABILITY TEST. Sung-Hou Kim, Department of Chemistry and Lawrence Berkeley National Laboratory,University of California, Berkeley,CA USA.

Analysis of several genomic sequences indicates that no known biological functions can be assigned to a large fraction of the genes, thus, no assays can be devised to discover or test their functions. Structural biology can play an important role in the search for and the discovery of the functions of these genes. Since the biochemical function of a gene product is tightly coupled to its three-dimensional structure, finding the structure or its folding pattern may provide important insight into the biochemical function of the gene product, which, in turn, may help in understanding its cellular function. Thus, the structural study of genomic products, "structural genomics," may be an important foundation for the understanding of the biochemical and cellular functions of their products, "functional genomics." To test this hypothesis we have been studying the structures of three classes of gene products with unknown structures from a hyperthermophilic Archeon, methanococcus jannaschiia: (1) protein families whose biochemical and cellular functions are known, but their mechanisms are not known; (2) protein families whose cellular functions are known, but their biochemical functions are not known; (3) "hypothetical" protein families for which neither cellular nor biochemical functions are known.

K13.01.001 SUPRAMOLECULAR HYDRATES: HYDROPHILIC *versus* HYDROPHOBIC HYDRATION OF MOLECULES IN THE SOLIDS. Janusz Lipkowski, Institute of Physical Chemistry, Polish Academy of Sciences, Kasprzaka 44, 01 224 Warszawa, Poland

Interaction of water with hydrophobic moieties, and the supramolecular complexes thus formed, are of importance from the point of view of both complexation equilibria and transport properties in aqueous media.

In the crystal structures of supramolecular hydrates two different modes of hydration co-exist. These are: *hydrophilic hydration*, in which water is H-bonded either to, typically, oxygen or nitrogen atoms of the guest species and *hydrophobic hydration* in which water molecules *enclathrate* lipophilic parts of guest moieties.

Structural studies of interaction between water and hydrophobic species have revealed a fascinating variety of the guest-host architecture. Water molecules aggregate to form all possible structure types ranging from small water clusters through one-dimensional chains or two-dimensional layers to extended three-dimensional networks of zeolite or clathrate structural type. The formation of channel structures has also been found. Host component may bear electric charge when containing ionic species replacing water molecules in the host skeleton. The simplest pattern of this sort may be obtained with ionized water (H_3O^+ or OH^-) or halogenide anions substituting some of the water molecules.

The most intriguing factor stabilizing the structures is hydrophobic hydration. It consists of multimolecular combination of weak intermolecular interactions which apparently are the structure determining factor, however difficult to visualize. The guest species play the important role of stabilizing a host framework, thus serving as a *template* in the crystal structure formation.

The illustration part of the paper will consist, in its most part, of recently determined (and partly yet unpublished) crystal structures of hydrates of crown macrocycles and their complexes. By this way both hydrophobic and hydrophilic hydration patterns may easily be demonstrated just by chosing hydration of pure macrocycles, their molecular or acidic complexes. In the last case strong hydrophobic interactions eliminate clathration effects.

K13.02.001 NANOSECOND TIME-RESOLVED CRYSTALLOGRAPHY. Keith Moffat, Department of Biochemistry & Molecular Biology, and CARS, The University of Chicago, Chicago, Illinois, USA.

Mechanism in all chemical and biological reactions involves change in structure, not merely static structure; and these changes can occur very rapidly, from the time scales characteristic of inter-atomic vibrations (femtoseconds) to seconds. Structural reactions can be initiated in the molecules in a single crystal of excellent diffraction quality, for example by illuminating the crystal by a brief laser pulse. The reaction is then followed by the subsequent time-dependence of the intensities of all Laue spots and from them, the X-ray structure amplitudes. That is, the experiments are of the pump-probe variety. The techniques are now in place to conduct such experiments on biological crystals on the nanosecond time scale. Results will be described on heme proteins such as myoglobin and on the simple, bacterial, blue light photoreceptor known as photoactive yellow protein, PYP. PYP has recently been shown to be representative of the so-called PAS/LOV domain proteins which are extremely widely distributed, in numerous biological signalling roles. Thus, it may exemplify a general signalling domain that can respond to light, voltage and chemical signals, either alone or when associated with suitable ligands.

I thank our numerous collaborators, in Chicago, at the ESRF and in Amsterdam. Supported by NIH.

K13.03.001 FRONTIERS IN CHEMICAL CRYSTALLOGRAPHY. H.-B. Bürgi, Laboratory of Crystallography, University of Bern, Freiestr.3, CH-3012 BERN, Switzerland

With the availability of high brilliance radiation sources and fast area detectors, diffraction studies requiring many measurements over a range of temperature, pressure, electric field or photon flux have become quite feasible and provide new information not obtainable from a single measurement.

The temperature evolution of a crystal structure is discussed as an example. Temperature dependence of population parameters can be interpreted in terms of equilibrium constants and changes in enthalpy and entropy for a variety of simple chemical processes, including molecular reorientation, conformational changes, and proton or other atom transfers. The temperature evolution of anisotropic displacement parameters allows to distinguish motion from disorder, but also from systematic error, either in the experiment or in the structural model, and to extract correlations between atomic displacements and associated frequencies of motion. Diffraction experiments over a range of temperature are thus a potentially rich source of information on dynamic processes and disorder phenomena in

crystals. The information is relatively easy to obtain and extends the scope of crystal structure analysis.

K13.04.001 PICOSECOND X-RAY DIFFRACTION.
Justin Wark, Clarendon Laboratory, Department of Physics, University of Oxford, Parks Road, Oxford, OX1 3PU, UK.

The timescale necessary for the recording of X-ray diffraction signals from crystals has reduced spectacularly in recent years: from the several minute continuous exposures towards the beginning of the century, through the first millisecond work in the early 1940's, down to the present day, when we are finally accessing the sub-picosecond regime. Nanosecond and picosecond diffraction sources have been developed using a variety of different methods, including using single bunches of electrons in synchrotrons, X-ray diodes, and emission from laser-produced plasmas. Bright laser-plasma K-α X-ray sources with a few hundred femtoseconds duration have recently been demonstrated, following the development of table-top terawatt laser systems. The ability to record diffraction signals on such short timescales is extremely interesting, as it may allow the observation of electron density during chemical reactions – which has been dubbed "watching molecular movies". Femtosecond timescale X-ray pulses are also being developed utilising synchrotron technology. This talk will review the historical development of these sources, discuss prospects for the future, and outline some of the possible applications of X-ray diffraction on such short timescales.

MICROSYMPOSIA

05OA MACROMOLECULAR MACHINES AND ORGANELLES

M05.OA.001 ROTARY MECHANISM OF ATP SYNTHASE. John Walker, MRC Laboratory of Molecular Biology, Hills Road Cambridge CB2 2QH

ATP synthase is an asymmetrical structure that proceeds through a series of asymmetrical states in its reaction cycle. The high resolution structures of the ground state and of a transition state analogue of the catalytic F1 domain support this view.

M05.OA.002 A DETAILED VIEW OF THE GTPASE ACTIVATING REGION OF THE RIBOSOME: STRUCTURE OF THE L11/RNA COMPLEX. V. Ramakrishnan[1,2], Brian T. Wimberly[1], Rebecca Guymon[1], John P. McCutcheon[1], and Stephen W. White[3], [1]Department of Biochemistry, University of Utah School of Medicine, Salt Lake City, UT 84132, USA, [2]MRC Laboratory of Molecular Biology, Hills Road, Cambridge CB2 2QH, England, and [3]Department of Structural Biology, St. Jude Children's Research Hospital, Memphis, TN 38105 USA.

The ribosome stimulates GTPase activity in the translational elongation factors. The GTPase activating region of the ribosome consists of a highly conserved complex of a 58-nucleotide region of 23S ribosomal RNA and ribosomal protein L11. Here we report the crystal structure of the complex. The RNA folds into a highly compact globular domain consisting of both familiar and novel structural motifs, while protein L11 consists of a C-terminal domain that binds tightly to the RNA and an N-terminal domain that makes only limited contacts with RNA. The structure suggests that the L11 N-terminal domain might function as a switch, by reversibly associating with an adjacent conserved region of RNA. The sites of mutations conferring resistance to the antibiotics thiostrepton and micrococcin are clustered around a narrow cleft between the RNA and a proline-rich helix in the L11 N-terminal domain. The antibiotics are proposed to bind in this cleft, thereby locking the putative switch into a single conformation and altering GTPase activity by elongation factors.

M05.OA.003 A 5Å RESOLUTION X-RAY CRYSTALLOGRAPHIC MAP OF THE LARGE RIBOSOMAL SUBUNIT. Nenad Ban [1,3], Poul Nissen [1], Peter B. Moore [1,2] and Thomas A. Steitz [1,2,3], [1] Department of Molecular Biophysics & Biochemistry, Yale University, New Haven, CT, [2] Department of Chemistry, Yale University, New Haven, CT, [3] Howard Hughes Medical Institute, Yale University, New Haven, CT, USA

The 50S subunit of the ribosome catalyzes the peptidyl-transferase reaction of protein synthesis. We have generated an X-ray crystallographic electron density map of the large ribosomal subunit from *Haloarcula marismortui* at 5 A resolution using data from crystals that diffract to 3 A. Phasing at this resolution relied on data from four heavy atom derivatives improved by density modification procedures. Our map at this resolution shows clearly resolved density for each of the two strands of RNA in those regions that are duplex. There are higher density bumps corresponding to backbone phosphates. Density for numerous proteins can be readily distinguished from that for RNA. Many of the proteins are seen to be crosslinking two or three regions of RNA duplex, perhaps functioning as large molecular staples. Non- duplex regions of rRNA can be identified but are difficult to interpret at this resolution. Extension of phasing to 3 A resolution appears feasible.

M05.OA.004 APPROACHING ATOMIC RESOLUTION IN RIBOSOMAL CRYSTALLOGRAPHY. Ada Yonath, Struc. Biol., Weizmann Inst., Rehovot and Max-Planck Unit for ribosome struc., Hamburg

The translation of the genetic code into polypeptide chains is performed on riboprotein organelles called ribosomes. The ribosomes are built of two subunits which associate upon the initiation of protein biosynthesis. The small subunit (0.85 mD in prokaryotes) provides the sites for mRNA binding, decoding of the genetic information and the initiation of the process. The large subunit (1.45 mD) catalyzes the formation of the peptide bond and provides the progression path of the nascent proteins.

Crystals, diffracting to 3 resolution, were grown from small and large ribosomal subunits of Thermus thermophilus and Haloarcula marismortui, respectively. Data extending to 3.8-7.5 A resolution were collected at cryo temperature with bright synchrotron radiation from native and heavy atom derivatized crystals of both subunits. Each of the resulting MIRAS-phased electron density maps contains regions similar in shape to that observed for the corresponding ribosomal particle by EM reconstructions.

The regions assigned to the ribosomal particles contain the key internal features (e.g. the large subunit tunnel). Details of the map include two main types of density distributions: (a) elongate continuous regions spanning the particles at various directions and showing typical tertiary and secondary- structure features of RNA (single strands and well separated double helices); (b) globular and ellipsoidal regions of lower density, appropriate for the accommodation of ribosomal proteins, some of which show the main-chain folds observed in crystals of isolated ribosomal proteins. Tracing the RNA chains and assignment of the proteins are underway.

For unbiased map interpretation, heavy atom markers are being attached at selected sites on the ribosomal surface either prior or after crystallization. These led to the elucidation of the sites of a specific cysteine and of several surface RNA strands. Examination of the map of the small subunit indicated conformation resembling that observed within the cryo EM reconstructions of the entire ribosome. Consequently, crystals were grown from particles trapped at their activated conformation prior to crystallization, or reactivation was performed while in the crystals.

05OB PRESERVATION AND DECAY AT CRYO TEMPERATURES

M05.OB.001 MACROMOLECULAR CRYSTAL ANNEALING: OVERCOMING THE FEAR OF FLASHING. Gerard J. Bunick*#, Joel M. Harp#, David E. Timm+, and B. Leif Hanson#, *Life Sciences Division, Oak Ridge National Laboratory, Oak Ridge, TN 37831-8080, #The University of Tennessee/Oak Ridge Graduate Program in Genome Science and Technology, and +Department of Biochemistry and Molecular Biology, Indiana University School of Medicine, Indianapolis, IN 46202.

Macromolecular Crystal Annealing was discovered at Oak Ridge National Laboratory and first presented in 1997 at the American Crystallographic Association meeting in St. Louis, Missouri. The flash cooling of macromolecular crystals for x-ray data collection has many benefits as well as the disadvantage of dramatically increased mosaicity for some crystals. Macromolecular crystal annealing has been shown to significantly

reduce the mosaicity of flash-cooled crystals without affecting molecular structure. Improvements in diffraction resolution have been reported for some macromolecular crystals.

The annealing procedure consists of transferring a flash-cooled crystal to a droplet of its original cryoprotectant solution at ambient temperature for approximately three minutes followed by re-flash-cooling to cryogenic temperature. The annealing process has been applied to crystals of many different macromolecules grown from different precipitants and using a variety of cryoprotectants. The method also has been applied to restore diffraction from flash-cooled crystals that were inadvertently partially warmed during transfer to or from cryogenic storage, to crystals that iced during data collection, and to characterize crystal diffraction prior to heavy-atom soak experiments. The favored annealing procedure and several variants will be described. Results will be discussed in relation to crystal mosaicity and radiation damage in flash-cooled macromolecular crystals.

Research sponsored by the Office of Health & Environmental Research, U.S. Department of Energy, under contract No. DE-AC05-960R22464 with Lockheed Martin Energy Research Corp., NIH GM29818, and NASA.

M05.OB.002 CRYO MEASUREMENTS CONDUCTED AT HELIUM TEMPERATURE. P. Kuhn, S.M. Soltis, SSRL, Stanford University, Stanford, CA 94309, USA

The lifetimes of crystals exposed to high intensity x-ray beams from synchrotron sources are finite even when the sample is cryogenically cooled in a nitrogen gas stream. We attempted to perform a systematic study of crystal decay in the x-ray beam depending upon the cooling temperature and cooling rates as well as the incoming x-ray energy. A custom made open flow cryostat was used to cool the sample to temperatures between 45 K and 110 K. The analysis shows that decreased temperatures have only marginal effects on crystal lifetimes. These results are consistent with theoretical results presented earlier (E. Garman, BSR 1998, Argonne, USA). First results will also be presented on new data collection strategies to optimize crystal lifetime and, therefore, data quality.

M05.OB.003 RADIATION DAMAGE AND BEAM HEATING IN PROTEIN CRYSTALS AT CRYO-TEMPERATURES. Colin Nave, SRS Facility, CCLRC Daresbury Laboratory, Daresbury, Warrington WA4 4AD, UK

The wide adoption of cryo-cooling methods has proved to be of tremendous benefit in overcoming the effects of radiation damage during protein crystallography data collection. It is frequently possible to collect a number of high quality data sets from a single crystal without significant errors due to radiation damage. However, smaller crystals are being examined at cryo-temperatures on the most intense X-ray sources and, it is then not always possible to collect a complete data set from a single sample. This was predicted, as primary radiation damage still occurs at cryo-temperatures [1,2]. In addition, it has been found necessary to attenuate or defocus very intense beams, in order to maximise the amount of data that can be collected from a single crystal. This is possibly due to beam heating effects at high intensity.

An overview of the process of radiation damage and beam heating will be covered, together with calculations of these processes under typical conditions. Some suggestions for mitigating the effects will also be given.

1. Henderson, R. (1990). Proc. R. Soc. London Ser. B, 241, 6-8.

M05.OB.004 STRUCTURE OF BOVINE HEART CYTOCHROME c OXIDASE AT CRYOGENIC. T. Tsukihara*, R. Nakashima%, E. Yamashita*, M. Yao*, T. Mizushima*, M. Odoko%, K. Shinzawa-Itoh%, & S. Yoshikawa%, *Institute for Protein Research, Osaka University, Yamada-oka, Suita, Osaka 565-0871, Japan, and %Department of Life Science, Himeji Institute of Technology, Kamigohri, Akoh, Hyogo 678-1201, Japan

Cytochrome c oxidase is the respiratory enzyme complex that is involved in dioxygen reduction coupled with proton pumping. The enzyme complex is consisting of two copies of 13 different subunits, two hemes, two copper centers, Mg, Na, Zn and phospholipids. Out of 13 subunits, 10 are transmembrane proteins, while three are extramembrane proteins.

The enzyme complex was crystallized by the batch method at 277 K from aqueous solution with nonionic detergent, 0.2 % decyl maltoside in 40 mM sodium phosphate buffer, pH 6.8, where the protein concentration was 9.0 % (w/v) and polyethylene glycol 4000 was used as the precipitant. Crystals were soaked in the glycerol solution prior to the cryogenic experiment. A crystal mounted with a fiber loop was frozen by dropping into liquid nitrogen.

X-ray diffraction experiment was carried out at BL41XU of the SPring-8 under the following conditions: temperature, 100 K by using Oxford Cryo-Cooling system; wave length, 0.708 A; crystal-to detector distance, 350 mm; detector, R-axis IV with 300 x 300 mm Imaging plates; oscillation angle, 0.65 degree; and exposure times, 78 or 117 seconds. Total of 429,322 independent reflections in the resolution range from 100.0 to 2.0 A were obtained from 3,685,319 observed reflections. R-merge was 7.7 %, and completeness, 95 %.

Electron density map at 2.0 A resolution showed up not only finer structures but also essential differences in comparison with 2.3 A analysis at room temperature.

M05.OB.005 CHANGES OF CELL DIMENSION DURING DATA COLLECTION OF A SINGLE VIRUS CRYSTAL. Lars Liljas[1,2], John Tate[1], Tianwei Lin[1], J.E. Johnson[1], [1]The Scripps Research Institute, La Jolla, California, USA, and [2]Department of Cell and Molecular Biology, Uppsala University, Uppsala.

A single, frozen crystal was used for data collection of cricket paralysis virus, an insect picorna-like virus. At data processing, it became evident that the data could not be scaled, and an analysis showed that early during the exposure, the crystal underwent a transition, corresponding to change in the c axis of 0.8 %. The crystal structure could be solved using the data collected after the transition. The atomic model built in electron density maps based on the "late" data could be used for phasing of a limited "early" data set to high resolution (2.4Å). Other problems in using cryo-temperatures for virus data collection will be discussed.

05OC PHYSICAL PROPERTIES AND STRUCTURAL RELATIONSHIPS

M05.OC.001 CMR MANGANITES: FROM THE CERAMICS TO THE THIN FILMS, B. Raveau, A. Maignan, C. Martin and M. Hervieu, Lab. CRISMAT (UMR CNRS 6508), ISMRA, 6 Bd du Maréchal Juin, 14050 Caen cedex France.

The manganites $Ln_{1-x}A_xMnO_3$ (A = Ca, Sr), with the perovskite structure form a large series of materials with colossal magnetoresistance (CMR) properties. The investigation of ceramics of these oxides allows two kinds of behaviors to be evidenced, depending on the sign of the carriers. In the hole doped

manganites the CMR effect results form a magnetic field induced transition from a paramagnetic insulating to ferromagnetic metallic state. In the electron doped manganites, the CMR effect originates from a competition between ferromagnetism and antiferromagnetism, in the vicinity of cluster glass region. Several factors are discussed, which govern the magnetotransport properties of these oxides : carrier concentration, average size of the A-site cation $\langle r_A \rangle$, and size mismatch σ^2. In those oxides, the magnetotransport properties are greatly affected by charge-ordering (CO) phenomena . The electron microscopy study of several series of compounds, shows that CO appears in the form of Mn^{3+} and Mn^{4+} stripes, distributed in a commensurate or incommensurate modulated way. The metastability of the CO state may be at the origin of the CMR effect in several materials. The destruction of the CO state and the appearance of CMR can be induced by a magnetic field but also by various radiations, and by Mn-site doping by chromium, cobalt and nickel.

The investigation of the thin film chemistry of the CMR manganites with the composition $La_{0.7}Sr_{0.3}MnO_3$, has allowed several superlattices to be synthesized using sequential laser ablation : X-ray diffraction high resolution electron microscopy studies show a perfect ordering of the layers "$LaMnO_3$" (LMO) and "$SrMnO_3$" (SMO) in the films. The study of the transport properties show that the SMO layers play the role of hole reservoir for the LMO layers. In the latter the holes are delocalized leading to CMR properties, with various characteristics depending on the nature of the superlattice.

M05.OC.002 RELATIONS BETWEEN STRUCTURE AND LITHIUM ELECTROCHEMICAL REACTIVITY IN VANADATES. S. Denis, E. Baudrin, S. Laruelle, M. Touboul and J-M. Tarascon, Laboratoire de Réactivité et de Chimie des Solides, 33 rue Saint-Leu, 80039 AMIENS, FRANCE.

Within the field of energy storage, vanadates have recently generated a new interest as these compounds were shown to be potential candidates for negative electrode material in Li-ion battery. Indeed, it was previously reported that such materials-based electrode display a large Li acceptance/removal at low voltage. For instance, crystallized $LiNiVO_4$, synthesized by the classical high temperature route can react with 7 lithium ions per formula unit when discharged to voltages lower than 0.2 V [1], leading to 800 - 900 mAh/g specific capacities, about twice greater than the actually used graphite electrodes. However, upon the first electrochemical discharge, it was noted that these materials tend to become amorphous. Therefore, our goal was to understand the lithium reaction mechanism within vanadates based on structural investigations.

For this purpose, we prepared different classes of vanadates based on monovalent, divalent and trivalent elements through a "chimie douce" method. Depending on the synthesis conditions, a large panel of compounds having different 3D packing of (VO_4), (VO_6) entities or differing in terms of long vs. local range order were obtained. An electrochemical investigation showed that all these materials, independently of their crystallization state tend to become amorphous upon the first discharge (ie: reduction), but their electrochemical performances are strongly dependent on both the water content and the nature of the counter-cation, which is directly involved in the lithium reaction process [2].

In order to explain the great acceptance of lithium ions within these materials, a structural investigation was undertaken during the first electrochemical cycle, by means of in-situ XRD, Mössbauer and XANES measurements. This study allowed us to propose a Li reaction mechanism different from the classical insertion/deinsertion process.

M05.OC.003 STRUCTURE AND ENERGETICS OF Li^+ DIFFUSION IN $Li_{0.5}CoO_2$ BY *AB INITIO* SIMULATIONS. M. Catti, Dipartimento di Scienza dei Materiali, Università di Milano II - Bicocca, via Cozzi 53, 20125 Milano, Italy.

The Li_xCoO_2 ($0 \le x \le 1$) system is well known, from *in situ* X-ray diffraction and electrochemical measurements, to intercalate Li^+ ions reversibly, providing thus a very important cathode material for rechargeable lithium batteries [1]. The structures of these phases are distortions of a FCC sublattice of O atoms, with alternating layers of Co and Li in octahedral holes, and partial occupancy of the Li sites according to the x value. For $x \approx 0.5$ the lattice is monoclinic, but no further structural details are available from the experiment. A theoretical study by *ab initio* quantum-mechanical methods has been undertaken, in order: (i) to predict the equilibrium crystal structure of the intermediate monoclinic $Li_{0.5}CoO_2$ phase; (ii) to determine the energy profile along the Li^+ diffusion path connecting octahedral and tetrahedral holes in the inter-layer region; (iii) to calculate activation energy values for the process of Li^+ transport within the structure. The method used is periodic Hartree-Fock supplemented by an *a posteriori* correction based on DFT (Density-Functional-Theory) estimate of electron correlation energy, such as implemented in the CRYSTAL code [2]. The results would indicate that, at equilibrium, lithium is slightly displaced from the centre of the octahedral hole, and attains a distorted pyramidal coordination consistent with *Pm* rather than *P2/m* symmetry. The computed energy profile of Li^+ along its diffusion path shows a saddle point corresponding to the tetrahedral hole, with a theoretical activation energy of 0.23 eV for oct.→tetr.→oct. hopping. The maximum of the energy curve occurs for direct jumps between adjacent tetrahedral sites, so that the diffusion path oct.→tetr.→tetr.→oct. is less favoured with $E_{act.} = 0.67$ eV.

M05.OC.004 EXPLORING ELECTROMECHANICAL COUPLING EFFECTS WITH RESONANT ULTRASOUND SPECTROSCOPY. J. Schreuer, E. Haussühl and W. Steurer, Laboratory of Crystallography, ETH Zürich, Sonneggstr. 5, CH-8092 Zürich, Switzerland

Employing the innovative technique of resonant ultrasound spectroscopy (RUS), we studied the elastic behaviour and electro-mechanical coupling phenomena of selected piezoelectric crystals such as $NaBrO_3$, α-quartz, $LiIO_3$ and $LiNbO_3$ between ambient temperature and 1400 K. Due to increasing electric conductivity most of the investigated crystal species show strong attenuation of their low-frequent electroelastic vibrations at elevated temperatures.

Our experimental set-up is based on the RUS-method [1] where the elastic constants are derived from an experimentally measured ultrasonic resonance spectrum of a free vibrating crystal with well defined shape. Advantages of this technique are (i) no medium is required for transducer sample-coupling, (ii) the small sample size and (iii) the short data acquisition time. The elasticity tensor is evaluated by an iterative non-linear least-squares procedure that matches observed and and calculated resonance frequencies by adjusting values for the elastic constants. The crucial step is the correct identification of observed modes. The eigenmodes correspond to stationary solutions of the Lagrangian which can be found by applying variational methods.

In the case of piezoelectric crystals the Lagrangian has to be extended by additional energy terms taking into account electro-mechanical coupling effects [2]. Usually the piezoelectric contribution to resonance frequencies is considerably larger than the experimental error. Thus, the RUS-method offers the unique possibility to study simultaneously the elastic, dielectric and piezoelectric properties of a crystal in a large temperature range.

M05.OC.005 CATION ORDERING IN LAYERED BISMUTH OXIDE FERROELECTRICS. P. Lightfoot, C. Hervoches, School of Chemistry, University of St Andrews, Fife KY16 9ST, UK, A. M. Kusainova, P. Berdonosov and V. A. Dolgikh, Dept. of Chemistry, Moscow State University, Moscow, 119899, Russia and S. Yu. Stefanovich, Karpov Institute of Physical Chemistry, Moscow, 103064, Russia.

We have recently been carrying out a thorough crystallographic study of two families of layered bismuthates which display interesting pyro- and ferro-electric properties. The families concerned are the so-called Sillen and Aurivillius phases. The Aurivillius phases, in particular, are currently very widely studied from the technological point-of-view and, indeed, $Bi_2SrTa_2O_9$ and related phases are now the materials of choice in ferroelectric RAM thin-film technology. Despite this commercial significance, the basic structural chemistry of these materials is very poorly understood. These structures contain fluorite-related cationic metal oxide layers of stoichiometry $[M_2O_2]$ or $[M_3O_4]$, which are sandwiched between anionic halide or perovskite-like blocks, respectively. The occurrence of non-centrosymmetricity and/or ferroelectric properties is found to be critically dependent on the nature of cation ordering within the fluorite or perovskite blocks, as well as the choice of halide. We shall illustrate this with reference to several well-characterised materials including $Bi_4Te_2O_9Br_2$, $BiTe_2O_5Cl$, $Bi_2SrNb_2O_9$ and $Bi_2Sr_2Nb_2TiO_{12}$. We highlight the importance of using a combination of crystallographic techniques *viz*., single crystal X-ray diffraction and variable temperature X-ray and neutron powder diffraction.

P05.OC.001 KINETICS OF DECAY OF A METASTABLE STATE OF ONE-DIMENSIONAL DISORDER SYSTEM. B.V. Petukhov. Institute of Crystallography of Russian Academy of Sciences, Moscow 117333, Russia.

Periodically degenerated energetic relief of the crystal lattice is a fundamental reason for the strong temperature-dependent migration kinetics involving the thermoactivated overcoming of barriers separating adjacent states. The migration of extended objects has some distinctive peculiarities due to the interaction of different degrees of freedom. Some examples are: crystal growth by the steps motion along crystal faces, plastic flow of materials by the dislocation motion along slip plains in the Peierls-Nbarro relief, dynamics of boundaries of two-dimensional phases on crystalline substrates, etc. In all of these cases the interaction of the macroscopically large amount of the different degrees of freedom may be described by one basic model: mass nucleation of kink-soliton pairs and subsequent propagation and merging of kinks and antikinks from neighboring pairs.

A solution of this model for perfect homogeneous systems goes back to the classical Kolmogorov's paper [1] (see also [2]). However, in many real materials there are numerous reasons for uncontrolled disturbances, which drastically modify the ideal Kolmogorov-Johnson-Mehl kinetics. The goal of the present paper is a solution of a generalized model including the influence of a random disturbance of the "white noise" type. An exact solution of the model has been obtained, which shows, in particular, that the rate of the decay of a metastable state of the disorder linear system undergoes a drastic change near a some critical value of the driving force. Below of the critical force the rate of decay becomes essentially slower due to the anomalous nature of the kink motion over random barriers.

P05.OC.002 USING OF PV-STATE EQUATIONS AND A CORRELATIVE CRYSTAL THEORY FOR THE INVESTIGATION OF ELASTIC PROPERTIES OF CRYSTALS. N. Pertaya, Solid Physics Department, South Ukraine University of Education, Odessa, Ukraine.

The receipt of PV-equations is the main problem of condensed matter physics. The new approach to the investigation of the elastic properties of crystals, consisting of using of the PV-state equations to determine the analytic connection between the stress tenzor, macrostrain tensor, the change of crystal volume and quantitative characteristics of the between-atom potential was developed in the present work. The PV-state equations were received with the due regard for the crystal anysotropy for the cases of cubic, hexagonal, rhombic and tetragonal symmetry groups.

Also PV-state equations were received in the nought and first approhimations of the correlation theory. The chain of the equations for the correlation functions (density matrixes) was used to calculate the motion of the crystal particles. On the basis of the expressions of first and second order distribution functions the thermal state equation of crystals was obtained in the nought and first approximations of the correlation theory.

The deformation tenzor was determined by X-ray method, the macrostress tenzor was calculated in accordance with the Hook's law for the textured anysotropic solids. The approbation of the present investigation complex was carried out on a-Ti alloys. These results can be the basis of the investigation of macro- and microproperties of real crystals.

P05.OC.003 NEW BISMUTH OXIDES IN THE SILLEN AND AURIVILLIUS FAMILIES. C. Hervoches and P. Lightfoot, School of Chemistry, University of St.Andrews, St.Andrews, Fife KY16 9ST, UK.

We have studied the crystallographic structure of several new phases in the Sillen and Aurivillius families of potential use as ferroelectric materials or ionic conductors.

These materials have a highly flexible chemical composition which affects the details of their crystal structure, which in turn is believed to play a critical role in their important electrical properties.

We have systematically explored the effects of chemical modification on crystal structure and physical properties in order to understand the relationship of composition, structure, and properties [1,2].

X-ray and neutron powder diffraction have been used to characterise several materials including Bi_2AO_4Cl (A = Er, Lu, Y), $Bi_2Sr_2Nb_2TiO_{12}$ and the solid solution $Bi_{2-x}Sr_{2+x}Nb_{2+x}Ti_{1-x}O_{12}$. The latter materials display an unusual cation ordering scheme, hitherto unobserved, which may have important implications for their properties.

P05.OC.004 ELECTRON DENSITY IN THE β-$Na_XV_2O_5$ OXYGEN BRONZES AT 9 K. R.P. Ozerov, Mendeleev University of Chemical Technology, Moscow 125047, Russia, B.N. Figgis and A.N. Sobolev, Department of Chemistry, and V.A. Streltsov, Crystallography Centre, The University of Western Australia, Nedlands 6907, WA, Australia, and V.L. Volkov, Institute of Solid State Chemistry, Ekaterinburg 620219, Russia.

Accurate X-ray crystal structure analyses of the β-$Na_xV_2O_5$ single crystal at room temperature and at 9 K have been undertaken in order to investigate the electron density of all metal atoms.

Nonstoichiometric compounds with the chemical formula of $Na_xV_2O_5$, where M is an alkali metal, copper or silver and x = 0.2-0.33, are known as the β-oxygen vanadium bronzes. Reason for such a name is the metallic character of some of their properties. It is generally considered that these properties originate from the special electronic states of the M and V atoms and interatomic interactions in the highly distorted coordination polyhedra.

A single crystal of β-$Na_xV_2O_5$ was grown from a melted mixture of $0.4NaVO_3+0.8V_2O_5$ by the Bridgman method in air. The sodium content (x = 0.31(3)) was determined from the site occupation number at the stage of structure refinement. There are three unique sites of the vanadium atoms in the crystal structure. Two of them (V_1 and V_2) are surrounded by a distorted octahedron of oxygen atoms. The oxygen environment around the third V_3 atom can better be described as pentagonal bipyramid. The deformation electron density (DED) examination revealed no noticeable qualitative distinction in three V atoms, although their charges calculated by Hirshfeld's method show definite difference. A significant DED accumulation near the Na atoms positions is also found. Multipole analysis of the results as well as quantum chemistry calculations are in progress.

The detailed intensity measurement of the 0k0 direction in the reciprocal space doesn't reveal any superstructure reflections with k odd which could be considered as a sign of the b axis doubling.

P05.OC.005 RELATIONSHIP BETWEEN THE CRYSTAL STRUCTURE AND MAGNETISM IN $Gd_5(Si_2Ge_2)$. V.K.Pecharsky[1,2], W.Choe[3], A.O.Pecharsky[1], G.J.Miller[3], and K.A.Gschneidner, Jr.[1,2], Ames Laboratory[1] and Department of Materials Science and Engineering[2], and Department of Chemistry[3], Iowa State University, Ames, IA 50011, USA.

The giant magnetocaloric effect has recently been observed in the ternary $Gd_5(Si_xGe_{1-x})_4$ compounds, where $0 \le x \le 0.5$ [1]. The ferromagnetic ordering temperature is lowered from 276 K at x = 0.5, i.e. $Gd_5(Si_2Ge_2)$ [1] to 240 K at x = 0.45, i.e. $Gd_5(Si_{1.8}Ge_{2.2})$ [1,2]. For the latter composition the magnetic phase transition occurs simultaneously with a crystallographic phase transition [2]. The crystal structure of $Gd_5(Si_2Ge_2)$ was studied at three different temperatures between 163 and 292 K by single crystal x-ray diffraction. All data were collected on a Bruker SMART CCD diffractometer using Mo K_α radiation. The low temperature magnetically ordered form of $Gd_5(Si_2Ge_2)$ crystallizes in the orthorhombic space group Pnma with unit cell parameters a=7.514(1), b=14.792 (2), and c=7.786(1) Å at 163 K; and a=7.513(1), b=14.797(2), and c=7.794(1) Å at 243 K. The high temperature paramagnetic form of $Gd_5(Si_2Ge_2)$ is monoclinic: space group $P2_1/a$ with unit cell parameters a=7.592(2), b=14.825(3), c=7.791(2), Å and γ=93.272(3)^o at 292 K. At room temperature the single crystal is a twin. Tight binding band calculations have been performed on $Gd_5(Si_2Ge_2)$ using the obtained crystal structure parameters to study the Gd-Gd bonding and the ordering of Si and Ge in $Gd_5(Si_2Ge_2)$. The relationship between the crystal structure and magnetism in $Gd_5(Si_xGe_{1-x})_4$ system is discussed.

Support by the Office of Basic Energy Sciences, Materials Science Division of the US DOE (VKP, AOP, and KAG) and by the National Science Foundation, grant No. DMR 9627161 (WC and GJM) is greatly appreciated.

P05.OC.006 EVIDENCE FOR DISTINCT POLYMER CHAIN ORIENTATIONS IN KC_{60} AND RbC_{60}. R. Moret, P. Launois, Laboratoire de Physique des Solides, Université Paris-Sud, 91405 Orsay, France, J. Hone and A. Zettl, Department of Physics, University of California at Berkeley and Materials Sciences Division, Lawrence Berkeley National Laboratory, Berkeley, California 94720, USA.

While earlier powder diffraction studies indicated similar structures for KC_{60} and RbC_{60}, we have shown that their relative polymer chain orientations are markedly different [1]. This is probably a key to the understanding of the contrasted electronic properties of these compounds.

The crystals were obtained by insertion of alkali metals into cubic C_{60} crystals at 400°C. Upon cooling to the room temperature polymer phase, orthorhombic variants are formed. In spite of the ensuing complexity we have performed detailed x-ray diffraction and diffuse scattering studies on these crystals. It is shown that the chains are orientationally ordered (no diffuse scattering). Furthermore, we have proved that KC_{60} and RbC_{60} possess different relative chain orientations about their axes, corresponding to the space groups Pmnn and I2/m, respectively. This implies that the intermolecular C_{60}-C_{60} environments are significantly different in the two compounds.

P05.OC.007 GREEN'S FUNCTION APPLIED TO ELASTIC PROPERTIES OF CUBIC CRYSTALS. Yuri Ivanov, Department of Solid physics, South Ukrainian University of Education, Odessa 270020, Ukraine

It's first carried out an analytical expression of equilibrium equation Green's function of cubic single crystal. The effective elastic moduli of some polycrystals in correlation approximation with use of this function have been obtained.

The use of correlation-approximation method for cubic crystals has been studied. The possibility of using this method in the case of any anisotropy of elastic properties has been discussed.

P05.OC.008 POLARONS IN INTERGROWTH TYPE ALKALI METAL TUNGSTEN BRONZES: EVIDENCES BY OPTICAL SPECTROSCOPY. C. H. Rüscher[1], A. Hussain[2] [1]Institut für Mineralogie der Universität Hannover, Welfengarten 1, D-30167 Hannover, Germany [2]Department of Chemistry, Dhaka University, 1000 Dhaka, Bangladesh.

Here we report the first optical spectra of intergrowth tungsten bronzes (ITB) of composition M_xWO_3 with $0.05 < x < 0.15$ and M = K, Rb, Cs. The structure type (e.g. /1/) consist of extended slabs of hexagonal tungsten bronzes (HTB) which are separated by slabs of WO_3 building units. X-ray and TEM pattern show an orthorhombic lattice with one long axis (a ≈ 2-3 nm) and two shorter axis (b ≈ 0.74 nm, c ≈ 0.76 nm), where the c axis is related to the shorter subaxis (c' ≈ 0.38 nm) of the HTB subunit. The optical reflectivity of crystal slices was measured with incident light polarized parallel to their unit cell axis (microscope technique, 600 - 20000 cm^{-1}). The spectra reveal in all cases broad absorption peaks. For E ‖ b highest absorption intensities and the lowest resonance frequency (1000 cm^{-1}) is observed, i.e. a reflectivity of up to 60 % below 4000 cm^{-1} and a minimum in reflectivity at about 8000 cm^{-1}. The E ‖ c component reveal a rather broad feature with slightly increased reflectivity between 1000 and 8000 cm^{-1}. For E ‖ a a resonance structure between 8000 and 16000 cm^{-1} is observed. The absorption is explained by photon assisted hopping of polarons. The electron charge carrier reveal its strongest coupling to phonons parallel to the a direction, and lowest parallel to the b axis. Supported within combined DFG / GTZ - project.

P05.OC.009 ATOMIC LEVEL PRESPECTIVE OF THE STRUCTURE OF PHASE DIAGRAMS : Li-Al ALLOYS. J.S. Tse, R. Rousseau, A. Ker and F.X. Lannuzel, Steacie Institute for Molecular Sciences, National Research Council of Canada, Ottawa, Ontario, Canada K1A 0R6.

The relationship between electronic and crystal structure for Li-Al alloys is investigated using electronic structure theory. In particular, we couple *ab initio* density functional calculations and tight binding electronic structure topology analysis *via* a moments decomposition of the density of electronic states. This procedure allows the rationalization of the stability of a crystal structure from the local structure motifs. We will show that the phase diagram for the known phases of Li-Al alloys can be understood by this topolgical analysis. The potential usefulness of the theoretical procedure is demonstrated by combining database mining for the prediction of the structure of a hypothetical metastable Al_3Li_2 alloy phase.

P05.OC.010 VALENCE ORDERING IN THE IODO-BRIDGED ONE-DIMENSIONAL MIXED-VALENCE DIPLATINUM(II,III) COMPLEXES. K. Toriumi, M. Mitsumi, Y. Ozawa, T. Yoshinari, and K. Akashika, Department of Material Science, Himeji Institute of Technology, Harima Science Garden City, Hyogo 678-1297, Japan, and H. Kitagawa, and T. Mitani, Japan Advanced Institute of Science and Technology, Ishikawa 923-1292, Japan.

Halogen-bridged mixed-valence diplatinum complexes $Pt_2(RCS_2)_4I$ (R= CH_3 (**1**), C_2H_5 (**2**), n-C_3H_7 (**3**)) with linear chain structures of repeating units {-I–Pt–Pt–I-} are particular interest because they are possible to take a variety of valence ordering [1]. The crystals of **1** which was first reported by Bellitto et al. [2] exhibit anomalous electrical conducting behavior (T < 300K, semiconductor; 300 K < T < 340 K, metallic) [3]. The variable temperature crystal structure analyses revealed dynamic disorder of the ligands [4].

In order to elucidate the relation between the solid state behavior and the valence ordering of Pt atoms on the linear chain, the compounds **2** and **3** were synthesized and their crystal structure analyses and electrical conducting measurements were carried out [5]. The M-I transition was observed for **2** at about 200 K.

Since the crystal structure analyses provided only the averaged structures, we tried to measure the diffuse scatterings corresponding to low-dimensional valence ordering of Pt atoms. Single crystal X-ray photographs of the compounds **1**-**3** were taken at variable temperatures by using the vacuum type X-ray camera developed by MAC Science Co., Ltd. and us or SPring-8 BL02B1 station. It was revealed that although the diffuse scatterings corresponding to the valence alternation along the linear chain have been observed for **2** above 200 K (metallic state), but changed to the Bragg spots below 100 K (semiconductive state). Similar phenomena were observed for the crystals of **3**.

05OD 30 YEARS OF RIETVELD REFINEMENT

M05.OD.001 THE RIETVELD METHOD. H.M. Rietveld.

Thirty years ago the use of powder diffraction was mainly confined to determining spacegroup and/or unit-cell dimensions. Only very simple crystal structures could be solved this way. Single crystal diffraction was the way to determine crystal structures and for most substances large enough crytals could be grown. However, for more and more substances of interest it was impossible to grow these large crystals, especially those required for neutron diffraction.

With the advent of computers, small compared with today's standards, it became feasible to use as data the very large number of step scanned profile intensities in a powder diagram instead of the fewer but severely overlapping integrated intensities.

The method, while originally developed for neutron diffraction, became widely used when it was also adapted to X-ray diffraction. Nowadays the method is used in more than 500 publications per year.

M05.OD.002 NEUTRON POWDER DIFFRACTION – A WORLD OF SUPERCONDUCTORS, GIANT MAGNETO-RESISTANCE ETC. Alan Hewat, Institut Laue-Langevin, BP 156X, Grenoble 38042, FRANCE.

Superconductors, Giant Magneto Resistance, Magnetic Frustration, Zeolite Intercalates, Structural Transitions… these are some of the success stories for Rietveld refinement with neutron powder data The citation index shows that this work had more impact than other neutron scattering experiments in the past 30 years, and in fact was among the most highly cited of all science in some years (eg see http://www.ill.fr/dif/citations/).

The most recent examples concern the mechanism of Giant Magneto-Resistance. A combination of neutron and synchrotron data was used to examine the subtle structural transitions responsible for the GMR effect, the detailed magnetic structure was obtained, and most importantly the 'stripe' structure that has recently generated such excitement, has been shown to be absent in well characterised materials (this meeting).

The most famous examples of the application of Rietveld refinement remain of course in the field of oxide superconductors, and in particular the ideas that lead to the successful search for

new materials. Neutron diffraction had already shown that the highest Tc materials were layer structures, very different from the original Bednorz and Muller material. New experiments at Argonne and Grenoble showed how the hole density in the conducting layer was controlled by 'charge-transfer' from reservoir layers, which then lead to a successful search for new materials with bismuth, thallium and mercury oxide charge reservoirs.

Neutron diffraction has proved to be essential for such work because of the absence of single crystals for very new materials, and because of the greater contrast obtained between oxygen and heavy metal atoms. New diffractometers such as D20 at ILL and GEM at ISIS will extend the application of neutron diffraction to very small samples, and to in-situ chemistry on such samples. The proposed super-D2B and a new machine on the proposed European Spallation Source will also extend applications to problems where very high resolution is needed.

M05.OD.003 APPLICATIONS OF THE RIETVELD METHOD TO INORGANIC MATERIALS. F. Izumi, National Institute for Research in Inorganic Materials, 1-1 Namiki, Tsukuba, Ibaraki 305-0044, Japan.

The past thirty years have seen dramatic developments in the Rietveld method. Further, synchrotron radiation sources and intense neutron sources have enabled us to measure high-resolution powder diffraction data in relatively short times. Imaging plates and position-sensitive detectors have improved counting statistics markedly to permit real-time diffraction experiments and measure intensity data for small amounts of samples. These advances in diffraction techniques have enhanced the utility value of the Rietveld method greatly.

The discovery of a series of high-T_c superconductors has made the Rietveld method much more popular because of its wide applications to their structure refinements. In particular, neutron Rietveld analysis was extensively used for three different types of structural studies:\ (1) determination of new structures, (2) relations between (defect) structures and physical properties, and (3) structural changes in special environments, *e.g.*, under low or high temperature and under high pressure. With Rietveld refinements adopting superspace group approaches, we determined the incommensurately modulated structures of Bi-based superconductors and the composite crystal $Ca_{13.6}Sr_{0.4}Cu_{24+y}O_{41+z}$.

The Rietveld method has been contributing to the development of industrial inorganic materials. One of the most outstanding examples is cathode materials in rechargeable lithium-ion batteries, *i.e.*, $LiNiO_2$, $LiMn_2O_4$, and their related compounds. Further, multi-phase Rietveld analysis is now routinely utilized in the quality control of clinker production in the cement industry, providing reliable mass fractions and structure parameters of alite, belite, $Al_2Ca_3O_6$, $Al_2Ca_4Fe_2O_{10}$, *etc*. owing to fitting of whole powder patterns.

We have recently developed a Rietveld-analysis program, RIETAN-98, with two innovatory features: partial profile relaxation and whole-pattern fitting based on a maximum-entropy method (MEM). Partial profile relaxation means that primary profile parameters of isolated reflections can be locally refined independently of secondary profile parameters. It was united with three split-type profile functions to obtain better fits between observed and calculated patterns, particularly in samples showing anisotropic profile broadening. Further, RIETAN-98 has been combined with a MEED program for the MEM to grow into an integrated software named REMEDY, which makes it possible to carry out MEM analysis and whole-pattern fitting alternately. REMEDY is very effective for modifying incomplete structural models and analyzing highly disordered structures as well as covalent crystals.

M05.OD.004 THE RIETVELD METHOD WITH LABORATORY X-RAYS. D. Louër, Laboratoire de Chimie du Solide et Inorganique Moléculaire, Université de Rennes I, 35042 Rennes, France.

The Rietveld method was applied to powder diffraction data collected with a conventional X-ray source a few years after its advent, using both transmission and reflection optics [1,2]. The delay for its application to X-ray diffraction data was essentially due to the more sophisticated line shape required to describe the observed line profiles. Since then the difficulties have been overcome and the Rietveld method is now familiar to laboratory diffractionists. Among available optics the choice of a diffraction geometry depends on the absorption properties of the material with respect to the wavelength. These practical aspects and the use of monochromatic $K\alpha_1$ radiation or $K\alpha_1$-$K\alpha_2$ doublet will be commented. The precision reached in Rietveld refinements as well as the sensitivity of the method to structural details will be illustrated by examples. However, the most spectacular results in structure analysis arose from the association of the Rietveld method with the other advances occurred in indexing procedures, in pattern decomposition algorithms and in structure solution. The development of *ab initio* structure determination from powder data has completely transformed the chemistry of families of powder materials. Laboratory X-rays are used to characterise the structure of different classes of solids, such as inorganic, coordination, organic and drug compounds. The Rietveld refinement method is applied at the final stage of the studies to demonstrate the relevance of the structure model and to obtain precise atomic coordinates. This will be illustrated from representative examples, including classes of powder materials whose chemistry has been transformed from the use of the Rietveld method. In addition, the impact of the whole profile refinement method, using laboratory X-rays, in the interpretation of structural changes occurring in dynamical studies will be illustrated.

M05.OD.005 SYNCHROTRON RADIATION - PICKING UP THE FLAME AND FANNING THE FIRE. A.N. Fitch, ESRF, BP 220, 38043 Grenoble Cedex, France.

With the arrival of the synchrotron, experienced users of neutrons, and new workers, were attracted towards the use of X-rays and the Rietveld method. Synchrotron radiation has several advantages for powder measurements. The collimation can be exploited to remove aberrations in peak positions that can affect conventional instruments. By working at higher energies with a spinning capillary, absorption and preferred orientation can be minimised. As dedicated instruments became available, the Rietveld method became the preferred way to refine a crystal structure from synchrotron data. However, high resolution data can reveal effects due to a sample's microstructure, and the peak shapes needed to be adapted to contend with anisotropy, strain, particle-size broadening, etc. By carefully tuning the energy, differences in the intensities close to and far from an absorption edge can be analysed to increase the experiment's sensitivity towards a resonantly scattering element. The easiest way to exploit this information was to adopt the Rietveld method to fit concurrently to more than one data set. The natural complementary between X-rays and neutron could also be more efficiently exploited in a joint refinement. The very high intensity at a synchrotron has led to developments in *in-situ* experiments. It is now possible, on a time scale of a few seconds, to collect data that can be refined by the Rietveld method, to reveal the evolution of structure in a sample undergoing rapid physical or chemical change. As the results from Rietveld refinements have been

demonstrated again and again to be reliable, confidence in the powder technique has grown, to the point that structures are now routinely *solved* from powder data, especially using the synchrotron. Whilst the Rietveld method is a method of structure refinement, the basic approach has been exploited to solve structures, by fitting to the diffraction data whilst moving a known fragment or molecule around the unit cell. These techniques are a direct legacy of the original approach, and the current interest in such methods ensures that the basis of the Rietveld technique will endure for years to come. The talk will discuss and illustrate these concepts.

P05.OD.001 AB INITIO STRUCTURE SOLUTION AS PART OF THE RIETVELD REFINEMENT PROCESS. A. Kern and A. Coelho, Bruker-AXS GmbH, Östliche Rheinbrückenstraße 50, D-76187 Karlsruhe

A new Rietveld program system (TOPAS) has been developed with particular emphasis placed on improving stability and convergence. TOPAS is built around a general non-linear least squares system written specifically to integrate various types of X-ray diffraction analyses. This includes the ability to refine laboratory/synchrotron/neutron powder diffraction and single crystal data simultaneously. Input to the program can be either hkl, 2θ and d-spacing intensity peaks, or structural data obtained in a free format. Conversions from ShellXTL, GSAS and FullProf formats are possible.

There are various minimization routines including the Marquardt method of refinement plus line minimization and parameter extrapolation techniques. Sparse matrix methods are used when refining thousands of parameters e.g. for lattice parameter refinement or when extracting integrated intensities.

A remarkable feature of TOPAS is the ability to solve structures by simulated annealing together with user defined penalty functions, rigid bodies and lattice energy minimization techniques including user defined force fields/equations. Rigid bodies take into account space group symmetry. They can be linked and rotated about any axes and hinges.

The numerical speed of TOPAS is an order of magnitude faster than that of existing Rietveld programs. As in addition no more refinement strategy is needed Rietveld refinements can be performed up to 100 times faster! Further key features of TOPAS are:

- Physically meaningful peak shapes can be generated using a new Fundamental Parameters Approach with all parameters refinable.
- Spherical harmonics to describe preferred orientation, anisotropic peak broadening and temperature factors.
- Fits to unequal x-axis steps.

05OE CRYSTALLOGRAPHY AND GEOSCIENCES

M05.OE.001 TOTAL SCATTERING MEASUREMENTS ON DISORDERED CRYSTALLINE SILICATES. Martin T Dove Mineral Physics group, Department of Earth Sciences, University of Cambridge, Downing Street, Cambridge CB2 3EQ

X-ray diffraction has been a pivotal technique in the study of minerals since the earliest days of the technique, and over the past decade or so this has been augmented by neutron powder diffraction. More recently we have been using total neutron scattering measurements to study crystal phases which clearly have considerable disorder on a short length scale. Total scattering involves analysing both the Bragg peaks and the diffuse scattering background, and the Fourier transform of the total scattering pattern gives the pair distribution function. Constrained reverse Monte Carlo methods allow one to construct atomic configurations that are consistent with the diffraction pattern, and these can provide information about the nature of the structural disorder. We illustrate this approach by studies of phase transitions in different silica phases.

M05.OE.002 THERMAL ANOMALIES IN TITANITE AND MALAYAITE. U. Bismayer, Mineralogy, University of Hamburg, Grindelallee 48, D-20146 Hamburg, Germany.

Titanite, $CaTiSiO_5$, and malayaite, $CaSnSiO_5$, exhibit a thermal anomaly near 500 K. Specific heat measurements, synchrotron X-ray diffraction, hard mode spectroscopy and high-resolution transmission electron microscopy [1, 2] were used to study synthetic and natural titanite. At temperatures above the structural transformation *P21/a - A2/a* anisotropic diffuse scattering occur in synthetic titanite and remain visible up to ca. 825 K, where the excess specific heat disappears. In natural crystals the phase transformation near 500 K is suppressed by impurities and defect induced renormalization phenomena alter the critical behaviour.

High-temperature X-ray diffraction and powder IR spectroscopy were used to study the thermal behaviour of malayaite [3]. No diffuse reflections were observed. The crystal structure data show no evidence of a symmetry-breaking phase transition near 500 K. The most obvious change with heating is a tumbling motion of the SnO_6 octahedra and an increase of the thermal displacement ellipsoid of the Ca atom. At this temperature IR spectra show a break in the variation of mode intensities and peak positions. Similarities to the thermal behaviour of the 825 K anomaly in titanite are discussed.

Financial support by BMBF (GUA 05647) and ARC is acknowledged.

M05.OE.003 PROPERTIES OF AL:SI ORDER-DISORDER PHASE TRANSITIONS IN FRAMEWORK SILICATES. T. Malcherek, CNR-CSCC, Dipartimento di Scienze della Terra, Via Ferrata 1, 27100 Pavia, Italy, H. Kroll, Institut für Mineralogie, Westfälische Wilhelms-Universität, 48149 Münster, Germany, E.K.H. Salje, Department of Earth Sciences, University of Cambridge, Cambridge CB2 3EQ, UK.

Using X-ray diffraction, TEM and IR-Spectroscopic methods, equilibrium behaviour and kinetics of cation ordering in the tetrahedral framework of the monoclinic feldspar $BaAl_2Ge_2O_8$ (BAGF) have been studied. Substitution of Ge for Si in natural 2:2 feldspar structures avoids difficulties encountered in direct measurement of Al,Si ordering by X-ray diffraction methods.

A mean field approximation was used to model the observed thermal equilibrium behaviour of the convergent order parameter Q_{od} and a coupled non-convergent order parameter Q_t. Q_{od} discontinuously falls to zero at T_{tr} = 1690K accompanied by a SG symmetry change I2/c↔C2/m. Local fluctuations of Q_{od} near T_{tr} could be observed using TEM DF imaging on quenched samples. The fluctuations indicate the Ising character of the microscopic properties and they agree with short range order observed by Hard Mode Infrared Spectroscopy.

The order parameter fluctuations have important consequences for the ordering kinetics if the feldspar is quenched to lower temperatures. The strong non-uniformity of Q_{od} causes changes in the mechanism by which the equilibrium state is reached. Thus, in comparison to conventional time dependent Ginzburg-Landau behaviour for a uniformly ordered structure, a

significant slowing down of the ordering kinetics is encountered during low temperature annealing.

Possible implications of the observed order-disorder behaviour for Al,Si cation ordering in natural felspar minerals and in other framework silicates such as cordierite are discussed.

M05.OE.004 CRYSTAL MINERALOGY OF SHALES FROM THE GULF OF MEXICO. L.E. Rendón [1], L.de Pablo, M.L. Chavez, R. Monsalvo, G. Miranda [2], [1] Instituto Mexicano de Tecnologia del Agua, Jiutepec, Mor., [2] Geoquimica, Instituto de Geologia UNAM Mexico D.F.

Swelling of active shales is associated with adsorption of chemical species and diagenesis. Active shale, Oligocene-age, containing 50.8% discrete illite, disordered anhydrous, $1H_2O$-, $2H_2O$- and $3H_2O$-layer smectite, and mixed-layer smectite/illite, and having a cation exchange capacity of 83.12 meq/100 g, upon hydration at the in situ temperature of 80°C desorbs 38% of the adsorbed Na^+, some Ca^{2+}, and none K^+ and Mg^{2+} to form predominant discrete illite and disordered $1H_2O$-layer smectite and minor anhydrous and $2H_2O$-layer smectite. Reaction with Na^+, K^+, Ca^{2+}, and Mg^{2+} electrolytes at 22°C reduces adsorbed Na^+ an additional 28% and develops ordered $2H_2O$-layer smectite of finer crystallite size (d(001) 14.59 Å-15.07 Å). At 80°C, 0.0001M electrolytes decrease adsorbed Na+ to 17.59 meq/100 g, K+, Ca2+ and Mg2+ remain constant, and form discrete illite, disordered 1H2O-layer (d(001) 12.21 Å-12.93 Å), $2H_2O$-layer (d(001) 14.34 Å-15.42 Å), and minor anhydrous smectite when the reacting electrolytes are K^+ (d(001) 11.85 Å) or Ca^{2+} (d(001) 10.70 Å). With 0.001M solutions transformation is to $1H_2O$-layer (d(001) 12.34 Å-13.09 Å), $2H_2O$-layer (d(001) 14.25 Å-14.92 Å), and anhydrous smectite when reacting with K^+ (d(001) 11.81 Å). Discrete illite at 22°C reverses readily to smectite and forms at 80°C when the shale reacts with weak electrolytes but not with strong ones which require additional hydration to develop illite. Spacings of the smectite complexes formed at 80°C by 0.0001M electrolyte and hydration are: With Na^+, 12.21 Å, 12.71 Å, and 14.34 Å; with K^+, 11.85 Å, 12.46 Å, and 14.50 Å; with Ca^{2+}, 12.44 Å and 14.42 Å; with Mg^{2+}, 14.48 Å and 15.42 Å. When the electrolyte is 0.001M, Spacings are: With Na^+ 13.08 Å and 14.52 Å; with K^+, 11.81 Å, 12.34 Å, 13.09 Å, and 14.59 Å; with Ca^{2+}, 14.25 Å, 14.92 Å and 12.08 Å; and with Mg^{2+}, 12.49 Å and 12.93 Å. At 80°C Mg^{2+} forms $1H_2O$-layer smectite complexes, Na^+ and K^+ $1H_2O$- and $2H_2O$-layer complexes, and Ca^{2+} only $2H_2O$-layer smectite complexes. The data supports that swelling, variable pore pressure, and instability in active shale are associated with adsorption and cation exchange between the surrounding solution and the smectite surface. Adsorbed cations and hydration leads to different smectite complexes which accommodate differently on the clay surface. Exchange appears to be dependent on activity coefficient gradients between the adsorbed layer and the surrounding solution.

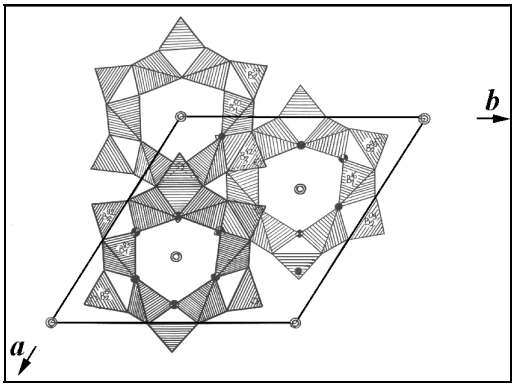
M05.OE.005 NEW DEVELOPMENTS IN CRYSTAL CHEMISTRY OF HIGH-PRESSURE HYDROUS SILICATE PHASES. C.T. Prewitt, H. Yang, J. Konzett, Y. Fei, Geophysical Laboratory and Center for High Pressure Research, Carnegie Institution of Washington, 5251 Broad Branch Road, NW, Washington, D.C. 20015-1305, USA.

High-pressure hydrous silicate phases have attracted much attention for the past 30 years because of their great implications for the presence of water in the Earth's mantle and effects on the Earth's processes. Previous studies on hydrous silicates were focused primarily on the MgO-SiO_2-H_2O system, and a number of phases were identified and labeled as 10Å, 3.65Å, A, B, C, D, E, F, G, and superhydrous B (the "alphabet phases"). However, recent studies showed that phase F is actually superhydrous B, the latter is actually phase C, and phase G possesses the same structure as phase D. Further coordinated work in synthesis and crystallography is apparently needed for a better understanding of crystal chemistry of the high-pressure hydrous phases in the MgO-SiO_2-H_2O system. Also, to provide a wider range of information, we have begun investigating more chemically-complicated hydrous silicate phases synthesized at high pressures and temperatures using the multi-anvil apparatus and have made considerable progress, including synthesis and characterization of the following hydrous phases:

1. ^{M4}K-substituted K-richterite, $K(KCa)Mg_5Si_8O_{22}(OH)_2$ (15 GPa, 1400°C);
2. Clinopyribole, $K_{0.96}Ca_{1.56}Na_{2.51}Mg_{6.01}Al_{1.12}Si_{12}O_{34}(OH)_2$ (10 GPa, 1200°C);
3. Hydrous phase (aenigmatite structure), $Na_2(Mg_{5.30}Al_{0.48})Si_{5.91}O_{18}(OH)_2$ (10 GPa, 1250°C);
4. Na-phase X, $(Na_{1.16}K_{0.01})(Mg_{1.89}Al_{0.14})Si_2O_7H_{0.65}$ (10 GPa, 1250°C);
5. K-phase X, $K_{1.54}Mg_{1.93}Si_{1.89}O_7H_{1.04}$ (16 GPa, 1300°C);
6. Fe-bearing hydrous phase, $Mg_{2.29}Fe^{3+}_{0.60}Si_{1.01}O_6H_{2.15}$ (14 GPa, 1400°C).

Structure refinements/determinations of these phases not only provide us with insights into crystal chemistry of high-pressure hydrous silicates, but also expand our knowledge of deep Earth mineralogy. Our results also suggest that a large number of new structures and relatively exotic phases in the mineral kingdom may be discovered as we further explore the pressure-temperature-composition space.

P05.OE.000 THE CRYSTAL STRUCTURE OF NEW LEAD DODECABORATE $Pb_6B_{12}O_{24}.H_2O$ WITH THE UNIQUE RING $[B_6\ B_6^{\Delta}O_{24}]^{12-}$. T.A.Korchemkina, E.L. Belokoneva, O.V. Dimitrova, Moscow State University, Vorob'evi Gory, Moscow, Russia.



New lead borate has been synthesized during search for new non-linear optical materials in hydrothermal conditions in PbO-B_2O_3-H_2O system. The crystal structure of it was determined using the heavy atom method without knowing the chemical formula. The dodecaborate $Pb_6B_{12}O_{24}.H_2O$ has the unique B-O unit: an independent six-member ring $[B_6B_6O_{24}]^{12-}$ of B-tetrahedra in the structure is surrounded by six B-triangles attached on the external side, sharing the corners. In contrast to many other borates, this unit does not contain OH^- groups, though it is centered by H_2O molecules. Each trigonal cell a=11.432(4), c=17.385(6) contains three rings, repeated by R-translations of R-3m space group. Rings are interleaved by sheets of Pb-polyhedra, parallel to plane ab, located on levels ~0, ~1/3, ~2/3.

The material researched, adds itself to a small group of four lead borates (with and without water), two of which proved to be non-linear optic ones. A newly discovered ring is an important addition to the borates classification.

P05.OE.001 THE HILGARDITE GROUP STRUCTURES AS MEMBERS OF THE OD-FAMILY. E.L. Belokoneva, T.A. Korchemkina, O.V. Dimitrova, S.Yu. Stefanovich, Moscow State University, Vorob'evi Gory, Moscow, Russia.

New centrosymmetric modification of natural hilgardite I $Ca_2[B_5O_9]Cl.H_2O$ - II $Pb_2[B_5O_9](OH).H_2O$ was hydrothermally synthesed. The comparison of two structures led to the conclusion they are built from uniform $[B_{10}O_{21}]^{-12}$ layers as well as synthetic III $Ca_2[B_5O_9]Br$ and may be described within the OD-theory. The symmetry of layer (λ-PO) and the symmetry operation which transfer layer to layer (σ-PO) or two dimentional unit into tree dimentional framework in the structure are described with the grouppoid

$[B_{10}O_{21}]^{-12}{}_{\infty\infty}$ P 1 1 (n) (λ-PO)
[1 1 (1//a//2)] (σ-PO)

For the structure I the transformation of layers is realized by a-glade, for II - by symmetry center 1, for III - by 2-fold axis. The resulting space group of compounds are different: monoclinic Aa and $P2_1/n$ for I and II and orthorhombic Pnn2 for III. All three are typical MDO-polytypes. Triclinic minerals: strontiohilgardite, tyretskite and isostructural syntethic IV $Ca_2[B_5O_9]Cl.H_2O$, as well as parahilgarditeV $Ca_2[B_5O_9]Cl.H_2O$ belong to the same family but with the modification of layer. The building unit of layer is helical chain $[B_5O_{11}]^{-7}$ with the symmetry 1, which undergoes n-glade symmetry operation in first I,II,III structures. It may undergo simple translation t (structure IV) or combination of n and t (n,n,t...) as it is in structure V. So we can write the grouppoid of other rank which describes the transfer of one dimentional unit (chain) into two dimentional (layer)

$[B_5O_{11}]^{-7}{}_{\infty}$ P(1)1 (λ-PO)
[(t//n)1] (σ-PO)

We can predict the structures with sequences 1,a..., or 2,a..., or 1,2..., or 1,2,a... in different variants in accordance with the first grouppoid. More complicate structures may exist until absence of order along the direction of periodicity. n,t...sequence along layer may also vary until disorder along layer. Thus the structures in OD-family are determined by ordering of two- or one-dimentional units (chain or layer). Different minerals of group may coexist in nature. More preferable will be such structures which are more thermodynamically stable and posses lowest entropy as it is typical for polytypes.

P05.OE.002 HIGH-PRESSURE CRYSTAL CHEMISTRY OF Al_2SiO_5 : *AB INITIO* PSEUDO-POTENTIAL CALCULATIONS. Artem R. Oganov, John P. Brodholt, G. David Price, Department of Geological Sciences, University College London, WC1E 6BT, London, UK.

Aluminium is one of the most abundant elements on the Earth, however, a great uncertainty still exists on the form of Al in the largest part of the planet - the lower mantle : some researchers propose $MgSiO_3$-perovskite as a main host of Al in the lower mantle, others propose hollandite-type phase of $(Ca,Mg)Al_2Si_2O_8$ or high-density phase of $MgAl_2O_4$. Recent works [1] showed that a high-pressure form of Al_2SiO_5 with V_3O_5-type structure, found experimentally at high *P-T*-conditions, can be the main host of Al in the lower mantle, comprising up to 5% of its volume. However, more recent experiments [2] have shown that this phase is not formed; instead, kyanite (Al_2SiO_5) transforms into a mixture of corundum (Al_2O_3) + stishovite (SiO_2).

We report results of *ab initio* calculations, based on density functional theory within the framework of generalized gradient approximation (GGA) with plane wave basis set and effective core pseudopotentials. We consider polymorphs of Al_2SiO_5 (kyanite, andalusite, sillimanite and hypothetical V_3O_5-like and pseudobrookite-like phases), SiO_2 (stishovite, quartz) and Al_2O_3 (corundum). A highly converged set of computational parameters was used in order to reproduce small energies of the phase transitions. A good agreement of crystal structures, bulk moduli, atomisation energies and the phase diagram with experiment was found. At the same time, a strong disagreement of calculated lattice parameters and density of V_3O_5-like phase of Al_2SiO_5 with experimental values of [1] is observed, suggesting that the phase synthesised in the latter work cannot be identified as V_3O_5-structured phase of Al_2SiO_5. Also, we found that the most stable high-pressure assembly in Al_2SiO_5 system is corundum+stishovite, and the value of the transition pressure (113 kbar) is in excellent agreement with experimental estimates (99-150 kbar).

P05.OE.003 PARTITIONING AND STRUCTURAL BONDING OF FLUORINE IN PHLOGOPITES AND SILICATE MELTS: A SOLID STATE NMR STUDY. M. Fechtelkord, H. Behrens, F. Holtz, Institut für Mineralogie der Universität Hannover, Welfengarten 1, D-30167 Hannover, Germany. and L. A. Groat, Department of Earth and Ocean Sciences, University of British Columbia, 6339 Stores Road, Vancouver, B.C. Canada V6T 1Z4

The micas biotite, phlogopite and muscovite are the preferred phases which incorporate fluorine beside the melts during differentiation of magmas. A detailed study of the fluorine local structure in melt and layer silicates may provide a better understanding of the effect of fluorine enclathration on the chemical and physical properties of the phases and on fluorine partioning.

To study the influence of the OH-/F-ratio and of the Tschermak substitution ($^{[6]}Mg^{2+} + {}^{[4]}Si^{4+} \rightarrow {}^{[4]}Al^{3+} + {}^{[6]}Al^{3+}$) on the local structure of fluorine in phlogopites eight samples with varying OH/F-ratios and compositions of $K(Mg_{3-x}Al_x)[Al_{1+x}Si_{3-x}O_{10}](OH)_{1.5}F_{0.5}$, $0.1 \leq x \leq 0.7$ were hydrothermally synthesized from gels. The phlogopite can be characterized in the ^{29}Si MAS NMR spectrum by three resonances at -83.2 ppm (Q^3(2Al)), -86.9 ppm (Q^3(1Al)) and -90.7 ppm (Q^3(0Al)). Based on the relative intensities of the signals, the calculated Si/Al-ratio can be estimated along the phlogopite-eastonite join [1]. The estimated Si/Al ratio are in good agreement with the initial ratios of the gel. In eastonites with $x \geq 0.5$ the formation of corundum limits the ratio of Si/Al to 2.0 for the phlogopites. The application of $\{^{19}F\}$ ^{29}Si CPMAS NMR shows an increase of the (Q^3(1Al)) and (Q^3(0Al)) signal intensities, which suggests a shorter distance of fluorine located in the cation layers to silicon atoms in the tetrahedral sheets predominantly bonded to other silicon atoms. The ^{19}F MAS NMR spectra show only one signal shifting in dependence on the Al- and F-content.

05OF NANOMATERIALS

M05.OF.001 FROM CLUSTERS VIA NANOSIZED RING-SHAPED AND SPHERICAL (ICOSAHEDRAL) CLUSTERS AND SUPRAMOLECULAR SPECIES TO MATERIALS. Achim Müller, Fakultät für Chemie, Universität Bielefeld, Postfach 100 131, D-33501 Bielefeld, Germany, e-mail: a.mueller@uni-bielefeld.de

In Nature, complex molecular systems like proteins have evolved (natura naturans) which are perfectly suited to their functions. These are produced in a sequence of steps under dissipative conditions – that is, far from quilibrium. The challenge for the chemist is to synthesize correspondingly

complex multi-functional molecules also under non-equilibrium (dissipative) conditions using multi-component one-pot reactions without having to separate and purify each single intermediate product. Relevant model reactions have been discovered in solutions of simple *oxoanions of the transition metals*: Novel types of molecular growth processes with feedback (including a type of induced cascade) are described leading to different *ring-shaped, electron-rich, mixed-valence, giant polyoxomolybdates with nanosized cavities*. These can – due to the generation of defects – be covalently linked together to form *chains* as well as *layered mesoporous compounds* with properties relevant for materials science. They can also start growing again. The largest polyoxometalate cluster obtained on the basis of this growth process to-date has 248 atoms. Remarkably, such giant ring species can also act as *hosts for other clusters forming new types of supramolecular compounds*.

The lecture will be highlighted with a report on the planned synthesis and structure of different *nanosized spherical clusters with icosahedral symmetry* which have similar structures as spherical viruses and *which can be linked in different ways even to layers(!)*. For the first time, discrete molecular species with structures related to some of the Archimedean solids will also be reported.

M05.OF.002 INORGANIC FULLERENE-LIKE MATERIALS AND NANOTUBES (IF) FROM LAYERED COMPOUNDS. Reshef Tenne, Yshai Feldman, Moshe Homyonfer, Gitti L. Frey, Yaron Rosenfeld Hacohen, Aude Rothschild, Department of Materials and Interfaces, Weizmann Institute, Rehovot 76100, Israel, Jeremy Sloan and John L. Hutchison, Department of Materials, Oxford University, Parks Road OX1 3PH, UK

Using the paradigm of carbon fullerenes, it was shown by Tenne and co-workers[1] that nanoclusters of layered compounds, like MoS_2, are unstable in the planar form and fold into hollow cage structures of various shapes: from spherical and polyhedral to nanotubes of a mm length and cross-section of 10-20 nm diameter (IF). Following this discovery a few methodologies for the systematic synthesis of large amounts of IF-MoS_2 and WS_2, were pursued. Recently, IF structures from various other layered compounds were synthesized. Intercalation of IF-WS_2 rendered these nanostructures as stable suspensions in aprotic solvents and photoelectrochemical cells were subsequently prepared. Recently, the first MoS_2 octahedra having 572 Mo atoms, were reported[2].

The structural, optical, electrochemical, and tribological properties of IF-MoS_2 (WS_2) were investigated in some detail. It was found by Frey et al.[3], that IF-MoS_2 (WS_2) are semiconductors with a tunable bandgap which scales with the size of the nanoparticles. The 2H polytype structure is locally preserved in these nanoparticles. Few extra Raman lines observed in the IF suggest a reduced symmetry compared with the bulk (2H) predecessor. The tribological properties of IF was shown by Rapoport et al.[4] to outperform the ubiquitous solid lubricants 2H-MoS_2 (2H-WS_2). This suggests an eminent range of applications for these nanomaterials. Other applications will be briefly discussed.

M05.OF.003 MAGNETIC (NANO) COLLOIDS. A. P. Philipse, Department of Chemistry, Utrecht University, Netherlands.

Preparation and properties will be discussed of magnetic colloids (iron, cobalt, ironoxide) in the nanometer size range, dispersed in a liquid phase. The particles are coated with a non-magnetic polymer or inorganic layer. The magnetic (dipolar) interactions between the (permanently magnetized) particles strongly depend on the particle radius and the thickness of the coating. This dependence gives rise to a rich variety in size and morphology of particle structures formed in presence or absence of a magnetic field. Experiments (and some ideas) on this structure formation will be presented.

M05.OF.004 STRUCTURE AND QUANTIZED CONDUCTANCE OF NANOWIRES STUDIED BY A COMBINED STM AND ELECTRON MICROSCOPE. K.Takayanagi [1], Y.Kondo, H.Ohnishi [2], Y.Ohshima [1]. [1] Department of Materials Sciences and Engineering, Tokyo Institute of Technology, Nagatuta, Yokohama, Japan. [2] ERATO project, Japan Science and Technology, Tachikawa, Tokyo, Japan

Metal nanowires were formed by the technique of scanning electron microscope (STM), and their structures were studied by ultra-high vacuum (UHV) electron microscopy. A miniaturized STM was built in an UHV electron microscope to investigate the electronic conductances the nanowires, simultaneously with their structures. Gold nanowires were found to be consisted of atom strands. Each of the strands conssisted of a linear chain of gold atoms. The structure of the gold nanowires were found to change as their diameter decreases, because of symmetry breaking. The linear chain of gold atoms, or a single strand of gold atoms, was formed finally between the two electrodes, being suspended in vacuum. The strand had anomalously long spacings between the gold atoms, compared with the nearest neighbour distance in the face centered cubic crystal.

Details on the structures and their conductance quantization are presented, in addition to the experimental details.

M05.OF.005 ABSTRACT NOT AVAILABLE. M. Moeller

P05.OF.001 MELTING OF Sn NANOCRYSTALS INVESTIGATED BY SURFACE BRILLOUIN SCATTERING AND X-RAY DIFFRACTION. C.E.Bottani[1], A. LiBassi[1,2], B.K.Tanner[2], A.Stella[3], P.Tognini[3], P.Cheyssac[4] and R.Kofman[4]. 1: INFM-Dipartimento di Ingegneria Nucleare, Politecnico di Milano, Via Ponzio 34/3, 20133 Milano (Italy) 2: Department of Physics, University of Durham, South Road, Durham DH1 3LE (UK) 3: INFM-Dipartimento di Fisica "A.Volta", Universita' degli Studi di Pavia, Via A.Bassi 6, 27100 Pavia (Italy) 4: Laboratoire de Physique de la Matière Condensée, URA 190, Université de Nice-Sophie Antipolis, 06108 Nice Cedex (France)

Brillouin scattering of light off surface acoustic phonons and synchrotron (Daresbury and ESRF) X-ray diffraction have been used together for the first time to study the size-dependent melting transition of tin nanocrystals embedded in a silica film on a Si(100) substrate. A jump in the spectral shift of the surface phonon peaks was detected across the melting temperature and the nature of the transition was confirmed by the vanishing of the tin-related Bragg diffraction peaks in the same temperature range. The observed melting temperature was found to depend on the nanocrystals size and to be different from the bulk tin melting temperature. A simple effective medium tretament of the elastic constants of the film containing solid-liquid inclusions explains the observed behaviour in the Brillouin spectra. A strong central peak, possibly related to entropy fluctuations, was also observed just before melting.

P05.OF.002 X-RAY DIFFRACTION STUDY OF NANOCRYSTALLINE ZrO_2 - Y_2O_3 POWDERS. D.G. Lamas and N.E. Walsöe de Reca, PRINSO (Programa de Investigaciones en Sólidos) CITEFA-CONICET-UNSAM, Zufriategui 4380 (1603) Villa Martelli, Pcia. de Buenos Aires, Argentina.

Zirconia-based ceramics have been widely investigated due to their excellent mechanical and electrical properties, which strongly depend on the crystal structures and phase changes. One of the most notable characteristics of some zirconia-based solid solutions is the existence of three tetragonal forms, all belonging to the $P4_2/nmc$ space group. The stable tetragonal form is called the t-form, which is restricted to the solubility limit predicted by the equilibrium phase diagram. There is also a t'-form with a wider solubility, but unstable in comparison with the mixture of the t-form and cubic phase. Finally, the t"-form has an axial ratio c/a of unity, but with the oxygen atoms displaced along the c axis from their ideal sites of the cubic phase (8c sites of the Fm3m space group). The t'/t" and t"/c boundaries have been investigated in several systems, including ZrO_2-Y_2O_3. However, only arc-melting ZrO_2-Y_2O_3 powders have been carefully studied.

In this work, the tetragonal forms presented in nanocrystalline ZrO_2 - X mol% Y_2O_3 (X = 2.8, 4, 5, 6, 7, 8, 9, 10, 11, and 12) powders synthesised by a combustion route have been studied by X-ray diffraction applying the Rietveld method. Crystallite sizes were about 10nm. It was found that the axial ratio c/a decreased with an increase of Y_2O_3 content and became unity at 9% Y_2O_3. The oxygen displacement from the ideal fluorite site was about 0.24Å for all compositions. Powders in the composition range of ZrO_2 - 9 to 12 mol% Y_2O_3 were calcined at 1000°C and 1400°C in order to investigate the influence of the crystallite size. All of them presented the t"-form, but with smaller oxygen displacement, which was about 0.15Å for powders calcined at 1000°C and 0.12Å for powders treated at 1400°C. Although these results must be confirmed by neutron diffraction, this work shows that the oxygen displacement strongly depends on the crystallite size, resulting in the enlargement of the t" region in comparison with arc-melting powders, which presented the t"/c boundary at 11% Y_2O_3.

P05.OF.003 MECHANICALLY INDUCED DISORDER IN INVERSE SPINEL FERRITES. V. Sepelak, Institute of Geotechnics, Slovak Academy of Sciences, 04353 Kosice, Slovakia, and K.D. Becker, Institute of Physical and Theoretical Chemistry, TU Braunschweig, 38106 Braunschweig, Germany.

The structural and magnetic evolution in nickel ferrite ($NiFe_2O_4$) and magnesium ferrite ($MgFe_2O_4$) caused by the high-energy milling has been investigated by X-ray diffraction, Mössbauer spectroscopy and electron microscopy. With the prolongation of the mechanical activation time, $NiFe_2O_4$ and $MgFe_2O_4$ are transformed into a metastable nanocrystalline state that is characterised by the mechanically induced cation redistribution between tetrahedral (*A*) and octahedral [*B*] sites. The reduced concentration of iron ions at (*A*) sites in the mechanically treated samples, leading to the variation in the number of magnetic and nonmagnetic (*A*)-site ions as nearest neighbours of the Fe^{3+}[*B*] ions, results in a broad distribution of magnetic hyperfine fields at the octahedral sites. The probabilities of the different [*B*]-site surroundings and the Mössbauer subspectral areas are used to calculate the cation inversion parameter in the mechanically activated ferrites. Good agreement between the degree of inversion obtained from both independent procedures is found to allow us to isolate from the [*B*]-site magnetic field distribution profile the contribution due to the varying number of magnetic and nonmagnetic (*A*)-site neighbours. The broadly distributed hyperfine magnetic fields at the Fe^{3+}[*B*] nuclei are attributed to the competing exchange interactions of the Fe^{3+}[*B*]-O^{2-}-Fe^{3+}[*B*] type with deformed bond angles. The mechanically induced cation redistribution leads to a reduction of the average magnetic field at [*B*] site. Taking into account the nanoscale nature of the mechanically treated samples, a superparamagnetic relaxation effect explains a collapse of the magnetic hyperfine fields far bellow the Curie temperature in strongly activated ferrites.

The authors would like to express their gratitude to the Alexander von Humboldt Foundation for support of V. S.

05AA MOTOR PROTEINS AND MUSCLES

M05.AA.001 STRUCTURAL STUDIES OF MYOSIN. Ivan Rayment, Cary B. Bauer, Andrew M. Gulick, Robert Smith, Matthew Schroeder, James B. Thoden, and Gary Wesenberg. Institute for Enzyme Research and Department of Biochemistry, University of Wisconsin, Madison, Wisconsin, USA.

Directed movement is one of the hallmarks of life and is accomplished by enzymes that convert the energy from the hydrolysis of MgATP into mechanical work. Understanding how this is achieved at the molecular level represents a major intellectual challenge. At this time it would appear that a very limited number of strategies have evolved to carry out this task. Three major classes of molecular motors have been identified, myosin, dynein and kinesin which play different roles in cellular movement. Of these, myosin is the most abundant and has been studied more extensively than any others. The last decade has seen a dramatic improvement in our understanding of the molecular basis of motility. Even so there is still much more to be learned. For example, although the first crystal structures of actin and myosin provided a wealth of information, in reality, they represented only a partial view of one point in the contractile cycle. To overcome this problem a series of structures of a genetically truncated and modified myosin heads complexed with an extensive series of substrate analogs, several non-nucleotide substrates and ATP itself have been determined. As discussed here these structures have provide considerable insight into how ATP hydrolysis is coupled to movement.

M05.AA.002 SCALLOP MYOSIN HAS AT LEAST THREE CONFORMATIONAL STATES. A. Houdusse [1], A.G. Szent-Gyorgyi [2], C. Cohen [3], [1] CNRS EP2075, Faculte de Pharmacie, Paris, France, [2] Biology Department, Brandeis University, Waltham, MA, USA, [3] Rosenstiel Research Center, Brandeis University, Waltham, MA, USA

Three conformational states of a proteolytic subfragment (S1) from scallop striated muscle myosin have been determined by X-ray crystallography. The most unusual one has been visualized from the crystal structure of scallop S1 complexed with MgADP, which has been solved at 2.5 Å resolution, and reveals a new conformation of the myosin head. In this structure, the converter and the lever arm are in very different positions from those in either transition or "near-rigor" state structures; moreover, - for the first time - the SH1 helix is seen to be unwound. Biochemical studies indicate that this conformational state corresponds to a weak actin-binding state (Nitao and Reisler, 1998, Biochemistry 37, 16704-10). We thus believe that this new structure represents one of the pre-hydrolysis ("ATP") states of the contractile cycle, in which the myosin heads stay detached from actin. The other two crystal forms, albeit diffracting to lower resolution (4Å), show that scallop S1 adopts a conformation in the absence of nucleotide similar to that seen in chicken skeletal myosin (Rayment et al. 1993 Science 261, 50-8) and a conformation in the presence of ADP.VO4 which is similar to that of transition state structures (Fisher et al. 1995 Biochemistry 34, 8960-72; Dominguez et al. 1998 Cell 94,559-71). Comparison of the overall organization of the myosin head in the three states show how the conformation of three flexible "joints" produces rearrangements of the four major subdomains in the myosin head with different bound nucleotides.

M05.AA.003 THE NCD DIMER CRYSTAL STRUCTURE REVEALS UNIQUE FEATURES 0F MINUS END DIRECTED KINESIN MOTORS. E. Sablin, R. Case, S. Dai, C. Hart, A. Ruby, R. Vale and R. Fletterick, University of California, San Francisco, CA 94143, USA.

Motors of the kinesin superfamily move either to the plus or minus end of microtubules. Crystal structures of the catalytic motor cores of conventional kinesin (a plus end motor involved in organelle transport) and NCD (a minus end motor involved in chromosome segregation) are nearly identical; therefore, the structural basis for their opposite polarity of movement is unresolved. Here, we show that the NCD “neck”, 13 class-specific residues adjacent to the superfamily-conserved catalytic core, is essential for minus end motility, since mutagenesis of the neck residues reverses the direction of NCD motion. By solving the 2.5 Å structure of a functional NCD dimer[1], we show that the NCD neck (a coiled coil) differs from the corresponding region in the kinesin neck (interrupted β strand) , although both necks interact with similar elements in the catalytic cores. The distinct neck architectures confer different symmetries to the NCD and kinesin dimers and position these motors with appropriate directional bias on the microtubule.

M05.AA.004 THE FASCINATING STRUCTURE OF AN ACTIN CROSSLINKING PROTEIN. Steven C. Almo, Elena Fedorov, Alexander Fedorov Dept. of Biochemistry, Albert Einstein College of Medicine

Actin crosslinking proteins assemble individual actin filaments (F-actin) into higher order aggregates, such as bundles and networks, that are involved in a wide range of functions including cell motility, cytokinesis and the establishment and maintenance of cell morphology. Crosslinking proteins generally contain two F-actin binding site, and it is this bivalency that allows for crosslinking. Fascin is a 58kD actin crosslinking protein first identified in sea urchin eggs. Homologs have subsequently been found throughout the coelomocytes, and in Drosophila, amphibians and mammals. Fascin localizes to a number of different F-actin based structures including microvilli and acrosomal processes in sea urchins and starfish, and the lamellopodia, filopodia and stress fibers in mammalian cells. The crystal structure of human fascin reveals four tandemly repeated 120 amino acid modules that display the beta-trefoil fold observed in interleukin- 1beta and fibroblast growth factor. The four domains are arranged to form a bi-lobed structure that displays near two-fold symmetry. The organization of this protein is discussed with respect to its crosslinking function.

M05.AA.005 STRUCTURE OF THE BACTERIAL TUBULIN HOMOLOG FtsZ IN 2D- AND 3D-CRYSTALS. Jan Löwe and Linda A. Amos MRC Lab. of Molecular Biology Hills Road Cambridge CB2 2QH UK

The three-dimensional structure of FtsZ has been determined by X-ray crystallography in the monomeric state and by three-dimensional electron microscopy in the polymerized state. During septation, the essential bacterial cell-division protein FtsZ forms a filamentous ring which divides the two daughter cells. FtsZ from the hyperthermophilic methanogen *Methanococcus jannaschii* has been cloned, expressed in *E. coli*, and the X-ray crystal structure of the 372 residues containing protein has been solved at 2.8Å resolution. FtsZ is a two-domain protein with a Rossmann-fold related GTPase domain and a second domain of unknown function. The three-dimensional structure of FtsZ is closely related to eukaryotic tubulin. Using sheets of polymerized FtsZ the low-resolution 3D structure of FtsZ protofilaments has been determined and shows dimers of FtsZ forming a double-protofilament. FtsZ protofilaments resemble tubulin protofilaments very closely. Taking everything together, FtsZ can be regarded as a true tubulin homologue with implications for the origin of the cytoskeleton.

M05.AA.006 NUCLEOTIDE-DEPENDENT CONFORMATIONAL CHANGES OF THE MYOSIN MOTOR DOMAIN AND ITS MONOMERIC ACTIN COMPLEX IN SOLUTION. K. Wakabayashi, Y. Sugimoto, S. Kimura, Y. Takezawa and T. Arata, Division of Biophysical Engineering, Graduate School of Engineering Science, and Department of Biology, Graduate School of Science, Osaka University, Toyonaka, Osaka 560-8531, Japan.

Nucleotide-dependent conformational changes of the myosin motor domain (subfragment-1, S1) have extensively investigated by synchrotron X-ray solution scattering. In the presence of MgATP, the radius of gyration (Rg) of S1 decreased to ~4.5 nm from ~4.8 nm of the nucleotide-free S1. Thus an S1 molecule becomes compact in the intermediate state having ADP and Pi during hydrolysis of ATP. This was confirmed by the fact that S1s bound ADP and phosphate analogs such as AlF_3, BeF_x and VO_4 had similar Rg values to that in ATP solution. Modelling studies using atomic data [1] have indicated that the compaction of the S1.ADP.Pi was caused by a large movement of a light chain-binding region, corresponding to an about 5-nm displacement at its tip. When an S1 bound ADP which mimicks a release of Pi had a Rg value between those of the S1.ADP.Pi and a nucleotide-free S1 and the magnitude of a movement of a light chain-binding region was half that in the S1.ADP.Pi model.

We succeeded in making the complex of a non-polymerizable G-actin and S1, and the solution structure of it was determined by X-ray solution scattering analysis. The Rg and the maximum chord length (Dmax) were ~4.9 nm and ~16.8 nm,

respectively. The best-fit model of the complex was obtained by putting the actin subunit on the tip of the catalytic domain of S1 where the N-terminal domain of G-actin attached to the region between upper and lower 50 kD domains in S1. In this model, S1 orientated with its long axis more perpendicular to the actin axis than in an acto-S1 model of the decorated actin filament. When MgADP bound to S1 in this complex, the Rg and Dmax decreased by about 0.3 nm and 2 nm, respectively. The best-fit model of the complex with ADP was obtained by rotating the two molecules each other through nearly 90^{o} around the long axis of S1 with retaining their binding sites.

P05.AA.001 X-RAY CRYSTALLOGRAPHY AND ELECTRON CRYOMICROSCOPY OF A MICROTUBULE MOTOR: THE NCD DIMER. F. Kozielski, S. De Bonis [1], W.P. Burmeister [2], C. Cohen-Addad, R.H. Wade [1]. [1] Institut de Biologie Structurale, 41 avenue des Martyrs, 38027 Grenoble Cedex 01, France, [2] European Synchrotron Radiation Facility, 38043 Grenoble Cedex 01, France

Drosophila ncd is a member of the kinesin superfamily of microtubule motor proteins. It is involved in chromosome segregation, moves towards the minus end of microtubules and has the motor domain at the C-terminus of its heavy chain. We expressed, purified and crystallized the functional homodimer (amino acids 295 - 700) in the presence of MgATP. The crystals, space group $C222_1$, two dimers per asymmetric unit, have unit cell dimensions a=116.2 Å, b=148.8 Å and c=261.5 Å. Using data collected at the ESRF, the ncd dimer structure was solved to 2.9 A by molecular replacement using the recently published perfectly 2-fold symmetric ncd dimer structure (Sablin et al., 1998, Nature, 395, 813 - 816) as a search model. This previous ncd structure was obtained from a different crystal form (P6(1)22) that has a single monomer per asymmetric unit. We compare the two ncd dimer structures and discuss their similarities and differences. We will show the results of docking our new atomic resolution structure into the three-dimensional reconstruction of the microtubule-ncd complex obtained by electron cryomicroscopy in the presence of ADP. Finally, we will compare these new results to those previously obtained for the conventional kinesin heavy chain dimer (Kozielski et al., 1997, Cell, 91, 985 - 994; Kozielski et al., 1998, Current Biology, 8, 191 - 198). This has the motor domain on the N-terminus and is a plus-end-directed motor involved in organelle transport.

P05.AA.002 THE TIME-RESOLVED DIFFRACTION STUDIES OF MUSCLE USING SYNCHROTRON RADIATION. A.A.Vazina, P.M.Sergienko [1], Rapp G., Kunst N. [2], A.M.Gadzhiev [3], M.A.Sheromov [4], [1] Institute of Theoretical and Experimental Biophysics of RAS, Pushchino, Moscow Region, 142292, Russia, [2] EMBL c/o DESY, Hamburg, D-22603, Germany, [3] Institute of Physiology of Az. AS, Baku, 370100, Azerbaijan, [4] Budker Institute of Nuclear Physics, SD of RAS, Novosibirsk, 630090, Russia

The ability of striated muscle to potentiate their twitch response after preliminary stimulation and/or fatigue has been studied. The changes of kinetic rates in the time courses of tension response and intensities of diffraction reflections at short-term stimulus history were investigated. Two different protocols were used for the collection of the data: a)frog sartorius muscle was stimulated by double pulse interval 30-300 ms; b)effect of potentiation by fatigue was examined. Experiments with time resolution of 1-10 ms have been carried out using SR of VEPP-3 (Novosibirsk) and DORIS (Hamburg). The time course of the intensity changes of equatorial reflections (1,0) and (1,1), the background underneath them, meridional reflections at spacing 44.0, 21.4, 14.3 nm and the time course of tension response P(t) have been studied. The model calculations of diffraction patterns at various radial or/and angle position of myosin cross-bridges are presented. The marked increase of tension response added by second pulse is accompanied by intensity flash of meridional reflection 14.3 nm. The monotonous character of another reflections time course is not disrupted.

We suppose in the active muscle the myosin cross-bridges of 3 thick filaments produce in the vicinity of every thin filament the short-living mesophase with 14.3 nm axial spacing (life time about 40 ms). The active myosin cross-bridges are not incorporated into helix range of thin filament. Thus the force generation of muscle proceeds upon interaction of the myosin thick and actin thin filaments in the incommensurate structural framework. We assume principle of dynamic correspondence of symmetries is crucial in biological motion [1].

05BB THE PHASE PROBLEM IN ELECTRON CRYSTALLOGRAPHY

M05.BB.001 PHASE DETERMINATION BY MAXIMUM ENTROPY AND LIKELIHOOD IN ELECTRON CRYSTALLOGRAPHY. C.J. Gilmore and A.A.Stewart, Department of Chemistry, University of Glasgow, Glasgow G12, 8QQ, Scotland UK, I.G. Voigt-Martin, Institüt für Physikalische Chemie der Universität Mainz, D-55099 Mainz, Germany and D.L. Dorset, Hauptman-Woodward Institute, 73 High Street, Buffalo, NY 14203-1196,USA.

Phase determination in electron crystallography is not easy. The data often suffer from systematic errors in the intensities arising from dynamical scattering; the sampling of reciprocal space is generally incomplete and the effective data resolution much less than the 1.1-1.3Å expected by direct methods. The maximum entropy (ME) method combined with likelihood evaluation first formulated by Bricogne [1] is capable of overcoming some of these problems, and, indeed, is often most effective with data at 2Å resolution or less.

In this formalism the data are normalised, and sets of phased reflections are generated by the use of origin fixing reflections combined with intensities in which the associated phases are permuted These phased data act as constraints in a constrained entropy maximisation to give an ME map, $q^{ME}(\underline{x})$. Each phase combination is subjected to likelihood estimation which assess how well the hitherto unphased reflection amplitudes are predicted from the FT of $q^{ME}(\underline{x})$.

We present here results on both small and macromolecules. Some of these are non-linear optical materials [2,3]; some taken from Dorset [4] and some are macromolecules [5].

M05.BB.002 CRYSTALLOGRAPHIC PHASE DETERMINATION IN ELECTRON CRYSTALLOGRAPHY. Douglas L. Dorset, Electron Diffraction Department, Hauptman-Woodward Medical Research Institute, 73 High Street, Buffalo, NY14203-1196 USA

Because multiple beam scattering is strongly expressed in electron diffraction, it has been often stated that true ab initio structure analyses would be virtually impossible, except for cases where the weak phase object would be satisfied (i. e. thin crystals of light atom materials). Recent experience with a variety of materials has modified this viewpoint somewhat. Actually, the only requirements for a successful determination of kinematical phases are two-fold: that reflections from the most significant parts of the unit cell transform can be measured and that the experimental Patterson function is well-correlated to the autocorrelation function of the actual crystal structure. These structures explain why, for example, a large 3D data set from triphenylene, giving a good fit to the known crystal structure, are not assigned accurate phase terms by direct methods; diffraction intensities from the most important unit cell projections are still missing from the sampled data. On the other hand, nearly complete electron diffraction data from an alloy are easily assigned phases by the tangent formula. Nevertheless, dynamical effects are still very pronounced in the latter case and much weaker in the former case. In general, the refinement step is where multiple beam perturbations impose the greatest challenge to structure improvement (but here dynamical effects can also be used as a refineable variable) even though they do not necessarily restrict the derivation of the initial phase model. Atomic resolution is also not required in some cases. Significant progress has been made in the direct phase determination of protein structures - for example, starting with a low-resolution basis set from the Fourier transform of an image and extending to the resolution of the diffraction pattern. More recently, filling in 'missing cone' information has been shown to give acceptable results, even though the amplitudes are not so well estimated as are the phases. True ab initio determinations have been possible for proteins which are well simulated by globular substructures, e. g. projections of α-helices. In this case, the problem is reduced to rescaling the data to simulate the pseudo-atomistic distribution of mass, as suggested originally by D. Harker. Supported by NSF CHE-9730317 and NIH GM-46733

M05.BB.003 THE PRECESSION TECHNIQUE IN ELECTRON CRYSTALLOGRAPHY. APPLICATIONS TO STRUCTURE DETERMINATION. J. Gjønnes, V. Hansen, E. Sørbrøden, P. Runde and K. Gjønnes, Centre for Materials Science, University of Oslo, Gaustadalleen 21, N-0371 Oslo, Norway.

Electron diffraction patterns from crystals are usually taken with a stationary beam (and crystal), in contrast to X-ray work where the crystal is rotated to produce integrated intensities. With the electron beam entered along a zone axis, dynamical scattering effects are exacerbated.

The recently invented precession technique [1] is a different approach to quantitative electron diffraction: Off-axis beam configurations are used, integrated intensities are obtained, dynamical effects are reduced, more reflections and three-dimensional data can be collected [2]. A 'guided beam' system [3] implemented on a Jeol 2000FX microscope in Oslo will be described. Principles for intensity calculations, relating to precession, and applications to structure determination of alloy phases will be presented.

M05.BB.004 INVERSION OF ELECTRON ROCKING CURVES DIFFRACTED FROM STRAINED CRYSTALS. R. Vincent, H. H. Wills Physics Laboratory, University of Bristol, Bristol BS8 1TL, UK.

Presently, quantitative analysis of the Bragg-diffracted intensities within convergent beam electron diffraction (CBED) patterns has been focused on the measurement of structure factors for perfect crystals. However, many crystals contain inhomogeneous strains within the illuminated column which are encoded into diffracted intensities in the rocking curves. The two-beam equations for calculating kinematic and dynamical rocking curves from a strained crystal are well known, but it is less obvious that the inverse problem can be easily solved when only the diffracted intensities are measured. Considering first the kinematic equation, the diffracted amplitude in standard notation is given by

$$A_g(s) = \int_{-\infty}^{\infty} U_g(z)\ \exp(-2\pi i g R(z))\ \exp(-2\pi i s z)\ \mathrm{d}z,$$

where $gR(z)$ is the component parallel to $\boldsymbol{g}$ of the displacement vector $\boldsymbol{R}$, measured in units of the planar spacing. The integral is taken between $\pm\infty$, but is non-zero only for $z \in [0, t]$, where t is the crystal thickness measured along z, the beam direction. This equation is rewritten as the Fourier transform pair $A(s) \Leftrightarrow U(z)\ \exp(-2\pi i g R(z))$, where subscripts have been omitted. For a crystal with constant U_g along z, the rocking curve becomes equivalent to the Fourier transform of a pure phase object with compact support of width t. There exists a unique solution for the phase function, which is recovered by an iterative method known as the Gerchberg-Saxton algorithm. Experimental results are described in [1]. For dynamical diffraction, the equations are non-linear, and a pattern-matching approach is required based upon a Fourier expansion of $R(z)$. An algorithm using global optimization methods was used to minimise the difference between observed and calculated intensities in dynamical two-beam rocking curves.

P05.BB.001 MAXIMUM ENTROPY METHODS FOR PHASE EXTRAPOLATION: PREDICTING THE MISSING CONE IN ELECTRON DIFFRACTION. Andrew Stewart and C.J. Gilmore Department of Chemistry, University of Glasgow, Glasgow G12, 8QQ, Scotland UK.

The missing cone problem arises in electron diffraction from experimental limitations on sample tilt, and the difficulties in getting suitably oriented specimens in data collection. This missing data can make the process of structure solution and refinement more difficult, but once a model has been derived maximum entropy methods can be used to predict both the phases and amplitudes of the missing reflections and so generate more accurate models.

To do this, the data are normalised, and a basis set is defined in which all the measured reflections with model-derived phases and experimental amplitudes are included. These data act as constraints in a constrained entropy maximisation to give a map, $q^{ME}(\underline{x})$ whose Fourier transform generates phase and amplitude information for non-basis set reflections which includes those in the missing cone as well as data outside the resolution limit.

We present here results on both small and macromolecules (with the former taken from Dorset, 'Structural Electron Crystallography', Plenum Press, 1995):

Basic Copper Chloride

Poly(1,4-trans-cyclohexanediyl Dimethylene Succinate) (Poly-t-CDS)

Poly(1-butene), Form III

Rubredoxin using ideal data

Rubredoxin using experimental data to 6Σ.

In all cases, the quality of extrapolation was good, no scaling of predicted intensities was needed and mean phase errors were often below 30^o.

The method has obvious potential for phase extension in protein crystallography, and we are currently exploring this. It is possible to use phase permutation methods to assist in this process by using trial phases for key unphased reflections.

We acknowledge support from Eastman Kodak, Rochester.

P05.BB.002 DIRECT MEASUREMENT OF PHASE-INVARIANTS AND STRUCTURE AMPLITUDES FROM 3 BEAM CBED PATTERNS. J. Etheridge, A. F. Moodie and C. J. Humphreys, Dept of Materials Science and Metallurgy, University of Cambridge, Pembroke St, Cambridge, CB2 3QZ, UK.

It has been shown theoretically that, for centrosymmetric crystals, the three-phase invariant and the magnitudes of three structure amplitudes are determined directly by the coordinates of two unique points identifiable in a three beam convergent beam electron diffraction pattern [1]. The experimental application of this result will be described and, in particular, it will be shown that the phase-invariant is readily determined, in some cases by inspection. Estimates of the magnitudes of the structure amplitudes can be made to sufficient accuracy for the determination of the crystal structure but not for the measurement of bonding. The conditions that optimise the accuracy in the measurement of a given three structure amplitudes will be described. Examples from a range of compounds will be presented.

P05.BB.003 GEOMETRY OF THREE BEAM PHASE DETERMINATION. A. F. Moodie, J. Etheridge and C. J. Humphreys, Dept of Materials Science and Metallurgy, University of Cambridge, Pembroke St, Cambridge, CB2 3QZ, UK.

For centrosymmetric crystals the locus of two beam intensity distribution in the convergent beam disc of a three beam pattern is a degenerate hyperbola, and the sign of the phase invariant is determined by the sheet on which the centre of the distributions lie. When the symmetry of inversion that leads to the degeneracy is relaxed by the smooth increase of the antisymmetric component of the structure amplitudes, a hyperbola of increasing gap is generated and the distribution of intensity increasingly departs from two beam form. The sign of the phase invariants is still determined by the sheet on which the "quasi two beam centres" lie but the magnitude depends on gap and position. Possible structural applications will be discussed.

P05.BB.004 THE VALIDITY OF QUASI-KINEMATIC THEORY IN ELECTRON CRYSTALLOGRAPHY. H. J. Whitfield and A. F. Moodie, Dept of Applied Physics, Royal Melbourne Institute of Technology, GPO Box 2476V, Melbourne, 3001, Australia and J. Etheridge and C. J. Humphreys, Dept of Materials Science and Metallurgy, University of Cambridge, Pembroke St, Cambridge, CB2 3QZ, UK.

It is dynamical interaction which leads to a direct and unique solution of the phase problem, albeit so far only within the three beam approximation [1]. For the last quarter of a century, however, many structures have been determined using a combination of high resolution electron microscopy and electron diffraction (preferably convergent beam) employing indirect iterative procedures which are necessarily non-unique. While, in general, the comparison of observed and calculated intensity distributions in both direct and reciprocal space necessarily involves n-beam dynamical computation, some classes of structures lend themselves to quasi-kinematical analysis. The conditions under which such treatments have some validity will be discussed. In the determination of atomic positions the procedures involved frequently absorb dynamical scattering effects into the atomic scattering factors, which then no longer describe the atomic potential. Even in the most favourable cases, refinement of the potential distribution, and hence, ultimately also of the atomic positions, will necessitate the comparison of full dynamical calculations with low temperature data.

05CC REAL TIME 'IN SITU' REACTION CHEMISTRY

M05.CC.001 THE DEVELOPING FIELD OF PHOTO-CRYSTALLOGRAPHY: TIME-RESOLVED STUDY OF LIGHT-INDUCED TRANSIENT SPECIES. P. Coppens, Department of Chemistry, SUNY at Buffalo, Buffalo, NY 14260-3000, USA.

X-ray analysis traditionally serves to elucidate the ground state structure of solids. This limitation can now be challenged. Following our analysis of novel low-temperature stable light-induced linkage isomers of transition metal nitrosyl complexes [1], we are developing methods for time resolved studies of transient species using synchrotron radiation [2]. A very fast shutter has been constructed [3], which is to be used in conjunction with a 5-10KHz pulsed Nd-YAG laser. To reduce the laser power requirements, the heat to be dissipated in the crystal, as well as exciton-exciton annihilation, crystals are engineered such that the photo-active molecules are diluted by inert species [4]. Candidates for time-resolved studies will be discussed and preliminary spectroscopic and crystallographic results will be presented.

Support of this work by the National Science Foundation (CHE9615586, CHE9522232) and the U.S. Department of Energy (DE-FG02-86ER45231) is gratefully acknowledged.

M05.CC.002 DIASTEREOSELECTIVE PHOTOCYCL-IZATION OF 2,4,6-TRIISOPROPYLBENZOPHENONE DERIVATIVES. S. Ohba, Department of Chemistry, Keio University, Hiyoshi 3, Kohoku-ku Yokohama 223-8522, Japan, and Y. Ito, Department of Synthetic Chemistry and Biological Chemistry, Kyoto University, Kyoto 606-8501, Japan.

Crystal-to-crystal photoreaction has potentialities to get information of the process of topochemical reaction by X-ray diffraction. However, the problem was the crystal cracking during the reaction in most cases. This problem could be technically

overcome by tuning the wavelength of light. On the other hand, the asymmetric synthesis utilizing crystalline environment is one of the promising fruits in solid-state reaction.

2,4,6-Triisopropylbenzophenones photocyclize efficiently into the corresponding benzocyclobutenols not only in solution but also in the solid state. The crystal structures of 3'- or 4'-substituted derivatives were reported along with some relationships between the crystal structures and photoreactivities [1]. An optically active substituent, (S)-methylphenyl-alanine, has been introduced to yield the non-centrosymmetric crystal structure. Asymmetric synthesis using the powder sample proceeded with a diastereomer excess (d.e.) of 87%. However, the recrystallization of the photoproduct gave only very thin needle crystals. By irradiation of light from 250 W ultrahigh pressure Hg lamp for 7 hrs through long-pass filter UV36 (T=15% at 350 nm), photoreaction in a single-crystal completed 100% without loss of crystallinity. The crystal structure after photocyclization indicates that the nearer methine H was predominantly abstracted by the carbonyl O atom in the reaction [2].

M05.CC.003 USE OF SYNCHROTRON RADIATION FOR "IN SITU" INVESTIGATION OF THE SOLID STATE REACTIONS. N.Z.Lykhov, A.V.Bessergenev, B.B.Bokhanov, Yu.A.Gaponov, V.P.Isupov, M.A.Korchagin, M.R.Sharafutdinov, B.P.Tolochko [1], S.G.Nikitenko [2], [1] Institute of Solid State Chemistry and Mechanochemistry, Novosibirsk, Kutateladze 18, 620128, Russia, [2] Institute of Catalysis, Novosibirsk, Lavrentev 5, 620090, Russia

The characteristics of chemical reactions in solids: (1) local process,(2) high velocity, (3) nuclei formation in the crystal volume - makes special methods of investigation necessary. Kinetics of solid state reactions were obtained for follow systems using X-ray diffraction of synchrotron radiation and XAFS: ceramic synthesis (WO_3+NiO); ceramic synthesis with phase transitions during reaction (MoO_3+NiO); polyphase systems synthesis ($YBa_2Cu_3O_6$); selfpropagating high temperature synthesis (Ni+Al, BaO_2+TiO + Ti); nucleation and growth of Ni particles 50 A size in $Al(OH)_3$ matrix; mechanochemical synthesis of quasicrystalls and theirs phase transformations; reactions of exothermic systems BaO_2+W. Investigations of the mentioned reactions shows, that combination of synchrotron radiation diffraction and XAFS are a powerful methods to research the dynamics of the phase forming in complex systems.

M05.CC.004 PHOTOINDUCED METASTABLE STRUCTURES IN SEVERAL ORGANIC CRYSTALS. Y. Ohashi, H. Uekusa, A. Sekine, T. Ohhara, M. Kawano, J. Harada, Department of Chemistry, Tokyo Institute of Technology, O-okayama, Meguro-ku, Tokyo 152-8551, Japan

The process of chemical reaction in a crystal can be observed by the stepwise X-ray crystal structure analyses if the crystallinity is kept during the reaction. We have found a variety of photoisomerizations of cobaloxime complexes in which the reactions proceed with retention of the single crystal form. Recently the technique was applied to observe the metastable structures in organic and metal complex crystals.

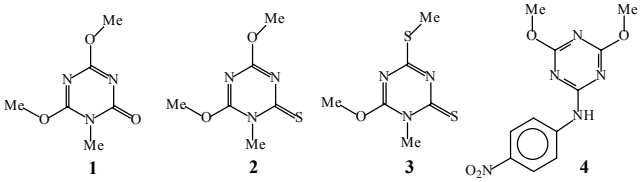
The first example is the 3-1 photoisomerization of the cyanopropyl group bonded to the cobalt atom in cobaloxime complexes. When the crystals were irradiated with a xenon lamp, the 3-cyanoproyl group was isomerized to the 2-cyanopropyl group and then was transformed to the 1-cyanopropyl group. Such a two-step reaction was clearly analyzed by X-ray and neutron structure analyses of the cobaloxime crystals. The second example is the metastable structure of the ruthenium complex with the NO group as an axial ligand. When the complex crystal was exposed to the light (<450 nm), about 8% of the NO group was upside down. The inverted ON group was clearly analyzed by X-rays at 103 K. And when the crystal was irradiated with the light (>600 nm), it was restored to the original one.

The third example is the metastable state of the photochromic crystal. When the crystal of salicylideneaniline was irradiated with the light (<370 nm), its color turned from pale yellow to dark red. The dark red color turned back by irradiation with another light (>530 nm). The metastable structure of the dark red color species was analyzed by X-rays. The result revealed that the photochromism of salicylideneaniline is caused by an interconversion between the enol and trans-keto forms.

The fourth example is the structure of a metastable radical pair of the hexaarylbiimidazolyl derivative. The C-N bond connecting the two triaryl-imidazolyl rings was cleaved by the irradiation to form a radical pair composed of two planar molecules. The CW-ESR experiments at 77 K clearly indicated a triplet-state signal of the radical pair. The crystal structure analyzed at 103 K showed the structure of the radical pair produced by the irradiation. The radical pair converted to the original form thermally, which was ascertained by X-ray analysis.

M05.CC.005 TOPOCHEMICALLY VERSUS NON-TOPOCHEMICALLY CONTROLLED SOLID-STATE METHYL REARRANGEMENT. M. Kaftory, E. Handelsman-Benory, M. Botoshansky, V. Shteiman, and M. Greenberg, Department of Chemistry, Technion Israel Institute of Technology, Haifa, 32000, Israel.

The combination of supramolecular architecture in solids together with the ability of molecules to react intermolecularly makes such systems valuable for the study of cooperate bulk phenomena. Recently we have studied the solid-state intermolecular methyl transfer in cyanurates and thiocyanurates. It was found that 1, 2, and 3 undergo topochemically controlled solid-state methyl rearrangements. The rearrangement product in each of the solid-state reaction is topochemically controlled and is dependent of the supramolecular architecture.



The product obtained from 1 was a result of O to N methyl migration, while those obtained from 2, and 3 resulted from O to S methyl migration. Compound 4, on the other hand, undergoes solid-state methyl rearrangement revealing at least four different products. It will be shown that this is a result of non-topochemically controlled solid-state reaction.

The structures - product relationships and the mechanism of the solid-state methyl rearrangement will be discussed.

05DD OPTIMISATION METHODS (sponsored by Tripos Inc.)

M05.DD.001 STOCHASTIC OPTIMISATION: SIMULATED ANNEALING AND THE GENETIC ALGORITHM. C. Jennison, Department of Mathematical Sciences, University of Bath, Bath BA2 7AY, UK.

Many practical problems of optimising high-dimensional functions with multiple local optima fall outside the domain of standard numerical algorithms. Recent years have seen considerable interest in two stochastic optimisation techniques, simulated annealing and the genetic algorithm, which use different forms of random search to solve such problems. In the following, we suppose it is desired to find the value of x which maximises an objective function f(x).

Simulated annealing starts with a random walk algorithm that one could use to draw a random value of x with probability proportional to f(x). However, as this random walk continues it is modified so as to sample from successively more peaked functions, accentuating the high values of f(x) and

diminishing the low values. Ultimately, the hope is that the process will become trapped in smaller and smaller regions surrounding the global maximum of f(x) and the global solution, or at least a near-optimal x, will be found. The genetic algorithm operates by creating a population of possible solutions, x, and letting these develop in a manner similar to natural evolution. Population members with higher values of the objective function f(x) are given a higher probability of selection as parents for the next generation. Offspring inherit components of x from both parents with occasional chance mutations. The aim is that solutions will 'evolve' towards the optimum and a good, or even an optimal,solution will eventually be generated.

I shall discuss theoretical foundations of both methods and note their messages for practical implementation. Examples will be used to illustrate qualitative points about each method and to make controlled comparisons.

M05.DD.002 APPLICATION OF THE DIFFUSION EQUATION METHOD TO GLOBAL OPTIMIZATION. H.A. Scheraga, Baker Laboratory of Chemistry and Chemical Biology, Cornell University, Ithaca, NY 14853-1301, USA

The Diffusion Equation Method (DEM) was originally designed to surmount the multiple-minima problem in the conformational analysis of molecules, by deforming the potential energy hypersurface by the DEM [1]. It has been applied to argon clusters [2], oligopeptides [3], and the predic- tion of crystal structures [4,5]. In recent applications [4-6], the unsmoothing (reversing) part of the DEM algorithm has been modified to include multiple trajectories, with perturbation at each stage of the reversing procedure, thereby improving the performance of the procedure.

The revised procedure has now been applied to the conformational analysis of very long polyalanine chains and of protein A [6], and also to the phase problem in crystallography.

M05.DD.003 GENETIC ALGORITHMS FOR MOLECULAR RECOGNITION. G. Jones [1], R.C. Glen [2], A.R. Leach [3], R. Taylor [4], P. Willet [5], [1] Arena Pharmaceuticals, 6166 Nancy Ridge Drive, San Diego CA 92121, USA, [2] Tripos Inc, 1699 South Hanley Road, St Louis MO 63144, USA, [3] Glaxo Wellcome Medicines Research Centre, Gunnels Wood Road, Stevenage SG1 2NY, UK, [4] Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK, [5] Department of Information Studies, University of Sheffield, Western Bank, Sheffield S10 2TN, UK

Genetic algorithms (GAs) are novel optimization algorithms which emulate the process of Darwinian evolution to solve complex search problems. Guided by the mechanics of evolution, successive generations of populations of artificial creatures called chromosomes search the fitness landscape of a problem to determine optimal solutions. The aplication of GAs to problems in computational chemistry and biology is the subject of much investigation.

Computational problems in molecular recognition are extremely demanding. Not only are powerful search engines capable of solving multiple minima problems required, but also an appreciation of the process of molecular recognition is required to generate suitable target functions. We have developed a GA for ligand docking that explores the full range of ligand flexibility and available binding modes. In validation studies involving 134 protein/ligand complexes a 72% success rate was achieved. Using similar techniques a related program was able to elucidate pharmacophores from a series of active compounds, while accounting for the conformational variance of the actives.

M05.DD.004 SIMULATED ANNEALING AS A TOOL FOR STRUCTURE DETERMINATION FROM POWDER DIFFRACTION DATA. W.I.F. David, K. Shankland and T Csoka, ISIS Facility, Rutherford Appleton Laboratory, Chilton, Didcot, Oxon. OX11 0QX, UK.

Over the past decade, there have been many attempts at structure determination from powder diffraction data. The algorithms used fall into two main types: traditional techniques such as Patterson and Direct Methods and, more recently, global optimisation methods based around techniques such as simulated annealing and genetic algorithms. This talk will focus on simulated annealing techniques with particular emphasis on algorithm development and its specific implementation in the area of structure solution from powder diffraction data [1]. Efficient algorithms will be described for both the search methods employed and the evaluation of candidate solutions. These algorithms will be illustrated with the structure solutions of drug structures ranging from polymorph pairs to multiple salt forms. The current limits of the technique will be discussed with a resume of remarkable successes and failures. The importance of

the inclusion of additional chemical information will be highlighted.

M05.DD.005 PHASING BY *AB INITIO* MODELLING: CONDITIONAL DYNAMICS, A NOVEL N-PARTICLE OPTIMIZATION METHOD. Piet Gros, Dept. of Crystal and Structural Chemistry, Bijvoet Center for Biomolecular Research, Utrecht University, Padualaan 8, 3584 CH Utrecht, The Netherlands.

For a direct phase determination method in protein crystallography we are developing an *ab initio* modelling (AIM) procedure. To enable optimization of randomly distributed loose atoms with respect to protein geometries we have developed a N-particle optimization method coined “Conditional Optimization” or “Conditional Dynamics”.

Direct phasing of protein-diffraction data sets at resolutions of 2 to 3 Å remains an elusive goal. Critical for a general solution to the phase problem will be the efficient use of available sources of information. In our procedure, we optimize randomly distributed loose atoms against observed crystallographic data and against prior structural data, i.e. known protein geometries. We developed a N-particle method that allows a rigorous treatment of geometrical restraints without the need of assigning fixed atom types or a fixed topology. Moreover, this procedure allows the incorporation of chiral restraints enforcing right-handedness of the model. This method of Conditional Optimization is being incorporated into an optimization protocol using maximum-likelihood based simulated annealing and multiple independent trials. The method of Conditional Optimization and examples on test calculations will be presented.

05EE MICROSTRUCTURE AND TEXTURE OF REAL MATERIALS

M05.EE.001 STRUCTURE - MICROSTRUCTURE RELATIONSHIPS IN CERAMIC OXIDES. V. Massarotti, D. Capsoni and M. Bini, Dipartimento di Chimica Fisica e CSTE-CNR, Universita’ di Pavia, Viale Taramelli 16, 27100 Pavia (Italy)

Solid solutions and ceramic oxides are widely used for applications in different fields: catalysis, design of devices, sensors and doped multilayer capacitors with peculiar electric properties, electrode materials in electrochemistry, semiconductors devices and homogeneous glass-ceramic superconductors. In all these cases and in many others the most recent research shows that microstructure has a definite influence on some peculiar properties. The precise determination of microstructural parameters is of great interest for the understanding of the correlations existing among grain and crystallite size, defects, composition and other properties of the materials.

A number of cases will be reported in which the microstructural aspects are remarkably important for the characterization of samples prepared in a very wide range of annealing conditions and for which is suitable to take into account the strain and size effects, to obtain the best interpretation of the observed peak profile broadening (1). In other cases, the explanation for the anisotropic peak broadening, observable in the diffraction patterns, are given in terms of line defects. On the basis of a recently proposed model, the effects of some kind of dislocations can be taken into account to fit the experimental peak-width (2). Using such a model, the microstructural features of cubic $LiMn_2O_4$ spinel, that can affect its electrochemical behaviour, can be investigated by line profile analysis of X-ray diffraction patterns.

M05.EE.002 SHORT AND INTERMEDIATE RANGE ORDER IN MATERIALS USING THE ATOMIC PAIR DISTRIBUTION FUNCTION METHOD. Simon J. L. Billinge, Th. Proffen, Department of Physics and Astronomy and Center for Fundamental Materials Research Michigan State University

Many of the most interesting recently discovered new materials are significantly structurally disordered. Furthermore, the disorder often plays an important in role in the interesting properties. It is clear that techniques which can characterize the short-range order in such materials will become increasingly useful. We have been developing the atomic pair distribution function (PDF) technique for analyzing x-ray and neutron powder diffraction data. This is a real-space approach which {\it yields the structure as a function of length-scale} on nanometer length-scale. Thus, if a material has locally ordered domains with some characteristic correlation length, the local structure can be found from the low-r region of the PDF. Also, in favourable circumstances, the domain size and inter-domain order can be determined.

I will describe the technique showing examples of how length-scale dependent structures can be obtained. I will discuss recent advances in data collection and modelling, and show the application to oxide materials which exhibit a microscopic electronic phase separation phenomenon.

We acknowledge funding from NSF 97-00966 and DOE DE-FG02-97ER45651

M05.EE.003 MATERIALS SCIENCE APPLICATIONS OF HIGH ENERGY SYNCHROTRON RADIATION. H.F. Poulsen, D. Juul Jensen and T. Lorentzen, Materials Research Department, Risø National Laboratory, DK-4000 Roskilde. U. Lienert and Å. Kvick, ESRF, BP 220, F-38043 Grenoble Cedex

High energy X-rays from synchrotrons are the basis of a new diffraction tool, combining high flux and large penetration power. Local micron-scale studies can be performed on materials science properties such as grain orientations, strain and phase identification within the *bulk* of millimetre thick specimens. The properties of the individual grains can be investigated along with mappings of the grain boundary topology. Likewise, embedded volumes and interfaces become accessible. Moreover, hard x-rays are well suited for *in-situ* studies of samples in complicated environments.

The prospect of the technique will be illustrated by a series of examples, ranging from local strain and texture measurements in gradient and composite type of samples to *in-situ* characterisation of the phase transformation and texturing mechanisms in high Tc superconducting tapes. Emphasis will be put on a series of recrystallisation experiments where the nucleation and grain growth of the individual grains is followed during an annealing.

In the end, 3DXRD, a new experimental station at ESRF will be presented. The station is dedicated to three-dimensional mappings of the microstructure. It operates in the energy range of 40-100 keV with a spatial resolution of 5x5x50 μm or better. The set-up utilises micro-focusing optics, high-resolution 2D detectors, and new techniques for improving the depth resolution: tracking and focusing analyser optics.

M05.EE.004 THE APEX STRUCTURE OF CO-PRODUCED CARBON AND BORON NITRIDE CONES. L.N. Bourgeois, Y. Bando, K. Kurashima and T. Sato, National Institute for Research in Inorganic Materials, Namiki 1-1, Tsukuba 305-0044, Japan.

Conical whiskers of layered compounds such as graphite and hexagonal boron nitride (h-BN) are interesting materials because their conical morphology results from the introduction of a local topological defect at the cone apex. In the honeycomb array characteristic of graphite and h-BN basal planes, such topological defect is thought to be a non-hexagonal ring (e.g. a pentagon or a square). These defects are known to form the basis of curved nanostructures like fullerenes and buckytubes. Therefore a comparison of their occurrence in two systems known to harbour nanostructures is worthy of study.

In this work, the defect structure at the apex of co-produced carbon and BN whiskers [1] is investigated by high-resolution transmission electron microscopy and electron diffraction. Analysis of high-resolution images shows that the cones are helical with helical pitch equal to one, and in some rare cases, two. This strongly supports a nucleation scenario involving the formation of a single ring defect as the cone nucleus. In addition, a careful measure of the cone apex angle for many cones, using electron diffraction patterns, indicates that the great majority of BN cones have apex angles corresponding to a square-like ring-defect. In contrast, pentagon-like defects are by far the most common type in carbon cones. This confirms theoretical studies [2] which showed that even-membered rings, and in particular squares, should be the most stable ring-defect in BN.

M05.EE.005 SINGLE GRAIN ANALYSIS OF STORED ENERGY IN COLD-ROLLED STEEL BY X-RAY MICRODIFFRACTION. M. Drakopoulos, I. Snigireva, A. Snigirev [1], O. Castelnau, T. Chauveau, B. Bacroix [2], C. Schroer [3], T. Ungar [4], [1] ESRF, 38043 Grenoble, France, [2] LPMTM-CNRS, University Paris-Nord, 93230 Villetaneuse, France, [3] II. Physikalisches Institut, RWTH, Aachen, Germany, [4] Eötvös University Budapest, 1445 Budapest, Hungary

Single grain properties like orientation, size, dislocation density, and internal strain may vary extremely even between neighbour grains, and therefor the material under research has to be regarded as heterogeneous in the micrometer scale. One process of great industrial and scientific interest which is dominated by these properties is recrystallisation. Plastic deformation or annealing lead to an heterogeneous strain- and dislocation field in the material and store energy which also is deposited heterogeneously in the volume. The progression of the following recrystallisation then strongly depends on the distribution of the stored energy inside the material. The dislocation- and strain-field can be experimentally observed with x-ray diffraction and quantitatively determined by line profile analysis of the diffracted beam [1].In this work the local strain- and dislocation state of single grains in a polycrystalline material was examined. The samples have been cold-rolled steels before recrystallisation. After taking an orientation map with Back Scattered Electron Diffraction (EBSD) the sample was further analysed with x-ray micro-diffraction. A 4-circle diffractometer with a xyz-stage for the sample was used. The incoming beam was focused with an Compound Refractive Lens [2]. The line-profiles have been recorded using a 2-dimensional gas-filled detector. For alignment of beam, grain-positions and diffractometer centre a alignment system based on a direct calibration with x-rays has been developed.For 20 different grains 6 orthogonal reflections per grain have been recorded. The average grain size was around 20 micrometer. The line profiles from different reflections result in a 3-dimensional information of the dislocation- and strain-state of single grains.

P05.EE.002 ANISOTROPY OF DIFFRACTION LINE PROFILE PARAMETERS AND REAL STRUCTURE OF MATERIALS. R. Kuzel, Faculty of Mathematics and Physics, Charles University, Ke Karlovu 5, CZ-121 16, Prague, Czech Republic

Powder diffraction line profiles often show significant anisotropy of certain parameters - positions (cubic lattice parameters), broadening, intensities (static Debye-Waller factors). This can be not only parasitic effect which should be avoided or corrected in structure refinement but it can also be a source of valuable information on real structure of materials - their micro- or nanostructure and/or lattice defect types. A short review of the problem is given and examples are presented with different explanation of the observed anisotropies.

The anisotropy of dislocation-induced line broadening indicates prevailing dislocation types as it has been shown for several hexagonal and cubic materials both theoretically and experimentally. Different line broadening anisotropies are characteristic of other lattice defects such as stacking faults, precipitates, dislocation loops. In fine powders, the anisotropy of line broadening can help to determine the shape of particles. Strong anisotropies of cubic lattice parameters observed on protective coatings were explained by significant sample inhomogeneity when differently oriented grains (texture components) had different microstructures and by the oriented microstresses. Severe anisotropy of static Debye-Waller factors (diffuse scattering - quasilines) observed in aged Cu-Be samples with precipitates could only be explained considering preferred orientation of the precipitates with respect to the surface.

P05.EE.003 DOMAIN TEXTURE OF Cu_3Au FILMS IMAGED BY COHERENT X-RAY DIFFRACTION. I. K. Robinson, J. A. Pitney, I. A. Vartaniants, R. Appleton and C. P. Flynn, Department of Physics, University of Illinois, Urbana, IL 61801, USA

X-ray diffraction with a coherent beam will preserve the crystallographic phase of the entire object under illumination. The interference between domains in a textured material is encoded as intensity modulations in the diffraction pattern which can be recorded with a high-resolution detector. In principle, this can be inverted to an *image* of the texture. We have recorded such diffraction patterns using the (100) and (110) diffraction peaks of a crystalline thin film of Cu_3Au with (111) orientation. Undulator radiation of 8.5keV from the Advanced Photon Source was required for the coherence. The texture in this sample is due to antiphase domains which are around 1000A in size. The diffraction patterns have been inverted using the Gerchberg-Saxton and hybrid-input-output algorithms to produce images of the domain texture. In this paper we will report our progress towards understanding the convergence of the algorithm and the uniqueness of the texture images we have obtained.

P05.EE.004 CRYSTAL STRUCTURE OF γ_1' MARTENSITE IN Cu-Al-Ni ALLOY. A.E. Skourikhin and A.T. Kosilov, Voronezh State Technical University, Physics of metals department, Moskovski prospekt 14, 394026 Voronezh, Russia, and A.Yu Vasilenko, Voronezh State Technology Academy, Physics department, prospekt Revoluci 19, 394000 Voronezh, Russia.

The thermoelastic γ_1' martensite formed upon cooling and room temperature aging in single crystal and polycrystal Cu-Al-Ni

alloy has been studied by means of X-ray diffraction. The main features are the appearance of (001) reflection and lowering of differences between intensities of (200) and (002) reflections for polycrystals. Specimens, appearance of (321) and (323) reflections and great decrease of intensities for (400) and (402) reflections in diffraction pattern of rotating single crystal, gradual changing of intensities for some reflection during aging.

Such a behavior allows to propose a modified 2H structure of γ_1' martensite. Namely, in the orthorhombic coordinate the each second layer parallel to the basal plane is shifted to the position (a/2-x,0,c/2) from the normal (a/3,0,c/2) with $a/8<x<a/6$ and a=4.382 Å, b=5.356 Å, c=4.222 Å. Some shuffling of (100) planes or individual atoms in [001] direction is believed. The last proposition follow from appearance of (001) reflection, relative intensities of (200) and (002) reflections and decreasing of (002) reflection intensity during aging.

The new stacking position of the each second layer parallel to the basal plane and shuffling in [001] direction are confirmed by a hard sphere model of atoms including relative dimensions of Cu and Al atoms and computer simulation of structure using the Morse potential and minimum energy condition.

05FF FERROIC STRCUTURES

M05.FF.001 STUDIES OF FERROIC CRYSTALS BY OPTICAL METHODS. A.M. Glazer Department of Physics, University of Oxford, UK.

Ferroic crystals are characterised by a variety of, in principle, switchable properties, which in turn means that they tend to exhibit within a single crystal several domain states. Optical properties, which are very dependent on small changes in the crystal structure, can be used to study these domain states. In particular, measurements of the linear birefringence are a particularly sensitive probe for this, and so techniques for making such experiments will be briefly reviewed. Originally, birefringence was measured by traditional compensator techniques, but with the advent of high-speed computing, high-resolution graphic boards and CCD cameras, it is now possible to make very precise and more informative birefringence measurements. One of the latest ways of doing this is to combine birefringence studies with modern techniques of image analysis, so that one can obtain information throughout the whole of the specimen simultaneously rather than a simple spot measurement. This will be illustrated by a microscope system that enables the optical retardation to be separated from orientation and absorption effects for any image. New techniques also for measuring optical rotation in crystals will also be discussed briefly.

M05.FF.002 FERROELECTRIC AND ANTIFERRO-ELECTRIC TRANSITIONS IN MIXED PEROVSKITES D. Pandey, Materials Science and Technology, Banaras Hindu University, Varanasi-221005, India.

This talk presents an overview of recent results on the structural phase transitions in (Sr,Ca)TiO3 [SCT], Pb(Zr,Ti)O3 [PZT] and (Pb,Ba)ZrO3 [PBZ]. (i) A combined x-ray, electron and neutron diffraction study on SCT has revealed a series of tilt transitions which play a crucial role in the stabilisation of ferroelectric (FE), glassy and antiferroelectric (AFE) phases. (ii) In PZT ceramics a combined high temperature x-ray and piezoelectric measurements has shown that the coexistence of the rhombohedral phase with tetragonal for the MPB compositions is not responsible for the maximum electromechanical response as hitherto believed for decades. (iii) In the PBZ system high temperature XRD and dielectric results have explained as to why it becomes relaxor for more than 25% Ba using Landau theory considerations.

M05.FF.003 RELAXOR FERROELECTRICS. R. Blinc, J. Stefan Institute, Jamova 39, 1000 Ljubljana, Slovenia.

Relaxor phases are typically found [1] in structurally disordered perovskites of the $A_yA'_{(1-y)}B_xB'_{(1-x)}O_3$ type. They are believed to provide a conceptual link between ferroelectrics and dipolar glasses and besides have found use in numerous applications in view of their outstanding electromechanical properties. The nature of the diffuse phase transition in the relaxors has remained the subject of some controversy. No macroscopic symmetry change has been observed down to the lowest temperatures in zero electric field. The low temperature state is characterized by a broad frequency dispersion in the complex dielectric constant, a logarithmic polarization decay, and a slowing dynamics. Randomly oriented pinned nanodomains induced by compositional fluctuations coexist with reorientable polar clusters. The basic open question is whether the relaxor phase represents (i) a ferroelectric state broken up into nanodomains under the constraint of quenched random fields or (ii) a dipolar glass state.

Measurements of the local polarization distribution function and of the Edwards-Anderson glass order parameter in $PbMg_{1/3}Nb_{2/3}O_3$ and $Pb(Sc_{0.5}Ta_{0.5})O_3$ via 2D NMR have shown that the results are very different from the ones previously obtained for dipolar or quadrupolar glasses but quantitatively agree with a newly proposed spherical random bond-random field model (SRBRF) of relaxor ferroelectrics. This model can in addition to other glassy features also quantitatively describe the anomaly in the temperature dependence of the third order dielectric nonlinearity which cannot be explained by a para- to ferroelectric transition in random fields. The SRBRF model also predicts that the peak in the nonlinear dielectric susceptibility disappears in the presence of a non-zero electric field as indeed observed, and that a ferroelectric long range ordered state appears for $E > E_c$.

M05.FF.004 THEORY OF MORPHOTROPIC PHASE BOUNDARIES. Yoshihiro Ishibashi, Department of Applied Physics, School of Engineering, Nagoya University, Chikusa-ku, Nagoya 464-8603, Japan

Solid solutions based on the perovskite ferroelectric crystals show excellent physical properties as sensors and actuators, especially when the composition lies close to the morphotropic phase boundary. This is due to the situations that, in the vicinity of the morphotropic phase boundary, the transversal electric susceptibilities tend to diverge, some components of elastic stiffness constants become extremely small and, as the result, the electromechanical coupling constant approaches unity. These phenomena can be easily explained by the Landau theory with the free energy function written in terms of the polarization components which are the bases of the T1u irreducible representation of the point group m3m[1]. At the morphotropic phase boundary, the free energy function is found to become almost isotropic in the space spanned by three polarization components. The results can be also applied to the family of the rare-earth Fe2 compounds, which are ferromagnetic (ferrimagnetic).

M05.FF.005 ELECTRON LEVEL STRUCTURES AND PHYSICAL PROPERTIES. M.Sakata, Department of Applied Physics, Nagoya University, Nagoya 464-8601, Japan,

In most structure analyses by X-ray diffraction for understanding physical properties and structural relationships, main interests are bond lengths. They can be easily calculated from the atomic coordinates, which are refined structural parameters in the least squares refinement. This type of work may be called atomic level structure analyses, because it concerns only the central positions of atoms. Huge amount of knowledge concerning bond lengths has been accumulated in the past years, which is very helpful to understand physical properties and structural relationships. Nonetheless it does not deny the importance of studying electron level structures, because many physical properties are closely related to the behavior of electrons in solid. Such a situation is the same in the case of ferroic structures, too. In particular, it is very important to study both atomic and electronic level structures of ferroic structures involving hydrogen atoms, because both structures may be very different due to deformation of electron clouds which belong to hydrogen atoms.

So far, such electron level structure analyses have been done by multi-pole analyses or difference Fourier transformations. Recently, a new sophisticated method to study electron level structures has been developed, that is, the Maximum Entropy Method (MEM). By MEM, electron level structures of quite a few crystalline materials have been so far obtained. These works seems to be proving that even from a X-ray powder data set where the number of structure factors determined is rather limited, MEM can yield a physically meaningful total electron density distribution, which agree with the observed structure factors within experimental errors as a whole.

To have better understanding of physical properties and structural relationships of ferroic substances, the recent results of electron level structures for 1) ferroic substances involving hydrogen atoms such as KDP and ADP, 2) non-hydrogen ferroic substances like $SrTiO_3$ and 3) some other topics will be discussed in the talk.

06OA MEMBRANE PROTEINS AND TRANSMEMBRANE SIGNALLING

M06.OA.001 STRUCTURE AND ACTIVATION BY DIMERISATION OF THE INTEGRAL MEMBRANE ENZYME OMPLA, OUTER MEMBRANE PHOSPHOLIPASE A. Bauke W. Dijkstra and Arjan Snijder, Laboratory of Biophysical Chemistry, Groningen University, Nijenborgh 4, 9747 AG Groningen, the Netherlands

Outer membrane phospholipase A (OMPLA) is an integral membrane enzyme located in the outer membrane of Gram-negative bacteria. Its structure has been determined by X-ray crystallography. Monomeric OMPLA consists of a 12-stranded anti-parallel β-barrel with a convex and a flat side and with approximate dimensions of 16x30x45 $Å^3$. The 12 amphipathic β-strands traverse the membrane in an up-and-down fashion forming a hydrophobic outer surface.

The active site contains Ser144 and His142, as established from chemical modification and site-directed mutagenesis experiments. It is located on the exterior of the β-barrel, positioned just outside the outer leaflet ring of aromatic residues. Besides the serine and histidine, the active site contains an asparagine residue (Asn156). Its carboxamide side chain is at hydrogen bonding distance from the Nδ1 atom of His142, probably fixing the orientation of the His142 side chain.

The activity of the enzyme is regulated by reversible dimerisation with the dimer being the active form. Covalent inhibition of OMPLA results in increased dimer stability which allowed for the crystallisation of the dimer. The monomers associate in a parallel fashion to form a homo-dimer such that the two active sites are located at the outer leaflet side of the membrane. Surprisingly little structural rearrangements occur (r.m.s. difference between monomer and dimer is 0.4 Å for 257 Cα atoms). The key interaction stabilising the dimer seems to be a double hydrogen bond formed between the side chains of glutamine 94 from one monomer and its counterpart in the other monomer, nearly in the middle of the membrane-embedded part.

Dimerisation results in productive active sites, with two substrate binding pockets created at the interface between the two monomers.

M06.OA.002 CRYSTAL STRUCTURE OF THE OUTER MEMBRANE ACTIVE TRANSPORTER FEPA FROM E. COLI. S.K. Buchanan[1], B.S. Smith[1], L. Venkatramani[2], D. Xia[1], L. Esser[1], M. Palnitkar[1], R. Chakraborty[2], D. van der Helm[2] and J. Deisenhofer[2]. [1]Howard Hughes Medical Institute and Department of Biochemistry, UT Southwestern Medical Center, 5323 Harry Hines Blvd., Dallas, TX 75235-9050, USA. [2]Department of Chemistry and Biochemistry, The University of Oklahoma, 620 Parrington Oval, Norman, OK 73019-0370, USA.

Ferric enterobactin receptor (FepA) is an 80 kD integral outer membrane protein from *E. coli* which binds ferric enterobactin (719 daltons) and transports it into the periplasm; it also serves as the receptor for colicins B and D. FepA belongs to the family of high affinity, active transport receptors which specifically transport iron chelates and vitamin B_{12} across the outer membrane, against a concentration gradient. FepA recognises and binds ferric enterobactin in the absence of other factors, but ligand transport requires energy derived from the proton motive force across the inner membrane. This is accomplished through physical interaction with an integral inner membrane protein complex, TonB-ExbB-ExbD, a part of which is believed to span the periplasm.

The structure of FepA has been solved at 2.4Å resolution by multiwavelength anomalous diffraction (MAD) on selenomethionine-containing crystals at 170ºC. Two distinct functional domains are revealed: (1) a 22-stranded β-barrel spans the outer membrane and contains large extracellular loops which appear to function in ligand binding, and (2) a globular N-terminal domain folds into the barrel pore, inhibiting access to the periplasm and contributing two additional loops for potential ligand binding. We postulate that these loops provide a signalling pathway between the coupled processes of ligand recognition and TonB-mediated transport. The blockage of the pore suggests that the N-terminal domain must undergo a conformational rearrangement to allow ligand transport into the periplasm.

M06.OA.003 TWO CONFORMATIONAL STATES OF THE LIGAND-GATED ALLOSTERIC MEMBRANE RECEPTOR FHUA. Dino Moras, Bernard Rees, André Mitschler, Luc Moulinier [1], Kaspar P. Locher, Ralf Koebnik, Jurg P. Rosenbusch [2], [1] Laboratory of Structural Biology (CNRS), IGBMC, 1 rue L. Fries, BP 163, Illkirch Cedex/France, [2] Department of Microbiology, Biozentrum, University of Basel, Klingelbergstr. 70, CH-4056 Basel/Switzerland

FhuA protein facilitates ligand-gated transport of ferrichrome-bound iron across Escherichia coli outer membranes. Its crystal structure, in the presence and absence of ferrichrome reveals two distinct conformations. The monomeric protein consists of a hollow, 22-stranded, antiparallel b-barrel (residues 160-714), which is obstructed by a plug (residues 19-159). The binding site of ferrichrome, an aromatic pocket near the cell surface, undergoes minor changes upon association with ligand. These are propagated across the plug, eventually resulting in substantially different protein conformations at the periplasmic

face. Our findings reveal the mechanism of signal transmission and suggest how the energy-transducing TonB complex senses ligand binding.

M06.OA.004 TRANSMEMBRANE SIGNALLING ACROSS THE OUTER MEMBRANE OF *E. COLI*: CRYSTAL STRUCTURE OF FHUA WITH BOUND LIPOPOLYSACCHARIDE. Kay Diederichs, Andrew D. Ferguson, Eckhard Hofmann and Wolfram Welte, Fakultät für Biologie, Universität Konstanz, M656, Konstanz D-78457, Germany, and James W. Coulton, Department of Microbiology and Immunology, McGill University, 3775 University Street, Montreal H3A 2B4, Canada.

Transport across the outer membrane of Gram-negative bacteria is mediated by distinct classes of transport mechanisms, including passive diffusion through non-specific porins, facilitated diffusion via substrate-specific porins, and active transport by energy dependent high-affinity receptors. FhuA, receptor for ferrichrome in *E. coli*, is a member of a family of integral outer membrane proteins, which, together with the energy transducing protein TonB, mediate active transport of ferric siderophores across the outer membrane. In addition to binding ferrichrome, FhuA also functions as the primary receptor for the structurally related antibiotic albomycin, for several bacteriophages, for the peptide antibiotic microcin 25, and for the bacterial toxin colicin M. Here we present the three-dimensional structure of FhuA in two conformations, with and without ferrichrome at 2.7 Å and 2.5 Å resolution, respectively [1]. The structure was solved by multiple anomalous dispersion phasing using data collected from a single selenomethionyl crystal at 100 K. FhuA is a β-barrel composed of 22 antiparallel β-strands. In contrast to the typical trimeric arrangement found with porins, FhuA is monomeric. Located within the β-barrel is a structurally-distinct domain, the 'cork', consisting mainly of a mixed four stranded β-sheet multiple short α-helices. Upon binding of ferrichrome-iron, conformational changes are transduced to the periplasmic pocket of FhuA, signalling the ligand-loaded status of the receptor. Sequence homologies and mutagenesis data are used to propose a structural mechanism for TonB-dependent siderophore-mediated transport across the outer membrane. Structural implications for energy transduction, bacteriophage binding and the use of siderophore-antibiotic conjugates are discussed. In addition, a single *E. coli* K-12 lipopolysaccharide molecule has been identified noncovalently bound to the membrane-embedded region of FhuA. The crystal structure of lipopolysaccharide, description of the interactions with outer barrel wall of the protein and a proposed binding motif for lipolysaccharide binding proteins is presented.

M06.OA.005 STRUCTURE OF BACTERIORHODOPSIN AT 1.55 Å RESOLUTION. Hartmut Luecke, Brigitte Schobert, Hans-Thomas Richter, Jean-Philippe Cartailler and Janos K. Lanyi, University of California, Irvine, CA 92697-3900, U.S.A.

The atomic structure of the light-driven ion pump bacteriorhodopsin and the surrounding lipid matrix was determined by x-ray diffraction of crystals grown in cubic lipid phase. At 1.55 Å resolution, features not seen before become evident. In the extracellular region an extensive 3-dimensional hydrogen-bonded network of protein residues and seven water molecules leads from the buried retinal Schiff base and the proton acceptor Asp^{85} to the membrane surface. Near Lys^{216} where the retinal binds, transmembrane helix G contains a π-bulge that causes a non-proline kink. The bulge is stabilized by hydrogen-bonding of the main-chain carbonyl groups of Ala^{215} and Lys^{216} with two buried water molecules located between the Schiff base and the proton donor Asp^{96} in the cytoplasmic region. The results indicate extensive involvement of bound water molecules in both the structure and the function of this seven-helical membrane protein. A bilayer of 18 tightly bound lipid chains forms an annulus around the protein in the crystal. Contacts between the trimers in the membrane plane are mediated almost exclusively by lipids.

M06.OA.006 ABSTRACT NOT AVAILABLE. R.M. Stroud

M06.OA.007 STRUCTURE ANALYSIS AND LIGAND-BINDING SITE OF THE BOVINE BRAIN PHOSPHATIDYLETHANOLAMINE-BINDING PROTEIN. L. Serre, B. Vallée, N. Bureaud, F. Schoentgen and C. Zelwer. Centre de biophysique moléculaire. C.N.R.S. Rue Charles Sadron, 45071 Orléans Cedex 2, France.

PEBP is a basic protein isolated from bovine brain, which binds *in vitro*, phosphatidylethanolamine as well as GTP. Although its precise biological role is still unknown, PEBP is present in mammalian cells exhibiting morphogenesis activity. Besides, sequence alignments showed that the mammal PEBP belongs to a protein family which also includes CEN, a protein involved in inflorescence architecture control, TSF1 a suppressor of cdc25 mutation in yeast, i.e. proteins which seem to be related to developmental processes.

To get new insights on PEBP function, we solved the X-ray structures of the bovine brain PEBP and of the PEBP complexed to the polar head of phosphatidylethanolamine. These structures show that PEBP and its family constitute a structural protein family that the phospholipid binding site is a small cavity located close to the protein surface. In a conserved region, the PEBP structure displays also two cis-peptide bonds that correspond to interesting natural mutations of *Arabidopsis* and Tomato plants.

Although these structures do not yet give clues on the precise *in vivo* function of PEBP, they show that PEBP exhibits some similarities with the C-terminal domain of a Rho GDP-dissociation inhibitor which negatively regulates Rho-family GTPases and the calcium/phospholipid binding-domains of synaptotagmin I, a synaptic vesicle membrane protein, and some phospholipases (cytosolic PLA2 and PLCδ1). We believe that PEBP may have a similar function and be a membrane binding protein as well, which would interact with other proteins and perhaps would modulate their catalytic activities.

M06.OA.008 CRYSTAL STRUCTURE OF SENSOR DOMAIN OF HEME-BASED OXYGEN SENSOR FIXL FROM RHIZOBIUM MELILOTI. H. Miyatake, S. Adachi, H. Nakamura, K. Tamura, T. Iizuka, Y. Shiro [1], M. Kanai [2], T. Tsuchiya [3], [1] The Institute of Physical and Chemical Research (RIKEN), RIKEN Harima Institute, 323-3 Mikazuki-cho, Mihara, Sayo, Hyogo 679-5143, Japan, [2] Faculty of Science, Kanagawa University 2946 Tsuchiya, Hiratsuka-shi, Kanagawa 259-1293, Japan, [3] Department of Molecular Genetics Medical Research Institute Tokyo Medical and Dental University, 1-5-45, Yushima, Bunkyo-ku, Tokyo 113-8510, Japan

FixL is a transmitter protein in the two-component system which acts as an oxygen-sensor and regulates histidine kinase activity when the symbiotic rhizobia resides in root nodules of host plants. The oxygen sensor domain of Rhizobium meliloti FixL (FixLN) was purified by His-tag and isoelectronic-focusing chromatographies. Dynamic light scattering measurement of FixLN thus obtained showed that the oxygen sensor domain of R. meliloti FixL is present as a homo-dimer in solution. A crystal of R. meliloti FixLN in the met (Fe3+) form was grown in 100mM

acetic acid/NaOH buffer at pH 4.6 in the presence of 200mM ammonium acetate using 40 %(w/v) PEG 4000 as a precipitant. A crystal of the ferrous CO form of FixLN was also prepared by reduction of the met crystal with dithionite under an atmosphere of CO. The crystals (0.2mm x 0.05mm x 0.01mm) belong to the monoclinic system (C2) with cell dimensions of a=60.94Å, b=37.44Å, c=54.14Å and beta=115.29°, and give X-ray diffractions with 1.7 Å resolution at station BL44B2 of SPring-8, Japan. The solvent content of the crystal was only 23 %, which was abnormaly low for protein crystals. Because all of soaking trials were failed, we carried out MAD experiment making use of the heme iron as an anomalous scatterer. Bijvoet difference Patterson maps show a clear peak corresponding to the heme iron in FixLN. The MAD electron density map calculated by program SOLVE was enough interpretable to build the initial model, with knowledge that FixLN belongs to PAS domain superfamily. PAS-containing proteins are likely to mediate macromolecular interactions along signalling pathways with their N-terminal regions. Interestingly, it was revealed that the FixLN formed a homo-dimer with the "N-terminal cap". The dimeric interaction was dominantly made by "leucin zipper-like" hydorphobic forces, supplemented with some salt bridges. This is the first crystallographic evidence which shows PAS-containing proteins make a homo-dimer with their N-terminal regions.

We will also discuss about how FixLN senses oxygen based upon structural comparison between met- and CO-FixLN, which is an oxygen mimic adduct. "Oxygen sensing mechanism by heme-doming" is proposed for B.japonicum FixLN by Gilles-Gonzalez et al. B.japonicum FixLN, however, presents as a monomer in crystal maybe because it lacks N-terminal cap. We will focus on this point that the heme-doming mechanism is also appliable to our R. meliloti FixLN, because there may be intrinsic difference in their assembly states.

M06.OA.009 STRUCTURE OF THE FIRST 3 DOMAINS OF THE TYPE 1 IGF RECEPTOR. T.P.J. Garrett[1], N.M. McKern[2], M. Lou[1], M.J. Frenkel[2], J.D. Bentley[2], G.O. Lovrecz[2], T.C. Elleman[2], L.J. Cosgrove[2,3] and C.W. Ward[2]. Biomolecular Research Institute[1] and CSIRO Division of Molecular Science[2], 343 Royal Parade, Parkville, Victoria, 3052, Australia. [3]Current Address: CRC for Tissue Growth and Repair, Adelaide, SA

The type 1 insulin-like growth factor receptor (IGF-1R) belongs to a family of vertebrate cell surface receptors which also include insulin receptor. However homologues have also been found in many invertebrates, including some of the simplest multicellular animals. The ligands for this family are protein hormones which induce a variety of metabolic and mitogenic responses. IGF-I and IGF-II are primarily produced as a consequence of growth hormone signalling and are essential for normal growth and development. They also seem necessary in malignant transformation of some cells. Insulin is a major mediator in glucose homeostasis and induces lipid, protein and glucose metabolism in a variety of tissues. Although many other cell-surface receptors dimerize upon binding their ligands the mature IGF-1R pre-exists as a disulfide-linked homodimer. Thus binding of the hormone to the extracellular portion is believed to induce a structural change in the receptor which is transmitted across the membrane to allow transphosphorylation of the tyrosine kinase domains.

We have determined the structure of the first three domains of the type 1 insulin-like growth factor receptor (L1-cys rich-L2 domains) to 2.6 Å resolution by X-ray diffraction. This corresponds to the first half of the extracellular portion and it contains two regions which have been implicated in ligand specificity. L1 and L2 are homologous and adopt the a fold which represent a new type of structural domain. The cys-rich region also shows unique structural features, being composed of small disulfide-bonded modules associated in a novel manner. At the centre of the molecule is a space of sufficient size to accommodate a hormone ligand. Two regions of the receptor which are involved in hormone-binding map to this site. Thus this structure gives a first view of how members of the insulin receptor family might interact with their ligands.

P06.OA.001 A NOVEL ELECTRON TRANSFER MECHANISM SUGGESTED BY CRYSTALLOGRAPHIC STUDIES OF CYTOCHROME *bc1* COMPLEX. Di Xia[1,2], Hoeon Kim[1], Chang-An Yu[2], Johann Deisenhofer[1], [1]HHMI and Department of Biochemistry, UT Southwestern Medical Center, Dallas, [2]Laboratory of Cell Biology, DBS/NCI/NIH, [3]Department of Biochemistry, Oklahoma State University.

The crystal structure of bovine mitochondrial cytochrome *bc1* complex, an integral membrane protein complex of 11 different subunits with a total molecular weight of 242 kDa, demonstrated a tightly associated dimer consisting of three major regions: a matrix region primarily made of subunits core1, core2, 6 and 9; a trans-membrane-helix region of 26 helices in the dimer contributed by cytochrome *b*, cytochrome *c1*, the Rieske iron-sulfur protein (ISP), subunits 7, 10 and 11; and an inter-membrane-space region composed of extra-membrane domains of ISP, cytochrome *c1* and subunit 8. The structure also revealed the positions of and distances between irons of prosthetic groups, and two symmetry related cavities in the trans-membrane-helix region upon dimerization of the *bc1* complex. Extensive crystallographic studies on crystals of *bc1* complexed with inhibitors of electron transfer (ET) identified binding pockets for both Qo and Qi site inhibitors. Discrete binding sites for subtypes of Qo site inhibitors have been mapped onto the Qo binding pocket, and bindings of different subtypes of Qo site inhibitors are capable of inducing dramatic conformational changes in the extra-membrane domain of ISP. A novel ET mechanism for the *bc1* complex consistent with crystallographic observations will be discussed.

P06.OA.002 CRYSTALLIZATION OF THE REACTION CENTER OF PHOTOSYSTEM II AND OF ISOLATED REACTION CENTER COMPONENTS. Noam Adir, Rina Anati, Valeria Cheredman, Yelena Dobrovetzki and Natalia Lerner Department of Chemistry, Technion, Technion City, Haifa 32000 Israel

Photosynthesis is the process by which plants transform the energy of the sun into useful chemical energy. The primary reactions occur between a variety of cofactor molecules bound to large membrane protein complexes called reaction centers. Of the different reaction center types, one of the most complex is that of Photosystem II, found in all higher plants, green algae and cyanobacteria. It is the site of the initiation of linear electron flow, proton gradient formation and oxygen evolution. Reaction center II (RCII) contains 9 proteins, 7 different cofactor types and has a molecular weight of about 280,000. RCII, isolated from either spinach or pea photosynthetic membranes, have been crystallized [1]. The crystals were grown from RCII monomers in the presence of mixtures of detergents at a higher detergent/protein ratio than previously reported for other membrane proteins. The crystals grew as hexagonal rods with dimensions of up to 1 x 0.3 x 0.3 mm. The crystals diffracted to a maximum resolution of about 6.5Å, and belong to a hexagonal space group with unit cell dimensions of a = 495Å, b = 495Å, c = 115Å, $\alpha = \beta = 90^{o}$, $\gamma = 120^{o}$. Thermoluminescence measurements of RCII from solubilized crystals showed that the crystallized RCII was competent in electron transfer to exogenous electron acceptors. These and other measurements detected heterogeneities in the crystallized RCII, which may be the reason for crystal disorder.

Because of the large size and complexity of RCII, we are also trying to isolate various protein components and determine their structure separately: *i*. Oxygen evolution in RCII is

dependent on the presence of a tetramanganese cluster, protected by a membrane-associated protein called the 33kDa OEC protein. We have successfully isolated this protein, purified to homogeneity and crystals have been obtained. *ii*. RCII is connected to the main antenna, LHCII by a number of intermediate membrane bound antenna molecules. One of them, CP29, has been isolated and crystals have been obtained. *iii*. Within the core of all RCII complexes is a unique dipeptide 15kDa transmembrane b-type cytochrome called cytochrome b_{559}. Overexpression of a unique fused gene product, reconstitution and crystallization trials will be described.

P06.OA.003 NEUTRON CRYSTALLOGRAPHY OF LH2 AT LOW RESOLUTION: THE LOCATION OF DETERGENT & AMPHIPHILE VOLUMES. S.M. Prince, T.D. Howard, R.J.Cogdell & N.W. Isaacs; University of Glasgow, Glasgow, G12 8QQ UK. D.A.A. Myles & C. Wilkinson; EMBL, B.P.156, 38042 Grenoble Cedex 9, France. M.Z.Papiz; Daresbury Laboratory, Warrington, WA4 4AD UK.

The peripheral light-harvesting complex (LH2)[1] from the purple bacteria *Rps. acidophila* strain 10050 is an integral trans-membrane protein complex. These LH2 complexes are constructed from nonomeric oligomers of a unit comprising two polypeptides with associated non-covalently bound pigment molecules. During isolation and when crystallised the hydrophobic trans-membrane portion of these molecules is enclosed in a detergent micelle[2]. This micelle is disordered at the atomic level and is not observed in the X-ray structure. Low resolution crystallographic experiments using the diffraction properties of neutrons and D_2O/H_2O contrast variation allow the location of volumes having systematic proton densities [3]. We will assign all of the discrete volumes in the LH2 crystals namely protein, solvent, detergent, phospholipid and amphiphile.

The information gained in this experiment will allow us to discover the influence of the detergent on crystalline packing and the location of any systematic lipid content in the crystal. We will also be able to precisely determine the trans-membrane portions of this molecule, and the interaction of the protein complex with the micelle.

P06.OA.004 CRYSTALLOGRAPHIC STUDIES OF A LOW-LIGHT LIGHT-HARVESTING COMPLEX A.M. Lawless, N. Hartigan, H.A. Tharia and M.Z. Papiz, CLRC Daresbury Laboratory, Daresbury, Warrington, WA4 4AD, UK

In photosynthetic purple bacteria, solar energy can be directly trapped by the carotenoids and bacteriochlorophylls of the light-harvesting system. Considerable impetus has been given to this field of research by the structure determinations of the Reaction Centre (RC) and Light Harvesting Complexes I and II (LH1, LH2). The relative numbers of LH2's expressed per RC:LH1 is determined by environmental factors such as temperature and light. Carotenoids fill the gap in the visible part of the spectrum where Bchl's do not absorb and protect against oxidation. B850 pigments stabilise and prepare the energy for transfer by linking together to form an energy storage ring. B800 pigments give additional light-energy capturing power and may add variability to the system allowing the complex to be tailored for specific environmental conditions.

The low-light LH2 complex from *Rhodopseudomonas palustris* has been characterised by HPLC. Sequence analysis of LH2 from cells grown at 300 lux was found to be a mixture of high- and low-light peptides. Crystals of this complex prepared in dodecylmaltoside were monoclinic (P2 or P21) a=99.4, b=133.4, c=180.4 Å and b=100.5^o and diffracted to 12 Å resolution. Crystal quality was found to be related to the ability to grow the cells below 90lux, thus reducing the heterogeneity of the complex. Cells grown at 50 lux produced LH2 >95% pure in terms of contamination from high-light peptides. Diffraction from these crystals has been consistent to around 5.2Å, although this is along one direction in reciprocal space. Data have been collected to 7.0 Å resolution and self rotation functions indicate an axis of NCS 50^o from the unique axis.

We hope to report further progress on this unusual LH2 complex which, in addition, has special spectroscopic characteristics and is markedly different to the other two LH2 complexes for which the structure is known.

P06.OA.005 CRYSTALLISATION & CRYOCOOLING OF COLOURED CRYSTALS - MORE ADVENTURES WITH LIGHT HARVESTING PROTEINS. Tina D. Howard [1], Steve M. Prince [2], Richard J. Cogdell [1], Neil Isaacs [2], [1] Division of Biochemistry, Davidson Building, IBLS, University of Glasgow, Glasgow, G12 8QQ, UK, [2] Protein Crystallography, Joseph Black Building, University of Glasgow, Glasgow, G12 8QQ, UK.

We have developed a method of slowly introducing a cryoprotectant into crystals of the integral membrane protein Rps. acidophila 10050 LH2. As a result of this new procedure the resolution of the structure has been increased from 2.5Å1 to 2.0Å. This method is currently being extended to a new tetragonal crystal form of the protein which we have recently obtained (current resolution 3.7 Å).

Crystals of similar proteins involved in light harvesting in different species of purple photosynthetic bacteria (wild type and mutant strains) have also been produced. Alongside optimising these conditions to improve the diffraction of these crystals, crystallisation experiments are being extended to the "core complex" and "LH1" proteins involved in the later steps of the photosynthetic process in purple photosynthetic bacteria.

06OB STRUCTURAL ENZYMOLOGY AND UNUSUAL CHEMISTRY

M06.OB.001 NiFe AND Fe-ONLY HYDROGENASES DISPLAY UNUSUAL COORDINATION TO ACTIVE SITE Fe. Juan C. Fontecilla-Camps IBS/LCCP, CEA-CNRS, Grenoble 38027, France

Many microorganisms are capable of either produce hydrogen, as a way to get rid of low potentiel electrons, or oxidize it to get reducing power. Often hydrogen-producers are found is association with hydrogen-consumers, forming ecosystems that have been proposed as a possible origin for eukaryotic cells (1). Hydrogen metabolism is, for the most part, carried out by two types of metalloenzymes: the NiFe and Fe-only hydrogenases. We have extensively studied these two classes of proteins from sulfate-reducing organisms using X-ray crystallography. A combination of crystallographic and IR spectroscopic analyses have established that the active site of the NiFe-hydrogenases is made out of a NiFe binuclear center displaying extensive cysteine thiolate and (Fe) CO and CN coordination (2-3). More recently, we have shown that a somewhat similar active site is present in the Fe-only hydrogenase from Desulfovibrio desulfuricans (4). The presence of triple-bonded molecules as ligands of Fe centers in the two evolutionary unrelated enzymes rises the question of the function of a low-spin, possibly low redox, Fe center in hydrogen catalysis. In addition to this similarity, NiFe and Fe-only hydrogenases share comparable electron transfer pathways made

out of cubane-type [4Fe4S] clusters and hydrophobic channels that appear to serve as privileged gas access paths to the active site (4-5).

M06.OB.002 A MOVIE OF CATALYSIS IN THE COPPER-CONTAINING QUINOENZYME AMINE OXIDASE. Carrie M. Wilmot[1], Janos Hajdu[2], Colin G. Saysell[1], Michael J. McPherson[1], Peter F. Knowles[1] & Simon E.V. Phillips[1]. [1]School of Biochemistry and Molecular Biology, University of Leeds, Leeds LS2 9JT, U.K. [2]Department of Biochemistry, Uppsala University, S-751 23 Uppsala, Sweden.

A series of structures has been obtained from the flash freezing of crystals of *E. coli* amine oxidase (ECAO) exposed to substrate, using the technique of X-ray crystallography. This, in essence, has provided a "movie" of catalysis composed of "snapshots" from the catalytic cycle of this ubiquitous enzyme. ECAO belongs to a family of copper-containing enzymes, which contain the organic cofactor 2,4,5-trihydroxyphenylalanine quinone (TPQ). Copper amine oxidases catalyse the oxidation of primary amine substrates to their corresponding aldehydes, with the subsequent release of ammonia and hydrogen peroxide.

Recently we have used a single crystal micro-spectrophotometer to examine the timecourse of the reaction in the crystal, as a function of rich spectral changes that occur upon the addition of substrate. We have flash frozen crystals at different time points during the reaction to maximise the amounts of spectrally distinct intermediates. These have been supplemented by anaerobic substrate-reduced flash frozen crystals, some of which are in complex with oxygen mimics. The structures (1.9-2.3Å resolution) reveal dramatic movements of the quinone cofactor. They also show the first known crystallographic observation of dioxygen bound to a mononuclear copper enzyme. The product aldehyde is seen to play a hitherto unexpected role in the reaction. Suggested roles for conserved residues within the active site are evident, as well as proton transfer pathways.

This work was supported by an EMBO short term fellowship awarded to C.M.W, and the BBSRC. These data were collected at the ESRF and Daresbury SRS.

M06.OB.003 STRUCTURE OF METHYL-COENZYME M REDUCTASE: IMPLICATIONS FOR THE CATALYTIC MECHANISM. U. Ermler and W. Grabarse, Max-Planck-Institut für Biophysik, Heinrich-Hoffmann-Straße 7, 60528 Frankfurt, Germany and S. Shima, M. Goubeaud and R.K. Thauer, Max-Planck-Institut für terrestrische Mikrobiologie and Laboratorium für Mikrobiologie der Philipps-Universität, Karl-von-Frisch-Straße, 35043 Marburg, Germany.

Methyl-coenzyme M reductase - the key enzyme of biological methane formation - catalyzes the reduction of methyl-coenzyme M to methane by oxidizing coenzyme M and coenzyme B to the corresponding heterodisulfide under participation of coenyzme F_{430}, an unusual Ni-porphinoid (1). This highly complicated biochemical reaction is embedded into a large protein complex of nearly 300 kDa arranged as a heterohexamer $(\alpha,\beta,\gamma)_2$ (2). The active site is buried in a hydrophobic segment of a 30 Å long narrow channel which is locked after substrate binding. Five post-translationally modified amino acids were observed at or close to the active site region. Crystal structures of methyl-coenzyme M reductase were determined from several catalytically inactive enyzme states that allow conclusions for different intermediates of the reaction cycle. Based on these studies and also based on spectroscopic and chemical data an enzymatic mechanism was proposed that involves radical intermediates and a Ni-methyl compound.

M06.OB.004 MULTISTEP CATALYSIS IN THE ZINC METALLOPROTEIN 3-DEHYDROQUINATE SYNTHASE. K.A. Brown and E.P. Carpenter, Dept. Of Biochemistry, Imperial College, London SW7 2AY,UK, and J.W. Frost, Dept. of Chemistry, Michigan State University, East Lansing, Michigan 48824-1322, USA, and A.R. Hawkins, Dept. of Biochemistry and Genetics, University of Newcastle upon Tyne, NE2 4HH, UK.

3-Dehydroquinate synthase (DHQS) is an NAD^+-dependent metalloenzyme which converts 3-deoxy-D-*arabino*-heptulosinate 7-phosphate (DAHP) to 3-dehydroquinate. It is a member of the shikimate pathway which is required for the synthesis of aromatic amino acids and other ring-containing compounds. The pathway is present in plants, bacteria, microbial eukaryotes and, most recently discovered, apicomplexan parasites including *Plasmodium falciparum* - the cause of malaria (1). Mutation of the *aroB* gene encoding DHQS results in attenuation of pathogen virulence (2). The absence of this pathway in mammals and its requirement for virulence has thus identified DHQS as a potential target for the development of new drugs with anti-microbial/anti-parasitic activity.

A long-standing interest in the catalytic function of DHQS exists because of its unusual ability to perform a number of chemical reactions in its active site, namely: alcohol oxidation, phosphate β-elimination, carbonyl reduction, ring opening, and an intramolecular aldol condensation. An important step towards understanding the complex mechanism of this enzyme is our recent determination of the crystal structure of DHQS from *Aspergillus nidulans* (3). This structure reveals an active site which possesses wide variety of interactions between metal, dinucleotide, substrate analogue and protein suggesting that this mechanism involves a complex interplay between all of these elements.

M06.OB.005 ABSTRACT NOT AVAILABLE. P. Babbit

P06.OB.001 ORBITAL STEERING & ENTROPY: A BIMOLECULAR PHOSPHORYL TRANSFER TRANSITION STATE AT 1.3Å RESOLUTION. Michael S. Chapman, Genfa Zhou, James L. Gattis, Pamela S. Pruett, Thayumanasamy. Somasundaram, W. Ross Ellington. Institute of Molecular Biophysics, Florida State University, Tallahassee, FL32306.

The structure of Arginine Kinase, a homologue of the ATP-buffering creatine kinase, has been determined as a complex with MgADP, nitrate, and arginine at 1.86Å resolution (Zhou *et al* 1998). The current refinement at approximately 1.25Å resolution will be presented with kinetic analysis of active site mutants. In

this transition state analogue complex, the γ-phosphoryl of ATP (which is transferred through a planar transition state) is replaced by a nitrate ion. In the stable complex the substrates ***are not*** constrained covalently. To our knowledge this is the first high resolution structure of an active bimolecular enzyme as a transition state analogue complex.

Structural and kinetic analysis of this system offers a unique opportunity to compare the fundamentals of mechanism in bimolecular reactions to the unimolecular reactions (hydrolases, isomerases, etc.) predominately studied in the past. As in unimolecular systems there is evidence of acid-base catalysis, strain, and charge bias enhancing activity. The structure also shows very precise alignment of substrates with angles of approach within a few degrees of ideal for in-line transfer of the ATP γ-phosphoryl. These observations are consistent with the proposals of Jencks & Koshland (*ca* 1970) that entropy reduction and/or the steering of orbitals along trajectories for nucleophilic attack may be the predominant means of catalysis in multimolecular reactions.

Zhou, G., Somasundaram, T., Blanc, E., Parthasarathy, G., Ellington, W.R., Chapman, M.S.. "Transition state structure of arginine kinase: Implications for catalysis of bimolecular reactions." PNAS. **95**: 8449-8454. 1998.

P06.OB.002 RNASES: DOMAIN SWAPPING AND A TIME-RESOLVED STUDY OF CATALYSIS. Ingrid Zegers, Joeri Deswarte, Remi Loris, Jan Steyaert, Lode Wyns, Department of Ultrastructure, Vrije Universiteit Brussel – VIB.

The structure of a trimeric domain swapped form of barnase was determined by X-ray crystallography at a resolution of 2.2 Å from crystals of space group R32. Residues 1-36 of one molecule associate with residues 41-110 from another molecule related through three-fold symmetry. The resulting cyclic trimer contains three protein folds that are very similar to monomeric barnase. Both swapped domains contain a nucleation site for folding, and domain swapping is consistent with the description of the folding process of monomeric barnase as the formation and subsequent association of two foldons. The formation of swapped multimers can explain the observation that barnase forms oligomers in acidic denaturing conditions. As the catalytic site of the swapped barnase is constituted by domains of different molecules, two different inactive mutants may regain activity through heterologous domain swapping. This is a new approach to the functional complementation of enzyme activity, and may be of use in a variety of domains. Domain swapping, the misassembly of proteins and alternate folded conformations have recently received much interest, as they are thought to be linked to diseases like Alzheimer's and prion-transmissible encephalopathies. The swapped form of barnase could serve as a model system for the study of these phenomena. Fortunately, the monomeric form of the protein, including its folding process, is extremely well characterized. The use of a substrate that is hydrolysed over a period of days has made it possible to analyse the reaction catalysed by RNase T1 by X-ray crystallography.RNase T1 was co-crystallised with exo guanosine 2',3' cyclic phosphorothioate (exo cGPS), and structures of the complex were determined at times ranging from 1 day to three months. The structures show the hydrolysis of exo cGPS to 3'-GMP over a period of a week, and a subsequent conformational change in the 3'-GMP product. It is shown that RNases catalyse the forward and reverse reactions of the equilibrium between a phsophodiester (or 3'-GMP) and a cyclic nucleotide via an inverse mechanism. In addition, the structures provide an explanation for the differential behavior of RNase T1 towards exo- and endo-cyclic thiophosphates.

P06.OB.003 STRUCTURE OF ASPARTATE β-SEMIALDEHYDE DEHYDROGENASE. A.T. Hadfield, Dept. Biochemistry, Bristol University, University Walk, Bristol BS8 1TD; G. Kryger[+], G.A. Petsko, Brandeis University, Waltham, MA 02254; J. Ouyang, R.E. Viola, University of Akron, Ohio. ([+]Curr. add: Weizmann Institute, Israel)

Aspartate β-semialdehyde dehydrogenase (ASADH) lies at a branch point in the biosynthetic pathway through which bacteria, fungi and the higher plants synthesize diaminopimelate and lysine from aspartate. Blocks in this biosynthetic pathway are lethal, making ASADH an attractive target for anti-bacterial, fungicidal, or herbicidal agents. The enzyme, which is active in *E. coli* as a dimer, catalyses the NADPH-mediated reductive phosphorylation of β-aspartyl phosphate, with a mechanism similar to glyceraldehyde-3-phosphate dehydrogenase. The structure of the apo-enzyme from *E. coli* has been solved using a combination of single isomorphous replacement and non-crystallographic symmetry, and used to solve, by molecular replacement, the structure of a ternary complex with NADP, phosphate and the substrate-mimicking inhibitor S-methyl cysteine sulfoxide.

Each monomer has two distinct domains. The N-terminal domain forms an approximate Rossmann fold, binding NADP. An α-helix, cradled by a six stranded β-sheet, is central to the second domain. This β-sheet forms the dimerisation interface. A two-helix bundle forms a third subdomain, which has the appearance of an arm lying across the top of the opposite monomer. Comparison of the apo and holo crystal structures indicates there is a closure of the two domains upon binding of the co-factor NADP. The active site contains residues from both domains, including a loop and an α-helix which are only ordered in the holo structure. The inhibitor forms a covalent bond with the active site cysteine, Cys 135, analagous to a long-lived covalent intermediate that has been characterised. The structures give insight into the mechanism of action of this enzyme both in terms of global structural changes and the contribution of individual amino acids to substrate binding and catalysis at the active site.

P06.OB.005 CRYSTALLOGRAPHIC STUDIES OF PLANT GLUTATHIONE TRANSFERASES. R. Thom and A. Lapthorn, Protein Crystallography, Dept. Chemistry, Glasgow University, University Avenue, Glasgow, G12 8QQ, UK

Gluthathione Transferases (GSTs) are ubiquitous enzymes which catalyse the nucleophilic addition of glutathione (GSH) to a chemically diverse series of substrates containing an electrophilic centre. In plants, in addition to conferring tolerance to commercially important herbicides, GSTs also bind auxin, act in the anthocyanin pigmentation pathway and provide cellular protection from oxidative stress.

In maize GSTs are the most abundant non photosynthetic enzyme in the plant cell comprising as much as 1% of the soluble leaf protein, existing as isoenzymes with distinct substrate specificities. A number of plant GST X-ray structures have now been elucidated allowing a more detailed understanding of the relationship between the enzyme structure and catalytic activity [1].

We report here the elucidation of the apo enzyme GST I from maize, in comparison with the ligand-bound structure indicating the mechanism for theta class GST isoenzymes.

Together with other GST structures this explains herbicide resistance and selectivity in maize as well as other crop plants.

P06.OB.006 STRUCTURAL EVIDENCE FOR A HYDRIDE TRANSFERRING MECHANISM IN QUINOPROTEIN GLUCOSE DEHYDROGENASE. A. Oubrie, H.J. Rozeboom, K.H. Kalk, B.W. Dijkstra Department of Biophysical Chemistry, University of Groningen, Groningen, The Netherlands

The soluble quinoprotein glucose dehydrogenase (s-GDH) from Acinetobacter calcoaceticus requires the cofactor pyrroloquinoline quinone (PQQ) to oxidise a wide range of mono- and disaccharides to their corresponding lactones [1]. Despite considerable effort [2,3], the reaction mechanism of s-GDH and other PQQ-dependent enzymes has not been resolved. We have elucidated the three-dimensional structure of the holo-enzyme, which folds into a beta-propeller structure consisting of six four-stranded beta-sheets. PQQ binds near the top of the barrel. A ternary complex of the enzyme with the inhibitor methylhydrazine (MH) revealed the presence of one covalent PQQ-MH complex, identifying the reactive part of the orthoquinone group. Moreover, a glucose binding study affords the first view of a quinoprotein-substrate complex. The interactions between glucose and s-GDH explain the enzyme's broad substrate specificity. On the basis of the position of glucose with respect to PQQ and the putative catalytic base His144 we have been able to formulate a reaction mechanism involving proton abstraction by His144 in concert with hydride transfer from glucose to the cofactor and subsequent tautomerisation to PQQH2.

P06.OB.007 ACYL-TRANSFER BY N-MYRISTOYLTRANSFERASE INVOLVES C-TERMINAL CARBOXYLATE AS A GENERAL BASE CATALYST. K. Fütterer[1], R.S. Bhatnagar[2], T.A. Farazi[2], J.I. Gordon[2], G. Waksman[1], Departments of [1]Biochemistry and Molecular Biophysics, and [2]Molecular Biology and Pharmacology, Washington University School of Medicine, Box 8231, St. Louis MO 63110, USA.

MyristoylCoA:protein N-myristoyltransferase (Nmt) attaches the 14-carbon fatty acid myristate to the N-terminal glycine of many eukaryotic and viral proteins. Pathogenic fungi, including *Candida albicans* and *Cryptococcus neoformans*, require Nmt for growth and replication making Nmt an important anti-fungal drug target. Nmt is specific for the rare lipid myristate as mandated for the proper function of its substrate proteins.

We have solved the x-ray crystal structure of *Saccharomyces cerevisiae* Nmt1p, to 2.9 Å resolution, bound to two ligands representing the lipid donor and acceptor substrates. The Nmt-fold possesses an internal pseudo-two-fold symmetry in which each half of the molecule is structurally homologous to the GCN5-related N-acetyltransferase superfamily, despite a lack of detectable sequence homology. The N-terminus of the peptide substrate analog is juxtaposed to the backbone carboxylate of the protein and in proximity to the "reactive" carbonyl of the myristoylCoA analog. This carbonyl faces two main chain amide nitrogens, which form an apparent oxyanion hole.We have developed a model for the catalytic mechanism based on the ternary complex structure: (I) the backbone carboxylate, acting as a general base, deprotonates the N-terminal ammonium of the substrate peptide; (II) direct nucleophilic attack by the peptide on myristoylCoA with acyl transfer proceeding through a single tetrehedral intermediate; (III) stabilization of the tetrahedral intermediate by the oxyanion hole.

The involvement of the enzyme's backbone carboxylate as a general base catalyst is unique. In order to test the proposed mechanism of catalysis we have started structure refinements of complexes involving natural substrates. We have shown through mutagenesis of nucleophilic side chains in the active site that acyl transfer does not involve an acyl-enzyme intermediate. Further mutagenesis studies involving the backbone carboxylate and residues forming the oxyanion hole have been initiated.

P06.OB.008 STRUCTURE AND ACTION OF 3-DEOXY-D-*ARABINO*-HEPTULOSONATE-7-PHOSPHATE SYNTHASE. R. H. Kretsinger, R. H. Bauerle and I. A. Shumilin, Department of Biology, University of Virginia, Charlottesville, VA 22903, USA.

In microorganisms and plants, the first step in the biosynthesis of aromatic compounds is the condensation of phospho*enol*pyruvate (PEP) and D-erythrose-4-phosphate (E4P) giving 3-deoxy-D-*arabino*-heptulosonate-7-phosphate (DAHP). This reaction is catalyzed by DAHP synthase (DAHPS). In *E. coli* there are three DAHPS isoforms, each specifically inhibited by Phe or Trp or Tyr.

The crystal structure of the Phe inhibited form of DAHPS complexed with PEP and Pb^{2+} was determined by MAD phasing. Data (C2 a = 210.7 b=51.1, c=147.7 Å, β=116.2°; tetramer per asymmetric unit) were measured at BNL, beamline X4A, to 2.6Å. The final R is 20.9%; Rfree is 26.7%.

The tetramer consists of two tight dimers whose monomers are joined by a pair of shared, three stranded β-sheets. The monomer, 350 residues, is a $(\beta/\alpha)_8$ barrel with several additional β-strands and α-helices. The PEP and Pb^{2+} are at the C-end of the β-strands of the barrel, as is a SO_4^{2-} inferred to occupy the position of the phosphate of E4P. The coordination of the Pb^{2+}, at the essential divalent cation site, is hemidirectional and involves, on one part, side chains of Cys61, His268, Glu302, and Asp326 as well as a water bridging to Lys97. The plane of PEP is 3.7 Å from the Pb^{2+} ion on the other side from the protein ligands. PEP is further coordinated by side chains of Arg's 92 165 & 234, Lys's 97 & 186, and His268. Numerous mutations that affect catalytic activity are distributed around the C-end of the β-barrel. Other mutations that reduce feedback inhibition cluster about a cavity near the two fold axis of the tight dimer and ~20 Å from the active site. The cooperativity of inhibitor binding is consistent with the proximity of the inhibitor binding sites to this dimer axis. The few residues responsible for tetramerization of two tight dimers in DAHPS(Phe) are highlighted by their differences in dimeric DAHPS(Trp) and DAHPS(Tyr).

P06.OB.009 STRUCTURE AND MECHANISM OF A CARBON-CARBON BOND HYDROLASE. D.E. Timm, H.A. Mueller, P. Bhanumoorthy [1], J.M. Harp, G.J. Bunick [2], [1] Indiana University School of Medicine, Indianapolis, Indiana, 46202, USA, [2] Life Sciences Division, Oak Ridge National Laboratory, Oak Ridge, Tennessee, 37831, USA

Fumarylacetoacetate hydrolase catalyzes the final step of tyrosine and phenylalanine catabolism, and its deficiency causes the fatal metabolic disease hereditary tyrosinemia type I. This enzyme catalyzes a novel biochemical reaction involving the hydrolytic cleavage of a carbon-carbon bond in fumarylacetoacetate to form fumarate and acetoacetate. Fumarylacetoacetate hydrolase (FAH) has no known sequence homologs and functions by an unknown enzymatic mechanism. The crystal structure of this enzyme determined by automated analysis of multiwavelength anomalous diffraction data represents the first structure of a hydrolase that acts specifically on carbon-carbon bonds.

This structure also defines a new class of metalloenzymes characterized by a unique alpha/beta fold. The structure of FAH complexed with its physiologic products suggests a variation of

the Asp-His-Ser catalytic triad mechanism, involving a His base hydrogen bonded to a Glu carboxyl group. The nucleophilic Ser side chain is replaced in FAH by a water molecule bound to a carboxylate ligand of a Ca2+. The octahedrally coordinated Ca2+ participates in catalysis by binding substrate, activating the water molecule and stabilizing a carbanion intermediate. Thus, the fumarylacetoacetate hydrolase structure represents a new class of metalloenzymes, suggests a unique variation of a common biochemical mechanism and reveals the molecular basis for mutations causing the hereditary tyrosinemia type I.

P06.OB.010 UNUSUAL FOLDED CONFORMATIONS OF NAD+. CRYSTAL STRUCTURES AND MOLECULAR DYNAMICS SIMULATIONS. J.J. Tanner [1], P.E. Smith [2], S.-C. Tu and K.L. Krause [3], [1] Department of Chemistry, University of Misouri-Columbia, Columbia MO 65211, USA, [2] Department of Biochemistry, Kansas State University, Manhattan, KS 66506, USA, [3] Department Department of Biology and Biochemistry, University of Houston, Houston, TX 77204, USA

Nicotinamide adenine dinucleotide (NAD+) is a ubiquitous biological small molecule and it is a major electron acceptor in the oxidation of fuel molecules. NAD+ adopts extended conformations when bound to enzymes, however, its solution structure is thought to be much more compact or folded. We report the 2.1 Å crystal structure of the enzyme flavin reductase P with NAD+ bound in the active site. NAD+ adopts an unusual, folded conformation in which the adenine and nicotinamide rings stack in parallel, with an inter-ring distance of 3.6 Å. The folded NAD+ binds with its pyrophosphate next to the cofactor FMN isoalloxazine and its nicotinamide C4 atom 10 Å from the putative site of hydride transfer on the isoalloxazine. Our structure offers the first crystallographic evidence of a folded NAD+, and it suggests that the folded state of NAD+ might be important for release of product from the enzyme. We analyzed the structure and dynamics of this folded NAD+ model using explicit solvent molecular dynamics simulations on the nanosecond time scale. These calculations reveal folding and unfolding transitions, and demonstrate that folded conformations are stable in solution.

P06.OB.011 LIPOXYGENASE REVISITED. Diana R. Tomchick[1], Krzysztof Lewinski[1], Anatoly Kiyatkin[1], Ted Holman[2], Janusz Steczko[3], Bernard Axelrod[3], Wladek Minor[1], [1]Department of Molecular Physiology and Biological Physics, University of Virginia, Charlottesville, VA 22906, USA, [2]Department of Chemistry and Biochemistry, University of California-Santa Cruz, USA, [3]Department of Biochemistry, Purdue University, USA.

Lipoxygenases are non-heme, non-sulfur iron dioxygenases that catalyze the hydroperoxidation of polyunsaturated fatty acids that contain one or more (Z,Z)-1,4-pentadiene moieties. The commonly accepted enzymatic mechanism involves hydrogen atom abstraction to form a pentadienyl radical, which reacts with oxygen. A large kinetic isotope effect, which implies hydrogen atom tunnelling, has been observed for both plant and human enzymes. Arachidonic acid is the predominant mammalian substrate, which yields products that are precursors of highly potent physiological effectors involved in such processes as carcinogenesis, asthma, vasoconstriction, inflammation and formation of atherosclerotic plaques. Development of lipoxygenase inhibitors as therapeutic agents is an extremely active research field, which would be aided by a better understanding of the structural basis of the reaction mechanism.

The paradigm for lipoxygenase kinetic, spectroscopic and other biophysical studies is the soybean L-1 isozyme, which crystallizes in a very high-resolution form (1.4 Å). A recent structure of an inhibited mammalian 15-lipoxygenase at medium resolution (2.4 Å) reveals a similar overall fold to the soybean enzyme, despite a much smaller size (ca. 670 vs. 840 residues). Certain aspects of the active site are not conserved between the two enzymes, including iron ligands and residues in the specificity pocket. We have analyzed the structures of numerous active site mutants of the soybean L-1 enzyme, and shall relate our structural, kinetic and spectroscopic results to the current mechanistic and structural models for wild type lipoxygenase specificity. Progress on complex structures of the soybean enzyme with several inhibitors and on the human 15-lipoxygenase will also be presented.

06OC CHEMICAL INSIGHTS FROM CHARGE DENSITY STUDIES (Sponsored by Dept. Chemistry, University of Glasgow)

M06.OC.001 UNUSUAL BONDS AND MOLECULAR PROPERTIES: FACTUAL OR FICTITIOUS? R. Destro, Department of Physical Chemistry and Centro CNR, University of Milan, I-20133 Milano, Italy.

Experimental electron densities in molecular crystals, as obtained from low-temperature X-ray diffraction data interpreted with an aspherical-atom formalism [1], almost routinely undergo topological analysis according to Bader's quantum theory of atoms in molecules (QTAM) [2]. It has been pointed out [3] that "such studies ... constitute probably the most active area of current research on experimental electron densities". The usual outcome is a corroboration of well-established chemical notions, with a full, quantitative characterization of all interatomic interactions.

However, in some instances expected critical points are not found, or unanticipated features of the charge density are revealed by the topological analysis [4]. Similarly, unusual values are sometimes obtained for molecular properties (*e.g.* dipole moments) derived from a multipole refinement of X-ray data. It appears that it is not always easy to distinguish between genuine features, hence new chemical insights, and artifacts due to limitations of the model adopted.

Examples of both kinds will be presented and discussed.

M06.OC.002 NEW INSIGHTS INTO THE EVALUATION OF ELECTROSTATIC MOLECULAR PROPERTIES FROM X-RAY DIFFRACTION DATA. Yuriy A. Abramov, Department of Chemistry, SUNY at Buffalo, Buffalo, NY 14260-3000 USA; chem9989@acsu.buffalo.edu

Different aspects of the evaluation of the electrostatic molecular properties, such as electrostatic moments and electrostatic interaction energy, will be considered starting from the X-ray refinement strategy. A multipole refinement of X-ray diffraction data is known as the most straightforward way of deriving these properties [1,2]. However, due to the lack of intrinsic physical (quantum mechanical) constraints in the unrestricted multipole refinement of observed structure factors, the static molecular multipole charge density is not guaranteed to be physically meaningful. This effect can introduce a pronounced *experimental basis set superposition error* in the evaluation of the electrostatic molecular properties. This error can be greatly reduced by a restricted multipole charge density model [3] in which atomic charges are constrained at κ–refinement values [1].

An application of the restricted multipole model to the evaluation of molecular dipole moments and intermolecular interaction energies in a number of α-amino acids and in 4-amino-4'-nitrobiphenyl will be presented. Experimental results will be compared with results of CHARMM force-field and quantum-mechanical calculations.

M06.OC.003 INSIGHT INTO INTRA- AND INTERMOLECULAR INTERACTIONS FROM TOPOLOGICAL ANALYSIS OF CRYSTAL CHARGE DENSITIES. Sine Larsen, Claus Flensburg, Hanne S. Bengaard and Henning O. Sørensen, Centre for Crystallographic Studies, Universitetsparken 5, 2100 Copenhagen, Denmark.

The topological analysis introduced by R.F. Bader for the analysis of theoretical charge densities [1] has also proven applicable for the analysis of experimental charge densities. Methods have also been developed for computation of the zero flux surfaces defining the atomic basins in the experimental charge densities [2], which enables calculation of the properties for atoms in crystals. These computational methods have been used to analyse the crystal charge densities for compounds that show unique intra- and intermolecular interactions.

It is not usual to find carbon as a ligand to Co(III), as we do in the classical Werner coordination compound $[Co(NH_3)_5 CH_3]\ S_2O_6$ [3]. Judged from the molecular geometry the four equatorial NH_3 ligands are distinctly different from the one that is trans to the coordinating CH_3^- anion. From the analysis of the experimental charge density it was possible to make a classification of the Co- ligand interactions and of the intermolecular interactions between the ions. Properties for the different fragments in the structure provided additional chemical insight.

Hydrogen bonds seem to be the most significant intermolecular interaction in molecular crystals and little attention is given to other weaker interactions in the crystal. The topological analysis is very useful to characterise the different hydrogen bonds. A detailed analysis of the theoretical and experimental crystal charge density of optically active para-fluoromandelic acid revealed bond critical points that correspond to much weaker interactions, that was not apparent from the geometrical analysis.

M06.OC.004 TOPOLOGICAL PROPERTIES OF VARIOUS AMINO ACIDS: A COMPARATIVE STUDY. P. Luger and R. Flaig, Institut für Kristallographie, Freie Universität Berlin, Takustr. 6,14195 Berlin, Germany, and T. Koritsanszky, Department of Chemistry, University of the Witwatersrand. Private Bag 3, WITS 2050, Johannesburg, South Africa.

It could be shown recently [1] that the combination of synchrotron radiation at a short wavelength of $\lambda \approx 0.5$ Å with a CCD area detector allows the collection of high resolution diffraction data, in a few days or even hours, which are well suited to obtain accurate charge densities. This short acquisition time makes the method applicable to larger molecules or to perform comparative studies of a class of chemically related compounds. Taking advantage of these experimental developments we have investigated the charge densities of seven amino acids. Thus, including those studied previously, data of about half of the 20 naturally occuring amino acids are available for comparison.

We report on a number of chemically important properties of these molecules, such as the electrostatic potentials, electric moments and topological figures of the densities derived in terms of the aspherical-atom formalism using the same refinement model and strategy. The agreement is found exceptionally good for the density values at critical points $[(r)\backslash vec]_b$ of chemically equivalent bonds and it is satisfactory for other topological parameters characterizing atomic interactions ($\nabla^2\ \rho([(r)\backslash vec]_b)$, bond ellipticity). Such a comparison can be considered as the first step towards experimental verification of Bader's concept on topological segmentation of molecules [2]. Further inportant aspect of these studies is the mapping and characterization of weak intermolecular interactions, that are of interest for biological recognition processes. Here the experimental Laplacian and the electrostatic potential play a significant role.

M06.OC.005 CHARGE DENSITY AND ELECTROSTATIC PROPERTIES OF NATURAL AND INDUSTRIAL ALUMINO-SILICATES: SUCCESS AND PROBLEMS. M. Souhassou, N.E. Ghermani, F. Porcher, S. Kuntzinger, Y. Dusausoy and C. Lecomte, LCM^{3}B, UPRESA CNRS 7036, Université Henri Poincaré, Nancy I, Faculté des Sciences, BP 239, 54506 Vandoeuvre-lès-Nancy Cedex.

Charge density analysis of natural and industrial zeolites as well as other alumino silicate minerals[1-7] will be described. Special care will be given to the determination of the net charges, moments and electrostatic potential, quantities very important for understanding the industrial potentiality of these materials.

Electrostatic features of coesite[2], natrolite[3], scolecite[4], spodumene[5], zeolite A[6] and X[7] will be compared and discussed. It will be shown that even if charge density is precisely obtained from accurate conventional or synchrotron data, calculation of some properties like net charges is still a matter of discussion.

P06.OC.001 CHEMICAL BONDING AND SUPERPOSITION EFFECTS ON THE ELECTRON DENSITY. Ivar Olovsson, Inorganic Chemistry, Ångström Laboratory, Box 538, S-751 21 Uppsala, Sweden, Halina Ptasiewicz-Bak, Institute of Nuclear Chemistry and Technology, Dorodna 16, 03-195 Warszawa, Poland and Garry J. McIntyre, Institut Laue-Langevin, 156X, F-380 42 Grenoble, France.

There appears to be conflicting experimental evidence on the redistribution of the charge density in the lone-pair and other regions of a molecule due to the interaction with its nearest neighbours. In some experimental as well as theoretical deformation density maps a decrease in the lone-pair density has

been reported, whereas in other cases an increase has been found. It appears that two major counteracting factors are responsible for these differences: an increase in the lone-pair density is expected due to the polarising influence of the neighbours, whereas simple superposition of the isolated monomer densities will lead to an apparent decrease due to the overlap with the negative contours of the neighbouring atom. Depending on which of these factors is the dominant one, an increase or decrease may thus be found.

In Uppsala a series of hydrates of transition metal hydrates have been systematically studied: $Na_2Ni(CN)_4 \cdot 3H_2O$, $Ni(NO_3)_2 \cdot 6H_2O$, $NiSO_4 \cdot 6H_2O$, $NiSO_4 \cdot 7H_2O$, $NiCl_2 \cdot 4H_2O$, $CoSO_4 \cdot 6H_2O$ and $CrCl_3 \cdot 6H_2O$. The object was in the first place to determine the electron density around the transition metal ion, but was also of special interest to study whether it would be possible to obtain good densities of the water molecules in the presence of such a heavy scatterer as a 3d metal ion.

The charge density has been determined at RT and 25-30K by multipole refinement against single crystal X-ray intensity data. The charge density based on the fitted deformation functions of all atoms in the structure is compared with the individual densities calculated from deformation functions of only the metal ion or the separate water molecules. In this way the effect of simple superposition of the individual densities has been studied. Polarisation of the lone-pair densities, reflecting the different co-ordination of the water molecules, is clearly evident.

P06.OC.002 TOPOLOGICAL ANALYSIS OF THE CHARGE DENSITY IN SHORT HYDROGEN BONDS. Jacob Overgaard, Georg K. H. Madsen, Bo B. Iversen, Finn K. Larsen, Department of Chemistry, University of Aarhus, Dk-8000 Århus C, Denmark, Garry I. McIntyre, Institut Laue-Langevin, BP 156, 38042 Grenoble CEDEX 9, France and Arthur J. Schultz, Intense Pulsed Neutron Source, Argonne National Laboratory, Argonne, IL 60439, USA.

Some short O-H--O and N-H--O hydrogen bonds (HB) have been characterized by combined analysis of X-ray and neutron diffraction data. The intramolecular keto-enol HB in benzoylacetone[1] with an O--O distance of 2.502(4)Å proved to be an asymmetric (1.25(1),1.33(1)Å) Low Barrier HB. The zero point vibrational energy of the proton exceeds the barrier of transfer allowing the proton to move between the oxygen atoms with a mean square displacement (m.s.d.) of 0.106 $Å^2$ at 20 K. Nitromalonamide is another compound with an intramolecular keto-enol HB. It has a shorter O--O distance (2.391(3) Å) yet a more asymmetric (1.14(1), 1.31(1) Å) single well HB. The proton has a m.s.d. of 0.031 $Å^2$ at 20 K as determined by neutron diffraction at the ILL high flux reactor. The topology of the charge density (CD) in these short O-H--O HB's are compared.

Short N-H--O HB's in the complex of betaine, imidazole and picric acid was studied similarly, based on diffraction data collected at 28 K, - synchrotron X-ray data by imaging plate detection at beamline X3A1, NSLS Brookhaven, and neutron diffraction data by white beam time-of-flight technique at IPNS, Argonne. The complex serves as a model for the active site of serine protease, the catalytic triad, and the system is attractive since it contains three different short N-H--O contacts (<2.7 Å) in the same crystal. Analysis of the CD shows that all three short HB's have hydrogen localized at the nitrogens and that none are LBHB. The H--O interactions are all predominantly electrostatic interactions ($\nabla^2\rho>0$ at the bond critical points) between closed shell atoms. Results of ab initio calculations for the systems are compared with the experimental results.

P06.OC.003 POLYHEDRAL REPRESENTATION OF ATOMS IN CRYSTAL STRUCTURES. T. Balic-Zunic, Geological Institute, University of Copenhagen, DK-1350 Copenhagen K, Denmark

The atomic domains in molecules or crystals are bounded by surfaces of zero flux in the gradient vector field of the charge density [1]. In electron density maps they can be recognized as surfaces of low electron density which separate neighbouring atoms, and define their domains. The atomic domains in crystal structures closely resemble polyhedra with faces perpendicular to interatomic vectors. Therefore, the most appropriate representation of an atom in a crystal is the atomic domain polyhedron. In topological analyses, e.g. in defining atomic coordinations or structural relations, the use of element-specific atomic models in the form of polyhedra with defined shape-size variations is superior to the traditional model of spheres with defined radii. In most inorganic crystal structures a satisfactory partition in atomic domains can be achieved also without accurately determined charge densities. The procedure is similar to the determination of Voronoi-polyhedra, supplemented by expected domain sizes. In the course of crystal structure partitioning the planes are put perpendicular to interatomic vectors at positions of the expected minima of electron density calculated from predetermined parameters. The closest polyhedron closed this way around an atom represents its domain. To determine the parameters for the calculation of plane positions an IAM-based procedure can give satisfactory results. For each element pair sums of the spherically averaged electron densities of overlapping atoms are calculated and the positions of minima determined over a range of interatomic distances. Over the range of bonding distances the position of minimum usually varies linearly with the interatomic distance, and can be defined by two parameters. The partition parameters, domain determinations, and some applications will be presented.

06OD CHALLENGING RIETVELD REFINEMENTS

M06.OD.001 QUANTITATIVE PHASE ANALYSIS OF PORTLAND CEMENT BY RIETVELD REFINEMENT. I.C. Madsen and N.V.Y. Scarlett, CSIRO Minerals, Box 312, Clayton South, Victoria 3169, Australia

The quantitative analysis of Portland cement by Rietveld refinement may well strike fear into the heart of even the hardiest crystallographer. This is due to the presence of a myriad of crystallographically ill-defined phases whose reflections exhibit a high degree of overlap in the powder pattern.

Non-XRD methods of quantitative phase analysis of Portland cement such as optical microscopy and the Bogue method have severe limitations. Optical microscopy presents a significant sampling challenge and the Bogue method, based upon the breakdown of XRF analyses into component phases, is dependent upon dubious assumptions. Single peak XRD methods are also fraught with danger due to the difficulty in finding free-standing peaks of sufficient strength to provide a reliable estimate of intensity.

Traditional Rietveld refinement requires detailed knowledge of the crystal structures of each of the component phases in the material. This is not possible in the case of Portland cement where the component phases do not always match the published structures due to (i) different levels of impurity substitution and (ii) variable degrees of hydration in the sulphate phases. Rietveld refinement of synthetic cement mixtures has shown the technique able to cope with the overlap problem when the crystal structures are known.

This paper describes the use of a modified Rietveld approach where the intensities of the diffraction peaks can be estimated by observation of patterns of the materials of interest. The main advantage of this approach lies in the ability to manually alter the individual peak intensities in the reflection intensity files to better match the observed peak heights in the pattern. The only requirement is that each of the I_{obs} be indexed and the unit cell dimensions known, thus allowing adjustment of the peak positions through refinement of the unit cell parameters (if necessary).

M06.OD.002 RIETVELD REFINEMENTS OF INCOMMENSURATE MODULATIONS IN COMPLEX OXIDES. D. Grebille and O. Pérez, CRISMAT, ISMRA, 14050 Caen Cedex, France, and G. Baldinozzi, Lab. CPS, Ecole Centrale de Paris, 92295 Châtenay-Malabry Cedex, France, and J.F. Bérar, Lab. de cristallographie, CNRS BP 166, 38042 Grenoble Cedex, France.

Incommensurate modulations are frequently encountered in the refinement of crystal structures. Their symmetry and structure can be properly described using the superspace formalism, which is now commonly implemented in refinement programs using single crystal diffraction data.

Unfortunately, single crystal data are not always available, or can be biased in the case of polydomain samples. In these cases, powder diffraction is very easy to use and Rietveld refinements have proved their efficiency in solving complex structures. In particular, in the case of incommensurate phases, the metric refinement is generally more accurate using a well resolved powder diffraction pattern, and the continuous measurement of the whole background allows to fix all the weak intensities of higher order satellite reflections for example.

The Rietveld refinement program XND [1] can now take advantage of the superspace symmetry description for the refinement of incommensurately modulated structures. Several examples are given concerning complex oxide structures:

- occupation and displacement modulation in the tunnel structure $Ba_2Ca_2In_6O_{12}$;
- modulated structure of the complex perovskite Pb_2CoWO_6 and comparison with an equivalent refinement using single crystal data;
- modulated structure of the ferrite $Bi_2Sr_3Fe_2O_9$ using neutron powder diffraction data and X ray single crystal data.

M06.OD.003 COMBINED RIETVELD AND STEREOCHEMICAL RESTRAINT REFINEMENT OF PROTEIN CRYSTAL STRUCTURES. R.B. Von Dreele, Lujan Center, Los Alamos National Laboratory, Los Alamos, NM 87545, USA

By combining high resolution x-ray powder diffraction data and stereochemical restraints, Rietveld refinement of protein crystal structures has been shown to be feasible. This talk will outline the procedures used for these refinements and show the quality of the resulting protein structure by comparison with known single crystal results and evaluation of protein stereochemical parameters.

Supported by US DOE/BES.

M06.OD.004 RIETVELD REFINEMENT OF THE ZEOLITE UTD-1, A 117 ATOM PROBLEM. Ch. Baerlocher, T. Wessels, L.B. McCusker, Laboratory of Crystallography, ETH, Zürich, Switzerland.

The zeolite UTD-1 has been shown to have a 1-dimensional channel system with 14-ring pore openings, but its structure, at least in the calcined form, has been reported to be an intergrowth of at least two polymorphs [1]. All of the polymorphs proposed have orthorhombic symmetry.

A new synthesis procedure using the fluoride method yielded a highly crystalline sample of UTD-1, so high-resolution synchrotron powder diffraction data were collected on the as-synthesized form at the SNBL in Grenoble (λ = 0.6480 Å, 1.8 - 37 $^\circ 2\theta$). The pattern could only be indexed on a monoclinic cell (a = 14.963, b = 8.4704, c = 30.010 Å, β = 102.7°) and the most likely space group appeared to be $P2_1/c$. By applying our new texture approach to structure determination from powder data, the crystal structure could be solved directly. The framework topology proved to be that of polymorph C of reference [1], but in the space group $P2_1/c$ it has 16 Si and 32 O atoms in the asymmetric unit. In order to verify that the new material is in fact fully ordered (i.e. a pure end-member), a Rietveld refinement was undertaken.

The location and orientation of the template cation (bis(pentamethyl-cyclopentadienyl)cobalt(III)) could be established easily from the difference Fourier map. However, because of short contacts between symmetry related molecules, its occupancy had to be restricted to 1/2. Furthermore, significant intensity differences for certain reflections were observed. A symmetry reduction to Pc solved both problems, but required a refinement with 117 non-hydrogen atoms (32 Si, 64 O, 1 Co and 20 C atoms) or a total of 349 positional parameters. Using 444 geometric restraints with a common weight factor of 1, the refinement converged with R_F = 0.043 and R_{wp} = 0.132 (R_{exp} = 0.101). This proves (1) that a true end-member for UTD-1 exists, and (2) that it is possible to refine complex structures with ca 350 structural parameters using the Rietveld method, if high quality synchrotron powder data are available.

R.F. Lobo, M. Tsapatsis, C.C. Freyhardt, S. Khodabandeh, P. Wagner, C.Y. Chen, K.J. Balkus, S.I. Zones and M.E. Davis, *J. Am. Chem. Soc.*, **119**, 8474 (1997).

M06.OD.005 SITING OF TITANIUM ATOMS IN THE TITANOSILICALITE CATALYST TS-1. J. Eckert, C. J. Hijar, K. C. Ott, Los Alamos National Laboratory, Los Alamos, NM 87545, USA, and R. Jacubinas, Engelhard Corporation, Iselin, NJ 08830-0770, USA.

The titanosilicalite TS-1 has proven to be one of the most important catalysts discovered in the last decade because it catalyzes the epoxidation of olefins with acqueous hydrogen peroxide under mild conditions. Its activity has been ascribed to Ti atoms inserted into the silicalite framework in place of Si. Despite the widespread use of this catalyst, however, very little is know about the actual siting of the Ti atoms. The principal reason for this is that there relative amount of Ti is very small (no more than one per 30 Si) and that these may be disordered over the 12 inequivalent tetrahedral (T) sites in the MFI structure. A number of theoretical studies did indeed predict random siting for the Ti atoms among the 12 T-sites. We describe the results of a series of neutron powder diffraction studies which clearly demonstrate that Ti siting in TS-1 is not random and discuss the implications thereof for the activity of these catalysts.

This work was supported by the United States Department of Energy under contract number W-7405-ENG-36 with the University of California. The work has benefitted from the use of facilities at the Manuel Lujan Jr. Neutron Scattering Center, a national user facility funded by the United States Department of Energy, Office of Basic Energy Sciences.

M06.OD.006 RIETVELD REFINEMENT OF REHYDRATED $AlPO_4$-34, A TRICLINIC NIGHTMARE. A. Meden, Faculty of Chemistry, University of Ljubljana, Slovenia, L.B. McCusker and Ch. Baerlocher, Laboratory of Crystallography, ETH, Zurich, Switzerland.

In its as-synthesized form, the molecular sieve $AlPO_4$-34, with a chabazite-like framework topology (**CHA**), is triclinic. This distortion from the ideal rhombohedral symmetry is caused by the presence of ordered Al-F-Al bridges. Upon calcination, the F-bridges are removed and the material adopts the higher symmetry. However, rehydration of the calcined material produces another well-crystallized, triclinic phase, which transforms to yet another triclinic phase at 23 ^{o}C. NMR spectra show that both 5- and 6-coordinate Al are present in both of these phases. The high crystallinity, the triclinic deformation, and the NMR results are indicative of an ordered arrangement of water molecules in the low-temperature structure. To elucidate this arrangement, and to clarify the reason for the change of symmetry upon hydration, a Rietveld refinement, using synchrotron powder diffraction data collected at 15 ^{o}C (SNBL at ESRF), was undertaken.

Refinement was initiated with a triclinically distorted chabazite-like framework structure, and the positions of the water molecules were located in a series of Fourier maps. Four models (in $P\bar{1}$ and $P1$, each with interchanged Al and P atoms) were investigated. Anisotropic peak broadening and peak asymmetry had to be fitted in the final refinement.

The low-temperature triclinic phase of hydrated $AlPO_4$-34 proved to be non-centrosymmetric with a total of 48 atoms in the asymmetric unit (including 12 fully occupied water postions). Five water molecules coordinate to Al atoms of the framework, producing two octahedral and one 5-coordinate Al. One water molecule is situated within the double six-ring and the rest are located in the central cage. The octahedral Al atoms are ordered along one of the *pseudo*-rhombohedral axes as in the case of the fluoride-containing triclinic precursor. The TG and NMR (1D and 2D) results are fully consistent with the refined structure.

06OE NEUTRON STUDIES OF STRESS/STRAIN

M06.OE.001 INSIGHTS ON POLYCRYSTALLINE DEFORMATION USING NEUTRON DIFFRACTION. M.A.M. Bourke. LANSCE, Los Alamos National Laboratory, Los Alamos, New Mexico, 87545, USA

By collecting neutron diffraction data during in situ uniaxial compression or tension tests - the origins of bulk deformation behavior can be studied at the microstructural level. Measurements at LANL have provided insights on disparate processes including; codeformation in multiphase systems, creep, twinning, stress induced phase transformations. Also a large effort has addressed the validation of micromechanical models (both self consistent and finite element) that attempt to describe the effects of anisotropic elastic and plastic behavior of specific grain orientations in a polycrystalline aggregate.

This talk will discuss the constraints and current limitations on these types of measurements at a pulsed neutron source. Interpretations from texture and strain evolution will be discussed for three examples; 1) micromechanical model validation in beryllium 2) twinning in a Uranium alloy and 3) stress induced phase transformations in NiTi and NiTi-TiC. Plans for a load frame furnace suite with a 250 KN 1500°C capability that will operate on a new neutron spectrometer, SMARTS, will also be outlined.

M06.OE.002 NEUTRON STRESS ANALYSIS IN ENGINEERING COMPONENTS. A.Pyzalla, Strukturforschung, Hahn-Meitner-Institut, Glienicker Straße 100, D-14109 Berlin, Germany

The significance of residual stresses with respect to the mechanical and technological properties of components, especially their strength and fatigue limit, has been acknowledged for almost one and a half century now. There are a number of applications that require the determination of the residual stress state within the whole component or at least within large parts of the component.

Whereas X-ray residual stress analysis is confined to near surface layers, absolute residual stress values in the bulk of components can be determined non-destructively by neutron diffraction. In case of multiphase materials phase specific residual stress values can be obtained. Thus, neutron residual stress analysis now is an important and in wide parts of the industry accepted tool with respect to the optimisation of multiphase materials and technical single crystals alloys, manufacturing processes and component's design but also for a verification of numerical calculations of the residual stress state.

Examples for engineering materials and components, which were characterised and optimised using neutron residual stress analyses are e.g. metal and ceramic matrix composites as well as single crystal turbine blades, turbine disks, impellers, extruded, shot peened and deep-rolled as well as brazed or welded components.

M06.OE.003 EXPLOITING SYNCHROTRON RADIATION FOR ENGINEERING STRESS MEASUREMENTS. P.J. Withers, *P.J. Webster, **A.M. Korsunsky, Manchester Materials Science Centre, Grosvenor St., Manchester, M1 7HS, *Telford Institute, Civil Engineering, Salford University, **Dept. of Mech., Manufacturing & Materials, University of Newcastle, UK

The arrival of third generation synchrotron sources has provided the engineer with very intense penetrating X-ray beams for residual stress analysis. Energies in the range 25-300keV are available, giving rise to penetrations of many centimetres in aluminium and significant distances even in steel and nickel. In this paper we introduce the basic principles and methods. Current methods are sub-divided into three distinct groups, white beam, monochromatic $\theta/2\theta$ and whole Debye Scheerer ring analysis methods are described. In each case the principal advantages and limitations will be discussed largely with reference to practical examples.

The white beam method provides a large portion of the diffraction profile making it well suited to the study of multiple phase materials and those with complex crystal structures. In addition, it is ideal for kinetic studies for which it is necessary to follow the evolution of a number of peaks. The energy resolution of current detectors tends to limit the maximum strain resolution achievable. The method will be introduced with reference to a recent study on stresses in thermal barrier coatings comprising a top-coat, bond coat and substrate.

Theta/two theta studies can provide excellent strain resolution, fast measurement times and reasonable spatial resolution (~100x100x800μm). This has meant that the technique is ideal for two and three dimensional mapping of residual strain distributions in a range of components. We will include examples of laser shock peening,TIG welding and stir welding. The insensitivity of the approach to near surface aberrations will also be discussed.

Debye Scheerer ring analysis using high energy beams provides a wealth of information about the in-plane stress state with very high lateral spatial resolution. It is best suited to plate and sheet type problems. The strengths and limitations of the method will be demonstrated with reference to stresses in Ti/SiC composites and in welded plates. Special attention will be

focused on ways of increasing the longitudinal definition of the gauge volume and the analysis of full diffraction ring data acquired using a CCD detector.

M06.OE.004 RESIDUAL STRESSES AND MICROSTRAIN INVESTIGATION IN FATIGUED TESTED SPECIMEN. M. Ceretti [1], K. Hirschi [1],B. Marini [2], J.M. Sprauel [3], J.P. Lauriat [4]; [1] Laboratoire Léon Brillouin, CEA Saclay, F-91191 Gif sur Yvette (France), [2] SRMA, CEA Saclay, F-91191 Gif sur Yvette (France), [3] Laboratoire MecaSurf, ENSAM, F-13617 Aix en Provence (France), [4] LURE, Université Paris XI, Orsay (France).

Neutron diffraction has been used to estimate plastic strains along the line of the crack of a fatigue test specimen made of commercial austenitic steel AISI 316. Some microstructural parameters, such as an average size of coherently diffracting blocks, mean-square microstrain and dislocation density have been deduced from the broadening of diffraction profiles using Keijser's approach. Three dimensional measurements were performed on three compact tension specimen with different load ratios. The dimension of the plastic zone close to the crack tip was estimated and the elastic lattice strains have been determined. The results are in agreement with finite element calculations. Complementary measurements were made by using synchrotron radiation at the sample surface. Plastic strains were determined using a recently developed model taking into account the contribution of elastic strain heterogeneity (ESH) on the profiles broadening. The obtained values of separated size, strain and ESH contribution are in a good agreement with those published elsewhere for this kind of steel characterised by a strong dependency on the type of the hkl reflection.

M06.OE.005 ENGIN-X: A NEW INSTRUMENT DESIGN FOR ENGINEERING STRAIN MEASUREMENTS. M W Johnson, M R Daymond, ISIS Facility, Rutherford Appleton Laboratory, Chilton, Didcot, Oxon. OX11 0QX.

Neutron strain scanning is a non-destructive technique that provides important insights into stress distributions deep within engineering components and structures. As such it has become an increasingly important tool within engineering, leading to improved manufacturing processes to reduce stress and distortion. It has also helped to define structural integrity lifing procedures more precisely.

We outline a new design for a neutron strain scanner, ENGIN-X, which will bring an order of magnitude increase in performance over current neutron strain-scanning instrumentation. The gain in performance has been achieved by establishing quantitative methods for defining the instrument's efficiency, and then maximising them in the design. The method of achieving the order of magnitude improvement will be described, and the possible applications of the improved instrument discussed.

A ten fold increase in performance over currently available technology will enable innovative research of direct relevance to the engineering industry in at least four particular areas: area strain mapping, deep measurements, high spatial resolution and real time studies.

06OF ADVANCES IN LIQUID STRUCTURE DETERMINATION

M06.OF.001 TOOLS FOR THE ANALYSIS OF LIQUIDS DIFFRACTION DATA. A K Soper ISIS Facility, Rutherford Appleton Laboratory, Chilton, Didcot, Oxon, OX11 0QX

The last ten years or so have witnessed the development of new methods for the interpretation of liquids diffraction data which are analogous to those already used by crystallographers for some 30 years. In essence all these new techniques attempt to build a 3-dimensional model structure of the system under investigation based on available diffraction data and other constraints on the structure that are known. The reconstruction of the structure of a liquid or disordered material is both easier and more difficult than the equivalent crystallographic problem: on the one hand there are relatively few, and only diffuse, peaks in the diffraction pattern to refine. Against this formally such a reconstruction from diffraction data alone is not possible, and the lack of crystallographic symmetry and long range order on which to build a model structure leads to serious ambiguities. In fact there is no single structure to be found, but instead an ensemble of structures, and it is the reconstruction of this ensemble that is at the heart of any disordered material structure refinement. To achieve this with any degree of reliability it is essential to include as much additional (e.g. chemical) information into the problem as is available. The talk will outline recent progress in this field, with examples from true liquids, amorphous materials, and materials with some crystalline character.

M06.OF.002 COMPLEMENTARY NEUTRON AND X-RAY DIFFRACTION FROM LIQUIDS. David L. Price, Marie-Louise Saboungi, Yaspal S. Badyal, Dean R. Haeffner and Sarvjit D. Shastri Argonne National Laboratory Argonne, IL 60439, USA

The high-energy x-rays available from synchrotron sources extend the range of liquids that can be readily studied with x-ray diffraction, especially liquids that are corrosive or have high melting points. Since the partial structure factors have generally different weights in the total structure factors measured by neutrons and by x-rays, the ability to measure both provides information at the partial level. In addition, a detailed comparison can provide information about the distribution of the electrons relative to the nuclei and about magnetic properties. These ideas will be illustrated by three examples of recent work at the Advanced Photon Source: molten iron chloride, liquid potassium-lead, and water.

Work supported by the U.S. Department of Energy, Office of Basic Energy Sciences, Division of Materials Sciences, under Contract W-31-109-ENG-38.

M06.OF.003 SINKING THE ICEBERG: STRUCTURES OF AQUEOUS SOLUTIONS OF HYDROPHOBIC MOLECULES. J.L. Finney, Dept of Physics and Astronomy, University College London, Gower Street, London WC1E 6BT, UK, D.T. Bowron, European Synchrotron Radiation Facility, B.P. 220, 38043 Grenoble Cedex, France, and A.K. Soper, ISIS Facility, Rutherford Appleton Laboratory, Chilton, Didcot, Oxon OX11 0QX, UK.

The hydrophobic interaction is central to much of chemistry and biology. However, the molecular mechanisms underlying it are poorly understood. The conventional rationale of Frank and Evans argues that the source of the entropic driving force is a structural ordering of the water molecules in the hydration shell of the non-polar group, resulting in an entropic gain as the hydration water is expelled to the bulk when two non-polar groups come together in solution.

Recent developments in both neutron and x-ray sources and instrumentation, coupled with new procedures to assist interpretation of the experimental data from relatively complex multi-component solution systems, have allowed us to determine in unprecedented detail the structures of molecules in solution. Not only can we see directly for the first time the hydration structure of a non-polar group in solution, but we can also see

how solute molecules associate in solution, as temperature, concentration, or other solution conditions are changed. Using recent results from ISIS and ESRF, the standard molecular interpretation of the hydrophobic interaction is seen to be incomplete. Further development of these procedures promises to give us the ability to effectively perform crystallography in the liquid state. Moreover, state-of-the-art procedures to model the experimental results promise a revolution in liquid structural studies similar to that brought about for powder crystallography through Rietveld refinement techniques.

M06.OF.004 THE STRUCTURE OF FLUIDS IN LAYERED MATERIALS. G.D.Williams, N.T.Skipper*, M.V.Smalley, J.K.Walters, A.K.Soper, Department of Physics and Astronomy, University College London, & ISIS, Rutherford Appleton Laboratory.

The presentation will discuss time-of-flight neutron diffraction studies of the structure of fluids intercalated into clays and graphite. The main focus will be on the determination of liquid density profiles normal to the solid surfaces, using oriented samples and isotopic labelling. Results for aqueous solutions in colloidal clay minerals show that two layers of partially oriented water form at each clay surface. The structure in this region is dominated by hydrogen bonding of water to the negatively charged clay platelets. In graphite-potassium-ammonia systems, a 2-dimensional liquid monolayer is formed, in which neither potassium nor ammonia is registered to the underlying graphite structure.

M06.OF.005 WHAT DO WE KNOW ABOUT HYDRATION WATER AND WHAT IS STILL THERE TO KNOW. Fabio Bruni, Dipartimento di Fisica, Universita di Roma III, via della Vasca Navale 84, ROMA I-00146, Italy

In the evolution of life systems, water has been a component of transcendent importance. Water is in fact one of the essential components of life, and its functions are manifold. At the microscopic level, discrete H_2O molecules or small clusters are implicated in the maintenace of biologically active conformations of nucleotides, proteins, and carbohydrates. Macrostructures, such as membranes, are stabilized and sustained by the presence of critical numbers of bound water molecules. In metabolism and synthesis, H_2O is the universal reagent in any process that involves hydrolysis, condensation, reduction, or oxidation, and that includes most biochemical reactions.

The physical properties of water close, or confined, to intracellular solid interfaces, such as the surface of proteins or membranes, still represent an open problem, and it is certainly true that for the extent with which its experimentally determined properties differ from its behavior when in bulk aqueous solutions, water is without peer. Moreover the modifications to its bulk behavior when water is in confined geometry is important for technological applications such as mining and corrosion inhibition as well.. Structural and dynamical properties of water may be affected by both purely geometrical confinement and/or interaction forces at the interface; reliable and realistic model systems have therefore to be studied in order to discriminate between the two cases. Recent results, obtained by mean of experiments and molecular dynamics simulations, on confined water will be presented and compared.

P06.OF.001 THE UBBELOHDE EFFECT IN ROOM TEMPERATURE LIQUIDS. C. J. Benmore, ISIS Facility CLRC Rutherford Appleton Laboratory, Chilton, Didcot, Oxon OX11 OQX, U.K. B. L. Tomberli and P. A. Egelstaff, Dept. of Physics, University of Guelph, Guelph, Ontario, CANADA, N1G 2W1, and J. Neuefeind, HASYLAB, Notkestr. 85, 22603 Hamburg, GERMANY.

The Ubbelohde or H/D isotope effect has been measured by a direct method for hydrogenated and deuterated molecular liquids at room temperature under their normal vapour pressures using 101.2 keV X-ray diffraction. The effect in both intra- and inter-molecular terms is revealed by small but observable differences between the electronic structure factors of the two liquids at the same temperature. After Fourier transforming, the data are analysed in terms of the changes in their electron density correlation functions. A brief description of the X-ray technique used to measure the Ubbelohde effect in liquids is presented and the results are discussed with regard to how the isotopic substitution influences both the intra- and inter-molecular structure of the liquid.

06AA STRUCTURAL MOTIFS AND MULTIDOMAIN PROTEINS

M06.AA.001 STRUCTURAL CLASSIFICATION OF PROTEINS: A GUIDE TO THE PROTEIN WORLD. Alexey G. Murzin, Centre for Protein Engineering, MRC Centre, Cambridge CB2 2QH, UK

Large protein structures can be divided into domains formed by separate folded segments of the protein chains. However, for the majority of known structures, the domain division is not unambiguous. There are several different definitions of protein domain that usually correlate but sometimes conflict with each other.

Structural classification of proteins, SCOP, suggests a consensus definition of the protein domain as its basic classification unit. SCOP, having embodied the known theories of protein structure and evolution, organizes all known protein domains hierarchically according their structural similarity and near and far evolutionary relationships.

In my review of known relationships amongst proteins of known structure, I will focus on several recurrent structural domains from multidomain proteins, in particular, those involved in the biosynthesis of nucleotides and nucleic acids. Selected examples will demonstrate various pathways from a simple to a more complex protein structure. They also will illustrate the origins of many different specialized functions from a small set of primordial structural and functional modules.

M06.AA.002 CARBAMOYL PHOSPHATE SYNTHETASE: A LONG JOURNEY HOME. Hazel M. Holden*, Frank M. Raushel§, and James B. Thoden*, *Department of Biochemistry, University of Wisconsin , Madison Wisconsin, 53705 §Department of Chemistry, Texas A&M University, College Station, Texas, 77843

Carbamoyl phosphate synthetase, hereafter referred to as CPS, catalyzes perhaps one of the most remarkable biological reactions ever described whereby carbamoyl phosphate is assembled from one molecule of bicarbonate, two molecules of Mg^{2+}ATP, and one molecule of glutamine. The carbamoyl phosphate so produced is subsequently employed in the biosynthesis of both arginine and pyrimidine nucleotides. Due in part to its important metabolic role and to the large number of substrates, products, and effector molecules that bind to it, CPS has been the focus of intense investigation for more than thirty

years Prior to the successful structural determination of the *Escherichia coli* CPS $(\alpha,\beta)_4$-tetramer in 1997, it was unclear how this enzyme was able to orchestrate the synthesis and stabilization of three separate reaction intermediates: carboxyphosphate, ammonia, and carbamate. From research in this laboratory, it is now known that glutamine and nucleotide binding sites are separated by more than 90 Å and, in accordance with most biochemical data, it has now been suggested that some type of substrate channeling occurs within the α,β-heterodimer. The structures of various CPS complexes will be discussed in light of this putative channeling. This work was supported in part by grants from the NIH (GM55513 to H. M. H. and DK30343 to F. M. R.).

M06.AA.003 STRUCTURE AND FUNCTION OF BOTULINUM NEUROTOXIN TYPE A. Raymond C. Stevens Department of Chemistry, University of California at Berkeley, Berkeley, CA 94720, USA.

Botulinum neurotoxin (BoNT), a food-borne pathogen produced by Clostridium botulinum, is a 150 kD protein with three ~50 kD functional domains: binding, translocation, and catalytic[1]. It acts by binding a receptor on pre-synaptic nerve endings and undergoing receptor-mediated endocytosis. The acidity of the endosome triggers the translocation domain to form a pore, allowing for the transfer of the catalytic domain across the membrane into the cytosol. The catalytic domain is a zinc metalloprotease specific for one of three proteins involved in synaptic vesicle membrane fusion. Substrate cleavage results in inhibition of neurotransmitter release and, ultimately, causes the paralysis seen in botulism. The crystal structure of BoNT serotype A has been determined to 3.2 Å resolution[2]. The binding domain shares structural homology with the tetanus neurotoxin binding domain[3]. The translocation domain structure reveals a striking pair of 105 Å long a-helices and a ~50 residue 'belt' which wraps completely around the perimeter of the catalytic domain, occluding access to the active site zinc. The unusual fold implies that the mechanism of pore formation and translocation for BoNT/A is radically different from that thought to occur in other bacterial toxins. The catalytic domain structure of BoNT/A reveals a buried, negative active site that imposes structural restrictions on the cleavage of its SNAP-25 substrate. The toxin appears as a hybrid of varied structural motifs and suggests a modular assembly of functional subunits to yield pathogenesis.

M06.AA.004 STRUCTURAL BASIS FOR THE RECOGNITION OF ANGIOGENIN BY PLACENTAL RIBONUCLEASE INHIBITOR, A LRR PROTEIN. A.C.Papageorgiou and K.R.Acharya, Dept. of Biology and Biochemistry, University of Bath, Bath BA2 7AY, UK, and R. Shapiro, Center for Biophysical and Biochemical Sciences and Medicine, and Dept of Pathology, Harvard Medical School, Boston, MA02115, USA

Human placental ribonuclease inhibitor (hRI) is a leucine-rich repeat protein (LRR) that binds to human Angiogenin (Ang), a blood-vessel inducing protein and member of the pancreatic RNase superfamily, with very high affinity (K_i<1fM [1]). The hRI-Ang complex has been successfully crystallised and the structure was determined to 2.0 Å resolution [2]. The hRI-Ang binding interface is large and encompasses 26 residues from hRI on 13 different repeat units and 24 from Ang on seven segments of Ang, resulting to 124 contacts in total. This structure, in combination with extensive functional data on the complex available from previous studies [3] now provides a detailed view of how Ang is recognised by hRI. A structural comparison with the porcine RI-pancreatic RNase [4] has been carried out in order to understand the association of the inhibitor with members of the RNase superfamily. Although the overall docking is similar in both complexes, it appears that the inhibitor is able to recognise distinctive features unique to each member of the family. A detailed analysis will be presented. The structural information derived from the hRI-Ang tight complex could provide a lead to design small, active hRI derivatives or mimics suitable for therapeutic use.

M06.AA.005 TROA, A ZINC-BINDING COMPONENT OF A T. PALLIDUM ABC TRANSPORT SYSTEM WITH NOVEL TOPOLOGY; C.A. Hasemann, Y-H. Lee [1], R.K. Deka, M.V. Norgard, J.D. Radolf [2], [1] Departments of Internal Medicine and Biochemistry, UT Southwestern Med. Ctr., Dallas, Texas 75235-8884, [2] Department of Microbiology, UT Southwestern Med. Ctr., Dallas, Texas 75235

The crystal structure of TroA, a zinc-binding protein component of an ABC transport system in Treponema pallidum, was determined at a resolution of 1.8 Å. The organization of the protein is largely similar to other periplasmic ligand-binding proteins (PLBP), in that two independent globular domains interact with each other to create a zinc-binding cleft between them. The structure has one bound zinc pentavalently coordinated to residues from both domains. Unlike previous PLBP structures that have an interdomain hinge composed of beta strands, the N- and C- domain of TroA are linked by a single long backbone helix. This helix interacts with both the N- and C-domains, constituting a firmer hinge than the beta strand hinge used in other PLBPs. This unique backbone helix was possibly adopted in evolution to limit the hinge motion associated with the exchange of zinc. TroA is a member of a large family of cation binding proteins from diverse bacterial species. Therefore, the structure of TroA represents a new structural family of ABC transporter metal binding proteins, distinct from the classical PLBP family.

P06.AA.001 STRUCTURE OF COAGULATION FACTOR X-BINDING PROTEIN COMPLEXED WITH GLA DOMAIN. H.Mizuno and Z.Fujimoto, National Institute of Agrobiological Resources, Tsukuba, Japan, and H.Atoda and T.Morita, Meiji Pharmaceutical University, Kiyose, Japan

Coagulation factor binding proteins from snake venom are heterodimers consisting of two homologous subunits. Each subunit has sequence homology to the carbohydrate-recognition domain of C-type lectin. These proteins have no lectin activity, but bind to their cognate Gla domains(GD). We have solved the structure of factor IX and factor X-binding protein(IX/X-bp) at 2.5 Å resolution.[1] The structure showed that a central loop projects into the adjoining subunit and contributes to an intertwinned dimer formation in a manner similar to domain swapping. This forces a large conformational change on the hinge region classically concerned in carbohydrate-binding, and may result in the disruption of the lectin active site. The next step is to

know the GD-binding site and to investigate the atomic details of the interaction with it.

Recently we have solved and refined the structure of factor X-binding protein(X-bp) complexed with factor X GD peptide 1-44 at 2.3 Å resolution with the crystallographic R factor of 0.20. The folding of X-bp is very similar to that of IX/X-bp. The GD-binding site is on a concave surface surrounded by the two subunits as expected from the structure of IX/X-bp. The structure of the GD is similar to that of Ca bound GD of prothrombin fragment I. Seven bound calcium ions are observed, one of which is involved in the interaction with X-bp. The detailed binding mode between X-bp and GD will be presented.

P06.AA.002 HIGH-RESOLUTION CRYSTAL STRUCTURES OF COMMON DOMAINS OCCURRING IN NUCLEIC ACID-BINDING PROTEINS. U. Heinemann, A.M. Babu, K. Decanniere, H. Delbrück and U. Mueller, Forschungsgruppe Kristallographie, Max-Delbrück-Centrum für Molekulare Medizin, Robert-Rössle-Str. 10, D-13125 Berlin, Germany.

Nucleic acid-binding proteins are commonly made of ubiquitous domains occurring in proteins of diverse function. Recently, we have analysed a set of common domains at high resolution finding surprising effects of mutations on protein stability, a known domain fold with an unlikely function and remarkably structural homology across a wide evolutionary divide.

Following our earlier work on bacterial cold shock proteins [1,2] we have now determined the crystal structure of the homolog from the thermophilic *Bacillus caldolyticus* at 1.17 Å resolution. A comparison with the structures of cold shock proteins with very similar sequence from mesophilic bacteria and the analysis of single-site mutants sheds light on the determinants of protein thermal stability.

The C-terminal domain of the transcription factor KorB from RP4-infected *Escherichia coli*, KorB-C, has a fold closely resembling the SH3 fold first seen in eukaryotic signal transduction proteins. The 1.7-Å crystal structure of KorB-C shows a unique dimer arrangement which is of functional importance.

The histones HMfA and HMfB from the hyperthermophilic archaeon *Methanothermus fervidus* [3] have been analysed at resolutions down to 1.48 Å. The proteins are surprisingly similar to the eukaryal histones as present in the nucleosome core particle. A closely similar mode of non-specific DNA binding is expected.

06BB STRUCTURE FROM PICTURES: DIRECT MACROMOLECULAR STRUCTURE DETERMINATION BY ELECTRON MICROSCOPY

M06.BB.001 STRUCTURE OF ROTAVIRUS AND FUNCTIONAL CORRELATIONS USING THREE-DIMENSIONAL ELECTRON MICROSCOPY. B. V. Venkataram Prasad[1], J. A. Lawton[1], and M. K. Estes[2] [1]Department of Biochemistry, and [2] Division of Molecular Virology, Baylor College of Medicine, Houston, TX 77030.

Rotaviruses are complex, relatively large (1000 Å) nonenveloped icosahedral viruses. They are the major causative agents of severe diarrhea in children and animals. Rotaviruses are double-stranded RNA (dsRNA) viruses belonging to the family *Reoviridae*. Of the eleven proteins encoded by the genomic RNA, six are structural and five are non-structural. Three-dimensional electron cryomicroscopy (cryoEM) has been used to study the virus structure not only in its native state but also in various functional states to establish structure-function relationship.

The mature rotaviruses are triple-layered particles (TLPs). During the process of cell entry the outer-most layer consisting of VP7 and the spike protein VP4 is lost and the resulting double layered particles (DLPs) become transcriptionally active. CryoEM of actively transcribing DLPs has shown that the nascent mRNA molecules are synthesized inside the intact DLPs, and are extruded through the channels at the icosahedral vertices. Difference imaging of the native and recombinant particles has shown that VP1 and VP3 which posses the enzymatic activities for transcription are anchored to the inner surface of VP2 at the icosahedral vertices. A significant portion of the genomic RNA is icosahedrally ordered and forms a dodecahedral structure surrounding these enzyme complexes. In recent studies the question of why the mature particles (TLPs) are transcriptionally inactive, and what is the interdependence of the various stages of transcription such as initiation, elongation, and translocation, has been addressed using anti-VP6 monoclonal antibodies which affect the transcriptional process in rotavirus. CryoEM studies of the DLPs complexed with these antibodies have shown that it is possible to gate the release of transcripts and affect transcriptional efficiency. We acknowledge support from NIH grants AI 36040 (BVVP), DK 30144 (MKE), and a training fellowship to JAL (GM-08280).

M06.BB.002 ALLOSTERIC MOVEMENTS IN THE CHAPERONIN ATPASE CYCLE. Helen Saibil, Alan Roseman*, Neil Ranson, Shaoxia Chen, Guy Schoehn, Department of Crystallography, Birkbeck College, Malet St, London WC1E 7HX, UK, and Brent Gowen, Department of Biochemistry, Imperial College, London SW7 2AY, UK *present address: MRC Laboratory of Molecular Biology, Cambridge CB2 2QH, UK

Chaperonin-assisted protein folding proceeds through cycles of ATPase action by the large chaperonin GroEL or its homologues, and involves concerted, rigid body movements of the 3 domains in each subunit. Transient binding of the small chaperonin GroES forms an enclosed chamber about 70 Å across, in which folding of a protein subunit takes place. Access to the chamber is regulated by the nucleotide cycle, which controls the binding and release of GroES. In addition, the domain movements cause an alternation between low and high affinity binding for non-native protein substrates, by changing the accessibility of the hydrophobic binding sites. Binding, encapsulation and release states alternate between the two back-to-back 7-membered rings of GroEL, with the movements communicated by subtle alterations of the inter-ring interface.

Using cryo EM we have obtained 3D reconstructions of chaperonin complexes in several different nucleotide states, revealing the very large hinge rotations that accompany the functional cycle. We have recently extended the resolution of our single particle analysis to 10 Å, and are currently trapping ATP-bound states by vitrifying cryo EM samples with a stopped-flow mixer/rapid freezing device. Reaction mixtures are trapped in less than 1 second, well within the 15 second half time for ATP hydrolysis. We are now characterizing GroEL-ATP and GroEL-GroES-ATP complexes, which are folding-active states. Combining the cryo EM maps with the atomic structures of the domains provides a detailed structural basis for understanding the allosteric mechanism of chaperonins and control of their interactions with folding protein substrates.

M06.BB.003 FINDING THE SMALL DIFFERENCE: ELECTRON CRYOMICROSCOPY OF A DECA-PEPTIDE BOUND TO HEPATITIS B CORE PROTEIN. B. Böttcher Institut für Physikalische Chemie, Universität Freiburg, Albertstraße 23a, 79104 Freiburg, Germany M.R. Dyson Peptide Therapeutics, 321 Cambridge Science Park, Milton Road, Cambridge CB4 4WG, UK (present address) K. Murray Institute of Cell and Molecular Biology, University of Edinburgh, Edinburgh EH9 3JR, UK R.A. Crowther Medical Research Council, Laboratory of Molecular Biology, Hills Road, Cambridge CB22QH, UK

It was recently shown that it was possible to determine the fold of the peptide chain in an icosahedrally organised particle without the necessity of having crystals [1]. The availability of field emission gun microscopes equipped with stable cryo stages was one major prerequisite for the collection of data of sufficient quality. Combination of thousands of particles from micrographs at different levels of defocus was needed in the subsequent image processing. We describe here how these methods were employed to locate a ten amino-acid peptide bound to the hepatitis B core protein [2]. The peptide had been selected to bind to the core protein and was then shown to block interaction of core with the long viral surface antigen [3]. Hepatitis B core protein can be expressed in E. coli where it assembles into icosahedral shells of two sizes containing either 180 (T=3) or 240 (T=4) subunits. For electron cryomicroscopy these shells were either frozen directly or mixed with the peptide (GSLLGRMKGA) prior to freezing.

Independent maps of all four types of shells (T=3 with and without peptide and T=4 with and without peptide) were calculated to a resolution of 8.3 Å. Because the expected differences in density were small, standard deviation maps were calculated, first for the native shells then for the native shells plus peptide and finally for the native and native plus peptide data combined. In the standard deviation maps for the combined data a set of strong peaks was seen at the tips of the spikes which was absent in the standard deviation maps from the single data sets. Difference maps between corresponding maps with and without peptide were then computed. These maps indicated that the peptide was bound at the tips of the spikes on the local 2-fold axes. From these results it is clear that electron cryomicroscopy and image processing of single icosahedrally organised particles is a powerful method to detect differences as small as a deca-peptide directly, without the necessity of extra labelling such as heavy atom clusters.

M06.BB.004 STRUCTURE OF GAP-JUNCTION INTERCELLULAR CHANNELS - FROM MAPS TO MODELS. V.M. Unger [1][3], N.M. Kumar, N.B. Gilula [1], M. Yeager [1][2], [1] The Scripps Research Institute, Dept. of Cell Biology, La Jolla, CA 92037, USA, [2] Scripps Clinic, Division of Cardiovascular Diseases, La Jolla, CA 92037, USA, [3] Max-Planck-Institute for Biophysics, Dept. of Structural Biology, 60528 Frankfurt/Main, Germany

Gap junction intercellular channels mediate electrical and metabolical coupling between adjacent cells. Our previous electron-crystallographic analysis of a recombinant gap junction channel revealed the arrangement of all the transmembrane alpha-helices in the twelve connexin subunits that form the channel. Furthermore, the density map at 7.5 Angstrom resolution suggested that the connexin polypeptide chains do not adopt an alpha-helical conformation within the extracellular space where two hemi-channels dock to form a cell-to-cell conduit. An extension of our data to an in-plane resolution of 6 Angstrom, reveals significant detail within the extracellular domain of the channel. Using this improvement, and by taking into account the clues obtained from multiple sequence alignments and biochemical data, we now propose an assignment of the predicted transmembrane alpha-helices in the sequence to the resolved transmembrane domains in the density map. Furthermore, we propose the likely molecular boundary of the connexin subunit. In our current model, residues on transmembrane helices 1 and 3 have direct access to the aqueous pore, while helices 2 and 4 are assigned to the two transmembrane domains in the structure that are in direct contact with the lipid bilayer. We have used this assignment to correlate the sequence of the four connexin transmembrane helices with individual cross-sections in the density map. The resulting model provides potential explanations for the disruptive effects of naturally occurring mutations associated with X-linked Charcot-Marie-Tooth disease and, for the first time, provides detailed predictions for the likely interaction between connexin subunits within the lipid bilayer.

M06.BB.005 MICROTUBULE STRUCTURE AND DYNAMICS. Eva Nogales [1][2], Kenneth H. Downing [2], [1] Department of Molecular and Cell Biology, UC Berkeley, CA 94720, US, [2] Life Science Division, Lawrence Berkeley Natl. Lab., CA 94720

Microtubules are built by the self-association of ab-tubulin dimers. The polymerization process involves the head-to-tail binding of dimers that results in the protofilament, and lateral interactions between parallel protofilaments to form the microtubule wall. We obtained the structure of the tubulin dimer by electron crystallography of zinc-induced tubulin sheets. Each tubulin monomer contains an N-terminal, nucleotide-binding domain, a smaller second domain, and a predominantly helical C-terminal region. A high resolution model of the microtubule has been generated by docking the crystal structure of tubulin into a 20-Å map of the microtubule . The excellent fit defines the orientation of the tubulin structural features within the microtubule, and provides a structural basis for the GTP-related dynamic behaviour of microtubules. The exchangeable nucleotide is exposed on the plus end, while the proposed catalytic residue in a-tubulin is exposed at the minus end. Longitudinal contacts between tubulin subunits bring the catalytic domain in one dimer in contact with the nucleotide of the next, linking, at the molecular level, the processes of polymerization and GTP hydrolysis Lateral contacts between protofilaments are dominated by the interaction of a g-phosophate-sensitive helix with the "M-loop", a loop with hinge elements that in b-tubulin contributes to the binding site of taxol.

P06.BB.001 A MODEL FOR *OCTOPUS* HEMOCYANIN DERIVED FROM ELECTRON CRYOMICROSCOPY AND X-RAY CRYSTALLOGRAPHY. M. E. Cuff, B. Gowen, K. I. Miller*, E. V. Orlova, A. Patwardhan, M. van Heel. Department of Biochemistry, Imperial College, London SW7 2AY, UK. *Department of Biochemistry and Biophysics, Oregon State University, Corvallis OR 97331, USA.

Octopus hemocyanin is a hollow cylinder with D_5 point group symmetry and a molecular mass of 3.4 MDa. Each 340kDa subunit has seven oxygen-binding units that are more protease-resistant than the intervening linker regions which occur serially along the polypeptide chain. Among all molluscan hemocyanins, these 'functional units' possess between 40-70% primary sequence identity and each contains one binuclear copper center that reversibly binds oxygen.

We have assembled a high resolution model for *Octopus* hemocyanin by docking the non-crystallographic dimer of functional unit Odg [1] into a 24Å map obtained by electron cryomicroscopy and angular reconstitution. Furthermore, this dimer appears to fit well into the density identified as the 'morphological unit' of the 15Å reconstruction of another molluscan hemocyanin, the type 1 from keyhole limpet [2]. Whereas the protomers in the crystallographic dimer are related by a near perfect 2-fold, this is not the case for the morphological unit where most are heterodimers. Also, it is likely that the precise angular relationship within and between these dimers varies with the cooperative state of the molecule. Nonetheless, our observations lead us to propose this structural dimer to be a building block for all molluscan hemocyanins. Employing the complete primary sequence for the *Octopus* hemocyanin subunit, we propose a path for the polypeptide chain within the decamer and possible divalent cation-binding sites.

06CC X-RAY AND NEUTRON COMPLEMENTARITY

M06.CC.001 OVERVIEW OF COMPLEMENTARITY BETWEEN NEUTRONS AND X-RAYS WITH TYPICAL EXAMPLES. C. Vettier, European Synchrotron Radiation Facility, France

The advent of third generation synchrotron sources has rendered more acute the debate on the complementarity between neutrons and x-rays. The unprecedented progresses made in the x-ray source brilliance have not been matched by parallel developments on the neutron side. As a consequence, the studies that were impossible with x-rays due to vanishing scattering cross sections or due to the need of extremely high resolution, are now feasible and potential results compare favourably with neutron results.

Two categories of research fields can be distinguished: studies for which the one or the other probe has a leading advantage in terms of cross section (scattering and absorption) and/or source properties (energy range, brilliance), and those for which the enhanced source characteristics have put performances of both probes at the same level. Progress made in instrumentation will be discussed. When considering various fields such as soft and hard materials science research, magnetism and biological studies, it is clear that both scattering probes are needed in condensed matter research. During this review, experimental results will be presented to illustrate the complementarity of neutrons and x-ray synchrotron radiation in many areas. It will be stressed that scientists must be aware of the capabilities of both probes and have easy access to them.

M06.CC.002 $PrBa_2CU_3O_{6+X}$; A CASE STUDY IN THE COMPLEMENTARITY OF X-RAY AND NEUTRON MAGNETIC SCATTERING. J.P. Hill [1], A.T. Boothroyd [2], D.F. McMorrow, N.H. Andersen [3], A. Stunault, C. Vettier [4], Th Wolf [5], [1] Dept. of Physics, Brookhaven National Laboratory, Upton NY 11973, USA, [2] Clarendon Laboratory, Oxford University, Oxford, OX1 3PU, UK, [3] Condensed Matter Physics and Chemistry Department, Riso National Laboratory, DK-4000 Roskilde, Denmark, [4] European Synchrotron Radiation Facility, BP 220, 38043 Grenoble Cedex, France, [5] Forschungszentrum Karlsruhe, ITP D-76021 Karlsruhem, Germany.

X-ray scattering as a probe of magnetism offers a useful complement to that of neutron scattering. Particular strengths include element specificity, high reciprocal space resolution and the ability to study very small volume samples. We illustrate the utility of this complementarity with a case study; an investigation of the magnetism of PrBa_2Cu_3O_{6+x}. This material is of great interest as an anomalous (non-superconducting) member of the (RE)Ba_2Cu_3O_{6+x} series, where RE=Y or a rare-earth. The element specificity of resonant x-ray magnetic scattering is exploited to study the magnetism of the Pr and the Cu in a model independent manner, and we unambiguously demonstrate that the Pr does order, resolving a debate in the literature. X-rays also offer extremely high reciprocal space resolution and this led to the discovery of a previously unknown incommensurate modulation. A strength of neutron magnetic scattering is the ability to perform energy resolved measurements and we utilize this to demonstrate that the modulation is static. Finally, high resolution x-ray measurements of the copper structure at higher temperatures reveal that it is commensurate, ruling out one model for the suppression of superconductivity in this material. These latter results represent the first observation of x-ray magnetic scattering from copper moments in a high-Tc compound.

M06.CC.003 SPHERICAL NEUTRON POLARIMETRY AND COMPLEMENTARITY WITH X-RAYS. E. Lelièvre-Berna and F. Tasset, Institut Laue Langevin, Av. des Martyrs, BP 156, 38042 Grenoble Cedex 9, France.

Spherical neutron polarimetry (SNP) is the only technique which can give access in (Q,ω) space to 16 measured quantities related to the 16 independent correlation functions involved in the most general mixed nuclear/magnetic neutron scattering process.

Among the interesting topics which can be investigated with this novel polarimetric technique, there are non-trivial magnetic structures and precise antiferromagnetic form factor determinations as well as magnetic excitations.

Compared to X-ray techniques, SNP gives a direct way of investigating spin/lattice correlation functions and is a powerful technique for determining antiferromagnetic configurations.

M06.CC.004 NEUTRON PROTEIN CRYSTALLOGRAPHY BY THE USE OF A NEUTRON IMAGING PLATE. N.Niimura, Advanced Science Research Center, Japan Atomic Energy Research Institute, Tokai-mura, Naka-gun, Ibaraki-ken, 319-1195, Japan

In the latter half of 20th century, X-ray single crystal structure analysis has been used to determine the three dimensional structures of biological macromolecules such as

proteins and DNA, to bring many of the mysteries of life sciences to light. This structural information contributes to the understanding of the physiological function of proteins and DNA. This field is called structural biology. Structural biology is one of the most important fields in the life sciences that will interest human beings in the 21st century. There is already clear evidence that hydrogen atoms and water molecules around proteins and DNA play a very important role in many physiological functions. However, since it is very hard for X-rays to determine the positions of hydrogen atoms in protein molecules, detailed discussion of protonation and hydration can be only speculative in many cases.

On the other hand, neutron diffraction provides an experimental method of directly locating hydrogen atoms. To date, there are relatively few examples of neutron crystallography in biology since it takes considerable time to collect a sufficient number of Bragg reflections due, in past, to the low flux of neutrons illuminating the sample. To use a large area detector is one way of the faster data collectin.

We have developed a neutron imaging plate (NIP), where the neutron converters, ^{6}Li or Gd were mixed with photostimulated luminescence materials on a flexible plastic support. [1] The dynamic range and spatial resolution of our NIP were obtained as 1:10^5 and less than 0.2 mm, respectively and the neutron detection efficiency of some NIP reached about 80 % at neutron wavelength 1Å.These distinctive features are applicable for neutron diffraction experiments from bio-macromolecules.

In this paper two examples of the application of NIP for neutron diffraction from a lysozyme single crystal were given. One is used for the Laue diffractometer (LADI) installed at ILL in Grenoble [2] and the other is for the diffractometer of monochromatic beam (BIX) installed at JAERI [3].

M06.CC.005 SMALL-ANGLE NEUTRON AND X-RAY SCATTERING STUDIES OF BLOCK COPOLYMER MICELLES: ISOTOPE EFFECT. Jan Skov Pedersen, Condensed Matter Physics and Chemistry Department, FYS-108, Risø National Laboratory, DK-4000 Roskilde, Denmark.

Block copolymers are constituted of two chemically distinct polymer blocks covalently bonded together. When dissolved in a solvent which is a selective solvent for one blocks, micelles are formed with a core of the non-soluble parts and a diffuse corona of the soluble chains. The small-angle scattering data from such systems can be analysed to quite high resolution by a recently calculated analytical form factor for a model with a homogeneous core surrounded by chains obeying Gaussian statistics [1]. In order to obtain as much information as possible on the structure, neutron contrast variation measurements can be performed on polymers with one of the blocks per-deuterated. By using deuterated and hydrogenated solvent, the core and the corona can be measured separately, whereas mixtures provides additional information on the interference term. We have studied micelles of *d*-polystyrene-polyisoprene of relatively high molecular weight (40000-40000 and 40000-80000) in decane. The micellar structure in the deuterated and hydrogenated solvent was also measured by X-ray scattering and unexpected isotope effects were found. The aggregation number of the micelles depend on the isotope form of the solvent unless the samples are extremely carefully prepared. In a related study we have found isotope effects for the aggregation state of *d*-poly(ethylene oxide)-poly(propylene oxide)-*d*-poly(ethylene oxide) in water. However in this case, the difference is evident already from the neutron data as variation of the length of the rod-like micelles is observed.

P06.CC.001 EFFECTS OF HYDROGEN BONDING ON COVALENT GEOMETRIES AS OBSERVED BY NEUTRON DIFFRACTION. Steiner, T., Institut für Kristallographie, Freie Universität Berlin, Takustr. 6, 14195 Berlin, Germany

Hydrogen bonds X–H···A affect the geometries of both involved groups. These effects are most pronounced for the bonds involving the H-atom, that are the X–H bond, the R–X–H angle and also R–Y–X–H torsion angles. To describe the effects, the position of the H-atom must be known with good precision, so that only structural data based on neutron diffraction experiments can be used.

Best known is the lengthening of the covalent X–H bond, which has been described for the homonuclear hydrogen bonds O–H···O and N–H···N by several groups of authors. For heteronuclear hydrogen bonds of various types, this effect has been characterized only very recently [(1) and references therein]. New experimental data are shown here, in particular on inter-anion hydrogen bonds which are treated controversially in the literature.

Much less is known on how hydrogen bonding affects covalent bond angles (1, 2) and torsion angles. Neutron diffraction data showing these effects are presented. In particular, the rotation of methyl groups bonded to C(sp3) by C–H···O hydrogen bonding, which has been subject of some dispute, is discussed.

06DD INDUSTRIAL ON-LINE X-RAY ANALYSIS

M06.DD.001 ORIENTATION MEASUREMENT OF AERO-ENGINE SINGLE CRYSTAL COMPONENTS. C.J.Small, C.C. Baxter, Rolls-Royce plc, P.O.Box 31, Derby, DE24 8BJ, UK.

The improvements in the operating efficiency of the modern gas turbine has driven the need for new materials with improved properties at elevated temperatures, particularly in materials for high-pressure turbine blade applications. This in turn has required the development of specialised single crystal casting technology. However the performance of such cast materials is critically dependent of the relative orientation of the crystal axes to the component geometry. As the process has an inherent variability there is a urgent need for an inspection techniques that can give an accurate determination of the crystal axes relative to the component geometry. The inspection technique must also be suited to the production environment, where high component numbers and lack of highly specialised NDE personnel call for a fast, expert system, which gives an unambiguous “pass or fail” decision. Rolls-Royce investigations into a wide range of inspection techniques has resulted in the development of S.C.O.R.P.I.O (Single Crystal Rapid Processing and Interpretation Operation), an integrated NDE system which satisfies all the above mentioned requirements. S.C.O.R.P.I.O is a development of the back-reflection Laué X-ray diffraction technique, which is extensively used in laboratories around the world. Traditionally the main drawbacks of the Laué technique as a production inspection method has been the costs and time involved in exposing and processing the film on which the diffraction patterns are recorded, and the time and level of expertise required to interpret the patterns. S.C.O.R.P.I.O overcomes the problems associated with film by using a Real-Time X-ray detector, the output of which is fed directly into a PC based analysis system.

This presentation will describe the design and application of the Rolls Royce S.C.O.R.P.I.O system and show how it is integrated into the turbine blade production process.

M06.DD.002 ROUTINE MEASUREMENTS OF HETERO-EPITAXIAL LAYERS. Mary Halliwell, Philips Analytical, Almelo, The Netherlands.

There are two approaches to making routine measurements using rocking curve analysis.

In the first a simple double crystal diffractometer is used with the sample laid on a horizontal table which incorporates X and Y translations. This offers a fast and convenient way to map variations in the layer, particularly the lattice parameter variations in heteroepitaxial layers. This method is favoured where the instrument can be dedicated to measuring layers which are all grown on substrates of the same material with approximately the same orientation and relatively simple analysis is required.

The second approach uses diffractometers where the achievable resolution is adjustable by using different combinations of monochromator crystals, and the intensity can be boosted by the use of multilayer mirrors. With these more versatile instruments a wide range of materials can be studied and the increased dynamic range allows for much more detailed analysis of layer structures.

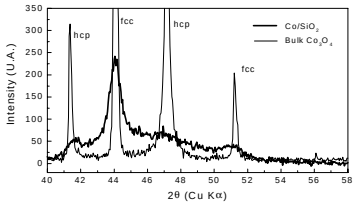
Rocking curve simulation using the Takagi-Taupin theory is the universal tool for interpreting the x-ray data from the complex layer structures grown for modern devices. Recent advances in automatic fitting of simulations will be discussed.

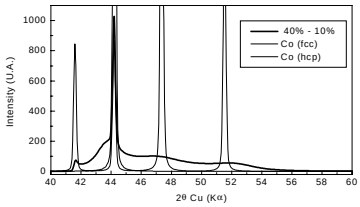
M06.DD.003 ON LINE MONITORING OF THE FISCHER TROPSCH REACTION. B. Rebours, O. Ducreux, J. Lynch and M. Roy-Auberger, Institut Français du Pétrole, 1 & 4 Avenue de Bois Préau, F-92852 Rueil Malmaison

Interest in Fischer-Tropsch reaction, which transform syngas ($CO + H_2$) into long-chain hydrocarbons of high purity, is increasing as environmental regulations on fuels are becoming more severe. The activity of cobalt catalysts in Fischer-Tropsch synthesis is usually attributed to the active sites located on the surface of cobalt metal particles formed after reduction. The activation and reaction process of such catalysts have been studied by *in situ* X-ray powder diffraction.

The sample holder of an XRK Anton Paar reaction cell allows reactant gas flow through a thick powdered sample of the catalyst and simulate a fixed bed reactor. The gas handling system of the reactor cell has been designed to mimic testing conditions of cobalt Fischer-Tropsch catalysts. Reactants and gas products are analysed at the exit by gas chromatography, and liquid products are condensed after the cell. Conversion rate and selectivity are followed as a function of the time. An associated microreactor working in the same conditions as the X-ray diffraction cell allows transfer of the tested catalyst to vacuum characterisation techniques such as XPS or TEM without any contact with air. These methods, with FTIR of adsorbed CO, contribute to interpretation of the results.

After activation of catalysts under hydrogen at atmospheric pressure, the XRD diagram of the cobalt metal phase, although containing some lines of both f.c.c and h.c.p cobalt metal forms, cannot be interpreted as a simple mixture of the two forms. The shape of the signal was simulated using DiFFax, and a model of unique metal phase with cubic/hexagonal stacking disorder was assumed.





Under Fischer-Tropsch conditions (503K, 3 bar, H_2:CO=9:1) XRD analysis shows the formation of a cobalt carbide and decrease of the metal phase over the period 80 to 300 hours on stream. The cobalt metal phase can be regenerated under hydrogen, with some structural modifications. The role of the carbide in the deactivation of the catalysts and in the selectivity toward long chain paraffins will be discussed.

M06.DD.004 ON-LINE PRODUCTION CONTOL IN THE CEMENT, PLASTER AND MINING INDUSTRIES. M. Bellotto, CTG Italcementi Group, Rue des Technodes, 78931 Guerville Cedex, France. keywords: on-line quantitative phase analysis, cement industry, plaster industry, mining industry.

The strive towards a better process control to limit production costs is pushing towards on-line analysis even those industries, like the cement, mining and gypsum ones, which are traditionally considered as « low tech ». Common features of such industries is the fact they process large volumes of solids, and that mineralogical control of the production is necessary. Thus X-ray diffraction is used, or is going to be used, as a sensor to monitor the processes, in very much the same way as a pH-meter or a thermocouple. The added difficulty comes from the sampling which, one way or another, is always needed before the analyses. During wall board manufacturing operations, gypsum is dehydrated in heated kettles to bassanite. Overburning the material to anhydrite results in excessive energy consumption and subsequent monetary losses, as well as in a quality degradation of the product. From a process control perspective an on-line mineral monitor of the gypsum content in the bassanite product from the kettles can be used to optimize burner control settings. The analysis can be accomplished by diverting a stream of bassanite from the kettles directly to the analyzer via a conveyor belt, with no sample preparation.

In the mining industry, phase quantification is used to control the flotation process and to dose the chemical additives. In such a way better economics and a regular production quality can be achieved.

In the cement industry on-line X-ray diffraction is used to measure the amount of unreacted « free » lime in the fired material (clinker) at the kiln outlet. The complete on-line clinker mineralogical analysis is possible, even if it is complicated by the complex phase assemblage typically observed, and by the polymorphism exhibited by the major phases. The use on-line of Rietveld quantitative analysis, currently performed in the central research laboratories, can be a solution to the difficulties encountered so far.

M06.DD.005 HIGH-RESOLUTION X-RAY DIFFRACTION AND QUALITY COTROL OF INP-BASED FIBER-OPTIC COMMUNICATION LASERS. Joka M. Vandenberg, Lightwave Devices Research,Lucent Technologies, Bell Laboratories,Murray Hill, New Jersey 07974-0636, USA

High-resolution x-ray diffraction(HRXRD) is emerging as the leading non-destructive characterization tool for the crystal growth of quantum well lasers. Over the years HRXRD has evolved from a sophisticated research technique into a wide range of industrial applications. In this talk I will discuss how HRXRD becomes an integral part in the development of improved device performance, process and quality control, and product yield. Within this framework, trends in x-ray diagnostics and characteristic x-ray features as well as dynamical simulations of InP-based multi- quantum well lasers and electroabsorption modulators will be presented, including some aspects of the selective area growth of lasers.

P06.DD.001 XRPD QUANTITATIVE PHASE ANALYSIS PERFORMED *IN SITU* AT HIGH TEMPERATURE. E. Mazzucato, A.F. Gualtieri, P. Venturelli and A. Viani, Dipartimento di Scienze della Terra, Università di Modena e Reggio Emilia, Modena 41100, Italy.

To our knowledge this is the first time quantitative phase analysis (QPA) is performed in non environmental conditions. The aim of this work is overcome the difficulties rising from strong peak overlap. The technique is applied to NiO based black ceramic pigments. In this system NiO, potential carcinogenic agent, combines with other phases to crystallise new spinel-like phases. Accurate quantitative determination of residual free NiO is essential because of its hazardous effects even at low concentrations. Unfortunately there are no widely accepted methods for such determination in ceramics so far, the main reason being experimental difficulties. In fact, QPA by X-ray powder diffraction (XRPD) may fail because all diffraction peaks of NiO overlap to those of spinel since the latter has a space group $Fd\ \bar{3}m$ with a≈8.4 Å and NiO has a space group $Fm\ \bar{3}m$ with a≈4.18 Å. To overcome this problem, in this work QPA has been performed *in situ* at high temperature to resolve the peak overlap of NiO and spinel by taking advantage of differential thermal expansion of the two phases (Fig.1).

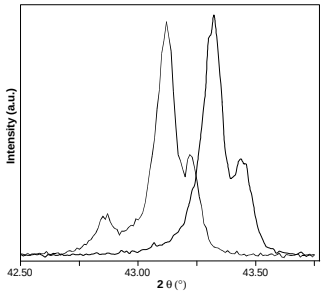


Fig.1. A sample containing 2 wt% NiO collected at room temperature (thin line) and high temperature (600 °C, thick line). The more intense peak [spinel (400)] hides the (200) peak of NiO at room temperature while at 600 °C these two peaks become well resolved.

06EE INTERFACES, THIN FILMS AND MULTILAYERS

M06.EE.001 ANALYSIS OF SEMICONDUCTOR QUANTUM-DOT SYSTEMS BY GRAZING INCIDENCE X-RAY SCATTERING TECHNIQUES. T. H. Metzger, I.Kegel, M. Rauscher, Z. Kovats, and J. Peisl, Center for NanoScience (CeNS) at Sektion Physik, Ludwig-Maximilians-Universität, D-80539 München and R. Paniago, Departamento de Física, Universidade Federal de Minas Gerais, Caixa Postal 702, 30123-970, Belo Horizonte, Brazil and V. Holy, Masaryk University, 61137 Brno, Czech Republic.

The growth of lattice mismatched semiconductor heterostructures often results in strain-driven, self-organised formation of islands with nanometer dimensions. The opto-electronic properties of such quantum dots are dominated by dot size and strain. We have developed x-ray scattering techniques at grazing incidence to analyse shape, strain and ordering of the dots. New results on three different semiconductor systems will be presented, demonstrating the versatility of the methods which can be applied to free-standing and buried dots:

In case of Ge islands grown on boron terminated Si(111) we applied grazing incidence small angle x-ray scattering (GISAXS) to assess their shape and size distribution. We find nearly perfect triangular pyramids, incoherently connected to the substrate. They are limited by three {113} facets and show a high degree of orientation alignment.

For the system InAs on GaAs (001) we find dome-like coherent InAs dots. An "iso-strain-scattering" technique has been developed to determine the lattice parameter distribution in the dots, which ranges between the lattice parameter of GaAs at the foot and InAs at the top of the dots. A linear interdependence of dot radius and strain is found. A similar analysis has been applied to ring shaped objects ("quantum donuts").

For Ge dots embedded in SiGe (001) superlattices, self-assembling processes yield vertical and lateral dot ordering. This ordering is quantified by applying a random walk argument to analyse grazing incidence diffraction measurements. The Ge dots on the sample surface form a disordered lateral square lattice. The vertical stack ordering of the Ge dots increases with decreasing Si spacer layer thickness.

M06.EE.002 THE STRUCTURE OF EPITAXIAL THIN FILMS. R.A.Cowley, Oxford Physics, Clarendon Laboratory, Parks Road, Oxford, OX1 3PU.

The structure of (110) Nb films grown on sapphire and (100) GaSb films grown on GaAs have been studied by high-resolution x-ray scattering techniques. In both cases there is a lattice mismatch between the film and the substrate and the structure of the film has been studied as the thickness increases from about 80Å to 5000Å. The films were grown in Oxford by MBE techniques for the Nb films and by MOVPE techniques for the GaSb films and the experiments performed with triple crystal diffractometers in Oxford, on the X-MAS beam line at the ESRF, and the X22A beam line at the NSLS. The results are qualitatively similar for both materials. Rocking curve scans through Bragg reflections from planes perpendicular to the growth direction show two components. A narrow component that shows the planes are on average flat over 50000Å and a broad component which has an approximately Lorentzian squared profile. For the GaSb films there are also incommensurate peaks with wave vectors corresponding to the separation of the mis-fit dislocations. As the thickness of the films increases the mean square fluctuation about the average position of the atomic planes increases and the correlation length of these fluctuations which is much longer than the separation of the mis-fit dislocations increases. The consequences of these results for the growth of seed layers and a comparison of the results with possible theoretical models will be discussed.

I am grateful to my many collaborators: A. Babkevich, J.P. Hill, N.J. Mason, A. Stunnalt, R.C.C. Ward, M.R. Wells and A.R. Wildes. Financial support was provided by the EPSRC.

M06.EE.003 X-RAY REFLECTIVITY AND DIFFUSE SCATTERING STUDIES OF PERIODIC MULTILAYERS. M.K.Sanyal, J. K. Basu, S.Banerjee, A.Datta and S. Hazra Saha Institute of Nuclear Physics, Calcutta - 700 064, INDIA

Specular reflectivity and off-specular diffuse scattering measurements of x-ray beams enables us to gather important

structural information regarding the top surface and buried interfaces of a periodic multilayer systems [1]. The merit of these x-ray scattering techniques will be illustrated using a MOCVD grown semiconductor multilayer and an metal-organic multilayer grown by Langmuir Blodgett (LB) technique. We shall present here an iterative inversion scheme [2] to extract electron density profile of a multilayer structure as a function of depth from the specular reflectivity data. In epitaxial semiconductor multilayers, understanding of interfacial roughness and inter diffusion is very important to develop proper devices. We shall demonstrate here the possibility of separating out these two contributions in the electron density profiles of interfaces by utilizing information obtained from the analysis of diffuse scattering data. The extracted compositional profile may be used [2] to calculate structural details of the film around (00l) diffraction peaks. Here we shall also present results [3] of reflectivity and diffuse scattering studies of cadmium arachidate LB films and formation of nanometer sized CdS particles in the interfaces of these films exposed to hydrogen sulphide environment.It was found that CdS particles remain confined at each multilayer interfaces. Logarithmic in-plane correlation, characteristic of capillary waves on liquid surfaces, was observed in both exposed and unexposed LB films.

M06.EE.004 RECONSTRUCTION OF SURFACE MORPHOLOGY FROM COHERENT X-RAY SCATTERING. I.A. Vartanyants, I.K. Robinson, J.A. Pitney, J.L. Libbert Department of Physics, University of Illinois, Urbana, IL 61801, US

Coherent X-ray Diffraction (CXD) is a new experimental technique that has emerged from the development of brilliant synchrotron-radiation sources of X-rays. While incoherent X-ray reflectivity from a rough surface would give rise to a superposition of pure specular and diffuse components, the equivalent CXD experiment yields an interference pattern that intermixes both of these components. CXD experiment performed in the specular reflectivity geometry after phase retrieval procedure could give a real image of the crystal surface (in analogy with the phase contrast imaging). In this work we will discuss the origin of these interference patterns seen in different CXD experiments and demonstrate a phase retrieval algorithm which can be used to invert it and reconstruct to one-dimensional height images. Convergence properties of this inversion algorithm will be analysed. Examples of phase reconstruction of the surface morphology of Si samples as a function of time will be demonstrated.

M06.EE.005 INTERFACIAL STRUCTURES OF BONDED SI WAFERS. R. Feidenhans'1, M. Nielsen, P.B. Howes [1], S. Weichert, F. Grey [2], J. Vedde [3], [1] Risø National Laboratory, DK-4000 Roskilde, Denmark, [2] Microelektronik Centret, Technical University of Denmark, DK-2800 Lyngby, Denmark, [3] TOPSIL Semiconductor Materials A/S, DK-3600 Frederikssund, Denmark.

Direct bonding of Si wafers is a process where two wafers are pressed together at high temperature to obtain covalent bonding between the wafers. This is a process increasingly used in micro technology devices. In order to investigate the atomic structure in the interface between the two wafers, we have performed synchrotron x-ray diffraction on a variety of different samples. The bonding is obtained in a two-stage process. First the two wafers with mirror flat hydrogen terminated (001) surfaces, are pressed together under clean room conditions. This yield a weak van der Waal type bonding. Secondly the wafers are heat treated at 1000 °C under a nitrogen atmosphere resulting in a much stronger covalent bonding.

The interface may be looked upon as a model grain boundary with zero tilt but with a predetermined twist angle (mutual rotation around [001]) given by the relative orientation of the two crystals. In the interface region the bonding produce a periodic displacement field determined by the rotational misfit, and this in turn give rise to satellite reflection in x-ray diffraction. By measuring the scattering from the satellites as function of the in-plane and the out of plane momentum transfer we get detailed information about the atomic structure of the interface. Measurements were done on samples with twist angles between 0.4° and 7.5°. We find that parallel to the interface the periodic displacement have a very long range order, presumably given by the bulk Si crystal. In direction perpendicular to the interface the range of the displacements, i.e. the interface thickness, is inversely proportional to the twist angle. The results are compared to calculated structure factors applying a model with a periodic net of screw dislocations.

Measurement have also been performed on samples with the same twist angle, but annealed to different temperature, which shows that the covalent bonding form around 800 °C.

P06.EE.001 GRAZING INCIDENCE X-RAY DIFFRACTION STUDIES OF (100) AND (111) ORIENTED FE/AU MULTILAYERS. B.D.Fulthorpe, J.Clarke, B.K.Tanner, Department of Physics, University of Durham, South Road, Durham, DH1 3LE, UK., P.A.Ryan, B.J.Hickey, Department of Physics, University of Leeds, Leeds LS2 9JT UK.

A series of Fe/Au multilayers grown by molecular beam epitaxy on either a MgO substrate with an Fe seed layer or a sapphire substrate with a Nb buffer have been studied using Grazing Incidence X-ray Diffraction at the XMaS beamline, ESRF Grenoble. In this surface diffraction scattering geometry the scattering planes are perpendicular to the plane of the film and measurements are sensitive to in-plane strain and atomic disorder.

Well defined 4- and 6- fold symmetries show the Au layer to be deposited with good (100) and (111) epitaxy in the MgO and sapphire systems respectively. The sharp, high intensity peaks indicate little in-plane crystalline disorder. In contrast, scans performed at the Fe 002 reflection show the crystalline quality of the deposited layers in both systems to be poor and of comparable perfection in each case. Alignment of the Fe 001 and Au 110 reflections in the Fe/Au grown on sapphire corresponds to lattice matching in this direction. Analysis of allowed reflections shows that a mixture of fcc and bcc Fe was present in the multilayers grown on sapphire.

The in-plane lattice parameter for Fe and Au was determined, from coupled $\theta/2\theta$ scans in the horizontal plane, to be in close agreement with standard bulk values with any deviation attributed to a small degree of in-plane strain. A strong Nb signal was detected in the sapphire system even though the Nb layer is well beyond the depth sensitivity of the incident beam. The Nb symmetry indicates (111) oriented epitaxial growth, similar to the Au layers, in contrast to RHEED measurements which suggest the Nb is deposited with a (110) epitaxy.This suggests the presence of Nb within the top 30Å of the multilayer stack which may suggest a surfactant growth mechanism.

P06.EE.002 LATERAL AND VERTICAL ORDERING OF SELF-ASSEMBLED GE/SI QUANTUM DOTS IN SUPERLATTICES. I. Kegel, T.H. Metzger, CeNS at Sektion Physik, Ludwig-Maximilians-Universität München, D-80539 München, J. Stangl, G. BauerInstitut für Halbleiterphysik, Johannes Kepler Universität, A-4040 Linz, Austria

We present a comprehensive ordering analysis of self-assembled quantum dots in a Ge/Si superlattice. The analysis of

both lateral and vertical correlations employs the *strain modulation* in the Si-spacer layers rather than the geometric contrast of the dots themselves. The small angle intensity modulation around different surface Bragg reflections is modeled with a one-dimensional approximation of lattice lines, yielding a nearest neighbor disorder parameter and a correlation length for different directions in the surface plane. In addition, the symmetry of the local ordering together with size and orientation of the pyramidal dots can be inferred from the experimental results. Lateral ordering is induced by the columnar stacking of the dots within the superlattice. The deviation of the dots' position from a perfectly aligned stack is analyzed in terms of a lateral random walk from layer to layer. The analytical expression for the scattering intensity in the vicinity of the surface Bragg peak shows that the quantum dots induce Bragg sheets, whose half widths along the growth direction q_z increase quadratically with lateral momentum transfer $q_{||}$. At large $q_{||}$, the half width levels off asymptotically to the value of an oscillation induced by a single bilayer. This behavior is confirmed by the experimentally determined functional dependencies. From the half widths, we are able to make quantitative estimates for the generic model parameter, describing the lateral shift in position of consecutive dots in a column. For the present case of dots with a square base, a geometrical stacking fault was derived.

P06.EE.003 TOTAL REFLECTION X-RAY AND FLUORESCENCE FOR SMALL D-SPACE MULTILAYER CHARACTERISATION. S.I. Zheludeva, N.N. Novikova, E.Yu. Tereschenko [1], N.N. Salaschenko [2], [1] Shubnikov Institute of Crystallography, Moscow, Russia, [2] Institute of Physics of Microstructure, N. Novgorod, Russia

Small d-space (0.8 - 20 nm) multilayers play an important role in X-ray optics, mainly as optical elements of normal incidence for "water window" range. The main problem of their characterisation in the process of adjusting deposition conditions is their low Bragg reflectivity due to drastic influence of interface perfection to multilayer parameters. The aim of the paper is to reveal the possibilities of multilayer characterisation using only X-ray total reflection (TR) angular range. The problem of obtaining information about multilayers (thickness and density of the layers, concentration gradients, interface interdiffusion and roughness) using besides X-ray reflectivity spectral selective angular dependence of X- ray fluorescence from definite layers is analysed. Special construction of the specimen containing multilayer is proposed. Theoretical aspects of secondary radiation yield from such systems (including the analysis of X-ray wave fields), experimental results and calculations for different small d-space structures at TR region are presented.

This work was supported by the Russian Foundation of Fundamental Research, project no. 98-02-16704.

P06.EE.004 THE EFFECT OF INTERFACE AND CRYSTAL PERFECTION ON MAGNETOTRANSPORT IN EPITAXIAL AU/FE MULTILAYERS. B.K.Tanner, T.P.A.Hase, B.D.Fulthorpe, S.B.Wilkins, Dept. of Physics, University of Durham, South Road, Durham, DH1 3LE, U.K. and P.A.Ryan, D.J.Dekadjevi and B.J.Hickey, Dept. of Physics & Astronomy, University of Leeds, Leeds, LS2 9JT, U.K.

X-ray reflectivity, diffuse scatter, fluorescence and surface diffraction, all at grazing incidence, have been used to study the relation between structure and magnetotransport properties of epitaxial Au/Fe multilayers grown by MBE on sapphire and MgO respectively. Despite the multilayers grown on MgO having rougher interfaces, the antiferromagnetic coupling and associated giant magnetoresistance are higher than for equivalent thickness layers grown on sapphire. High resolution high angle X-ray diffraction shows the (001) MgO substrates result in (001) oriented Au layers and the *a* plane sapphire and its (110) Nb buffer give (111) orientation Au layers. Both multilayers have crystallographically abrupt interfaces with little interdiffusion, the MgO system showing parabolic dependence of the rocking curve width with satellite order, as predicted for a rough inteface by the model of Holý *et al*. Under prolonged exposure to the focussed beam at the XMaS beamline at the ESRF, high order satellites disappeared from a multilayer on sapphire, indicating that substantial interface diffusion was occurring. Grazing incidence diffraction data show good in-plane order and little strain in the Au layers grown on either substrate. The quality of the Fe layers is relatively poor and similar in the two cases. Alignment of the [100] direction in the Fe with the [110] in the Au was observed in the system on sapphire. A six-fold symmetric diffraction pattern of sharp peaks, which could not be attributed to either the Au or the Fe lattice and corresponded to a lattice spacing of 2.33Å, was also observed in this system. Grazing incidence fluorescence measurements as a function of angle show unequivocally that Nb exists in the Au/Fe multilayer above the buffer layer. Simulation of the angular dependence of the fluorescence data shows that this is not simply a surface layer.

P06.EE.005 QUANTIFICATION OF ORDERED DOMAINS IN III-V COMPOUND HETEROSTRUCTURES. M.S. Goorsky, R.R. Hess, C.D. Moore, R.L. Forrest, and T. Neilsen, Department of Materials Science and Engineering, UCLA, Los Angeles, CA 90095-1595

We determined the degree of ordering in single layer $In_xGa_{1-x}P$ on GaAs and $In_yGa_{1-y}As$ on InP epitaxial heterostructures and in GaAs-based solar cells using double axis and triple axis x-ray diffraction. Although ordering in III-V heterostructures has been observed using x-ray diffraction techniques, little information about the degree of ordering or the crystalline perfection of the ordered domains has been reported. In this study, the ½ (115) ½ (113) reflections were employed to detect the presence of CuPt-type ordering. The ½ (115) reflections were investigated in both glancing and skew geometries to determine the parameters of the ordered regions and the presence of different ordered variants along different crystallographic directions. Reciprocal space mapping provided information about the origins of peak broadening in the ordered domains; unlike earlier studies which only employed double axis measurements, we determined that the broadening originates from a combination of tilts and finite domain size. Comparison of the superlattice and fundamental zincblende reflections (½ (115) and (224) have comparable footprints) provided for a means to quantify the extent of ordering; these values were confirmed with transmission electron microscopy and photoluminescence measurements.

06FF MOLECULAR MAGNETS

M06.FF.001 CLUSTERS AND EXTENDED ARRAYS WITH PARAMAGNETIC METAL IONS AND NITROGEN DONOR LIGANDS. Kim R. Dunbar,* Cristian Campos, Rodolphe Clerác, Jennifer A. Smith and Paul Szalay, Department of Chemistry, Texas A&M University, College Station, Texas, 77840.

The use of polypyridine-type ligands in closed-shell supramolecular chemistry is well-documented, but their use in open-shell metal systems has been much less explored. We are using both convergent and divergent synthetic methodologies to assemble paramagnetic metal ions with bis- and tris-chelating ligands based on bipyridine, terpyridine, and bipyrimidine functionalities. Depending on the choice of co-ligands and the topology of the nitrogen donors, one can design clusters with square, rectangular and trigonal-based geometries. Ligands such

as bis-pyridylphenazine (bptz), tetra-pyridylpyrazine (tppz), and hexaazatriphenylene (hat) are among some of the bridging ligands being employed in these studies. Other molecular assemblies under investigation employ octahedral metal ions in the synthesis of paramagnetic squares and cubes with cyano or metal-dicyano linking groups. The choice of capping ligands are two *cis*-directing bidentate chelates for the squares and *fac*-coordinating tris(pyrazolylborate) "caps" for the cubes. The magnetic properties of the various clusters under investigation are being explored in hopes of gaining further insight into the influence of size, shape, single ion anisotropy and magnitude of ground state S values on the magnetic properties of large paramagnetic clusters.

M06.FF.002 DESIGN OF CRYSTAL AND MAGNETIC STRUCTURES OF TRANSITION METAL COMPLEXES WITH ORGANIC FREE RADICALS. H. Iwamura, N. Koga, and K. Inoue National Institution for Academic Degrees, Nagatsuta, Midori, Yokohama 226-0026, Faculty of Pharmaceutical Sciences, Kyushu University, Maidashi, Higashi, Fukuoka 812-8582, and Institute for Molecular Science, Okazaki, Aichi 444-8585, Japan

Bis- and tris(aminoxyl) radicals and di(4-pyridyl)diazomethane form with M(hfac)2 {M = Mn(II) or Cu(II), and hfac = hexafluoroacetyl-acetonate} crystalline complexes having linear, cyclic, and network structures. Organic 2p and metal 3d spins in these complexes order at 3.4-46 K depending on the dimension of the extended structures and the magnitude of the exchange coupling between the adjacent spins. In the crystals of one-dimensional systems, the polymeric chains are isotactic in that free radicals or hexacoordinated metal centers have severally the same sign of chirality along any given chain. When the chains are syndiotactic, they form rings or cross-link to form two-dimensional honeycomb or three-dimensional parallel-crosses networks.

M06.FF.003 MULTIFUNCTIONAL COORDINATION COMPOUNDS: DESIGN AND PROPERTIES. Silvio Decurtins, Department of Chemistry and Biochemistry, University of Bern, Freiestrasse 3, CH-3012 Bern

Our laboratory has reported on the synthesis and structure determination of coordination solids which typically behave as host/guest compounds with different lattice dimensionalities. Thereby, the idea of a reasonable strategy looks straightforward: mix metal ions with a preference for a particular coordination geometry with bridging ligand systems - and it is important to control both the kinetics and thermodynamics of the assembly process - then, a crystalline network will nucleate and grow. As a consequence, a whole class of a new material with a specific chemical composition but with a wide variety with respect to the incorporated metal ions from the transition-metal series and the lanthanide series has been synthesized and structurally well defined. The benefits are twofold: First, a valuable know-how in the synthesis and crystal engineering of extended molecular network compounds has now been established which clearly will be of great value for the synthetic development of further supramolecular materials. Second, a broad range of physical techniques, like magnetization studies, photophysical studies and neutron scattering experiments, has been applied for the investigation of the whole spectrum of the inherent physical properties.

M06.FF.004 EXTENDED STRUCTURES OF METAL DICYANAMIDES AND THEIR MAGNETIC ORDERING. K.S. Murray, S.R. Batten, G.D. Fallon, P.Jensen, B. Moubaraki, D.J. Price and E.H-K Tan, Chemistry Department, Monash University, Clayton, Victoria 3168, Australia.

In 1997/98 a series of known transition-metal dicyanamide complexes [1] of type α-$M(N(CN)_2)_2$ were found to adopt a single 3D-network rutile-like structure in which the octahedral M(II) ions are connected by three-connecting $N(CN)_2^-$ ligands. Detailed structural and magnetochemical studies on this isostructural family of compounds made by ourselves [2] and two other groups [3,4] revealed a fascinating and diverse array of types of long range magnetic order. Thus, the Cu(II) complex is a paramagnet, Co(II) and Ni(II) complexes are ferromagnets and Mn(II) and Fe(II) complexes are spin-canted antiferromagnets (weak ferromagnets), with ordering temperature of less than 20K. Structural and electronic reasons for these differences in magnetism will be presented.

A large series of 2D-linked compounds of type $M(N(CN)_2)_2(L)$, where M = Mn, Fe, Co, Ni, Cu and L = pyrazine and 4,4'-bipyridine, will be described, some of which display interpenetrating double-net structures. To date, most of these compounds display weak coupling without long range orders. Anionic complexes of type $[M(N(CN)_2)_3]^-$ also display beautiful sheet-like extended structures.

M06.FF.005 POLYNUCLEAR HOMO- AND HETERO-METALLIC CLUSTERS AND CHAINS - STRUCTURE AND MAGNETISM. L.K. Thompson, C.J. Matthews, S.R. Parsons, L. Zhao and D.O. Miller, Department of Chemistry, Memorial University, St. John's, Newfoundland, A1B 3X7, Canada, and C. Wilson and J.A.K. Howard, Department of Chemistry, University of Durham, Durham DH1 3LE, UK.

Polyfunctional, donor rich diazine ligands, with both N-N and O bridging groups, react with a variety of transition metal cations in a self assembly process to produce a series of homo-metallic and hetero-metallic spin coupled clusters. Tetranuclear clusters with square M_4O_4 cores (M=Mn(II), Co(II), Ni(II), Cu(II)) and rectangular mixed bridge $M_4(N\text{-}N)_2O_2$ cores (M=Co(II), Cu(II)) are formed by direct reaction of the ligands with metal salts. Mixed metal, rectangular and square clusters ($Fe(III)_2Co(II)_2(N\text{-}N)_2O_2$, $Fe(III)_2\ Ni(II)_2O_4$) form in an unusual self assembly process starting with a mononuclear Fe(III) complex and reacting with the other metal salt. Pentanuclear, homoleptic Mn(II) and Co(II) clusters are formed in an unprecedented self assembly process where the trigonal bi-pyramidal cores involve just alkoxide bridges between metal centres, and there is an exact match between the coordination algorithm of the metals and the donor groupings of the six coordinated ligands. A strategy for cluster growth by building upon a Cu_4O_4 core with a ligand which has additional exterior coordination capacity will be illustrated with an unusual 4+1 pentanuclear complex, and by a tactic in which two identical spin-coupled dinuclear Cu(II) fragments are tied together with a strapping ligand to form a tetranuclear Cu(II) cluster. The structural and magnetic properties of key examples of these novel classes of clusters will be discussed and the magnetic properties explained in terms of the bridging interactions.

The structures and magnetic properties of some trinuclear and tetranuclear Ni(II) and Cu(II) complexes of a group of extended, flexible diazine ligands will also be described, including a novel tetrahedral Ni(II) cluster, and a linear, spiral trinuclear Ni(II) derivative.

M06.FF.006 MAGNETIC PHASE DIAGRAMS FOR MOLECULE-BASED FERROMAGNETS. Olivier Kahn, Laboratoire des Sciences Moléculaires, Institut de Chimie de la Matière Condensée de Bordeaux, UPR CNRS No 9048, 33608 Pessac, France.

The goal of our lecture is to introduce the dimension « magnetic anisotropy » in the field of molecule-based magnets. For that, we will focus on three cyano-bridged $Mn^{II}Mo^{III}$ compounds synthesized from the $[Mo^{III}(CN)_7]^{4-}$ precursor. Two of the compounds have a three-dimensional structure. Their formulas are $Mn_2(H_2O)_5Mo(CN)_7 \bullet nH_2O$, with n = 4 for the α phase, and n = 4.75 for the β phase. One of the compounds, of formula $K_2Mn_3(H_2O)_6[Mo(CN)_7]_2 \bullet 6H_2O$, has a two-dimensional structure, with K^+ cations and water molecules located between double-sheet layers. The compounds crystallize in the monoclinic system, and the lattice symmetries are very low. For the three compounds, we succeeded to grow well-shaped single crystals suitable for magnetic anisotropy measurements. These measurements have revealed the existence of several magnetically ordered phases for the three-dimensional compounds, and of field-induced spin reorientations for the three compounds. For the very first time in the field of molecular magnetism, we were able to determine the magnetic phase diagram for each compound. We obtained additional information from magnetic data recorded in the ac mode, with both zero and non-zero static fields. Finally, we found that when the non-coordinated water molecules are released, the long-range magnetic ordering temperatures are shifted toward higher temperatures. Irrespective of the structural details, the Mo^{III}-C-N-Mn^{II} interaction was found to be ferromagnetic. We will discuss this unexpected result, and propose a mechanism accounting for this. We will also discuss the factors governing the magnetic anisotropy of the compounds.

P06.FF.001 TEMPERATURE AND PRESSURE DEPENDENCE OF THE CRYSTAL STRUCTURES OF SPIN CROSSOVER FE(II) COMPOUNDS. P. Guionneau, J.F. Létard, Y. Barrans, J. Gaultier, D. Chasseau, O. Kahn, Laboratoire des Sciences Moléculaires, Institut de Chimie de la Matière condensée de Bordeaux, UPR 9048, Pessac, France, J.A.K. Howard, Durham Crystallography Group, Chemistry Department, Science site, Durham DH1 3LE, U.K.

The electronic transition called spin crossover is commonly encountered among metal complexes. This phenomenon derives from the existence of two different configurations for the metallic ion characterized by different spin states. In general, such a transition can be induced by thermal changes, pressure effects or exposure to electromagnetic rays and be smooth or abrupt, accompanied, or not, with a hysteresis phenomenon. The series of the $Fe(PM\text{-}L)_2(NCS)_2$ spin crossover complexes, provided us the occasion to study similar molecules with very different features of temperature or pressure induced transitions. The crystal structures of four complexes were determined in the high spin state (high temperature) and in the low spin state (low temperature) allowing us to link the topology of the intermolecular interactions to the features of the transitions. For instance, the strong combination of intersheet and intrasheet intermolecular contacts between phenyl rings seems to be the relevant parameter which govern the abruptness of the transition. In the same way, the increase of the hysteresis effect is related to the presence of strong intermolecular contacts associated with an irregular iron network in the high spin state. The pressure strongly affects, in a reversible or irreversible mode, the temperature of transition and the width of the hysteresis.

P06.FF.002 MOLECULAR DISTORTION IN A NICKEL COMPLEX COUPLED TO A REVERSIBLE PHASE TRANSITION WITH SUPRAMOLECULAR AGGREGATION. Fernando Palacio,[§] Larry R. Falvello,[†] Michael A. Hitchman,[‡] Isabel Pascual,[†] Arthur J. Schultz[¶], Horst Stratemeier,[‡] Milagros Tomás,[†] Esteban P. Urriolabeitia,[†] and Dianna M. Young[¶], [†]University of Zaragoza - C.S.I.C., Department of Inorganic Chemistry, Plaza San Francisco s/n, E-50009 Zaragoza, Spain. [‡]University of Tasmania, Department of Chemistry, Box 252-75, Hobart, Tasmania 7001, Australia. [§]C.S.I.C.-University of Zaragoza, Department of Condensed Matter Physics, Plaza San Francisco s/n, E-50009 Zaragoza, Spain. [¶]Intense Pulsed Neutron Source, Argonne National Laboratory, Argonne, IL 60439-4814, USA.

The six-coordinate coordination complex trans-[Ni(cyan-*N*)$_2$(NH$_3$)$_4$] has been characterized in the solid state by x-ray and neutron diffraction at temperatures ranging from 11 K to 298 K, by electronic spectroscopy over the temperature range 14-297 K, and by magnetic susceptibility measurements from 1.8-300 K. At room temperature the solid has the space group Fmmm, and the nickel center lies on a site of mmm symmetry. At lower temperatures, the space group changes to Cmcm without appreciable change in the unit cell parameters, and the molecule lies at a site of m2m symmetry. The shape of the molecule changes smoothly with temperature variations from room temperature down to about 140 K, in a behavior characteristic of second-order phase transformations. The molecular shape varies, but by lesser amounts, below 140 K. Possible causes of this phenomenon are discussed. The increase in intensity on cooling of some of the bands observed in the polarized crystal spectrum of the complex is consistent with the change in structure of the complex. Bonding parameters derived from the transition energies indicate that the cyanurate produces a very weak ligand field, which is consistent with the long metal-ligand bond length to this ligand. The magnetic properties of the solid display Curie-Weiss behavior through the temperature range of the most pronounced molecular shape changes, but antiferromagnetic interactions become significant below 50 K, with antiferromagnetic ordering at 2.61 K. The propagation pathways for the magnetic interactions are inferred.

P06.FF.003 ELECTRON DENSITY DISTRIBUTIONS OF Cu(II) AND Co(II) COMPLEXES SHOWING MAGNETIC INTERACTIONS. M. Yasui, N. Akiyama, R, Takayama, T. Ishikawa, D. Hashizume and F. Iwasaki, Dept. of Applied Phys. and Chem. The Univ. of Electro-Communications, Chofu, Tokyo 182-8585, Japan.

Recently some transition metal complexes showing magnetic interactions were investigated [1]. We have carried out the structure analyses of Cu(II)-pyrimidine and Co(II)-pyrimidine complexes which show magnetic interactions. In these complexes, metal atoms are bridged by a pyrimidine to form a one-dimensional chain and a three-dimensional network for Cu and Co complexes, respectively. Such a polymeric structure is considered to be essential for magnetic interactions. In order to elucidate the correlation between magnetic properties and interactions of bridging ligands with 3d electrons, the electron density distributions of $[Cu(II)(NO_3)_2(pm)_3]$ (**1**) (ferromagnetic interactions), $[Cu(II)(NO_3)_2(pm)_2(H_2O)_2]$ (**2**) (antiferromagnetic interactions) and $[Co(II)Cl_2(pm)_4]$ (**3**) (antiferromagnetic interactions) were investigated with a multipole refinement technique using X-ray intensity data at a low temperature. The Cu atom in **1** is coordinated square pyramidally by two O atoms and three N atoms. Additionally, two weak interactions between O and Cu are observed. In **2**, the Cu atom is coordinated octahedrally by four O and two N atoms. The Co atom is coordinated octahedrally by two Cl and four N atoms in **3**. The deformation density maps of **2** show six peaks around the Cu

atom, which are located to avoid the ligands. These peaks can be assigned as 3d electrons. Electron densities for lone-pairs of ligands are also clearly observed. In the case of **1**, the Cu atom has a pseudo seven-coordination so that the interpretation of electron densities around the Cu atom gives some difficulties. The multipole refinement on **3** is in progress.

07OA PROBLEMATICS IN MACROMOLECULAR STRUCTURES: (I) PHASING (sponsored by Rigaku)

M07.OA.001 DETECTING AND EXPLOITING NON CRYSTALLOGRAPHIC SYMMETRY IN MOLECULAR REPLACEMENT

. Jorge Navaza, CNRS, France.

Crystal structures containing many independent molecules in the asymmetric unit are in general may be difficult problems to solve by MR. The reason of the difficulties cannot be ascribed solely to the inherent limitation of the usual formulation of the method, i.e. rotation searches performed independently of the translation ones. Indeed, very often the best values of rather robust criteria correspond to wrong one-body positions. Therefore, it is the overall strategy of the method, based on locating one body after the other that fails if the first bodies are not correctly placed.

The symmetry elements detected by the self rotation and the Patterson functions, associated to strong correlations between the positions of the molecules in the asymmetric unit, may be used to reduce the effective number of independent bodies to be located by MR. A distinction is made between 'frustrated' crystallographic symmetries, i.e. those that are almost crystallographic ones, and 'standard' non-crystallographic symmetries, which are taken into account by specific techniques. These have been successfully applied to many body macromolecular crystal structures, with important save in time and computational effort [1].

M07.OA.002 PUSHING THE BOUNDARIES OF MOLECULAR REPLACEMENT WITH MAXIMUM LIKELIHOOD.

Randy J. Read, Department of Haematology, University of Cambridge, Cambridge Institute for Medical Research, Wellcome Trust/MRC Building, Hills Road, Cambridge CB2 2XY, UK.

As the database of known macromolecular structures grows exponentially, the molecular replacement method can solve ever more crystal structures. Nonetheless, it sometimes fails, perhaps because of the use of heuristic target functions. The great success of maximum likelihood in structure refinement suggests that likelihood-based targets may have a similar impact on molecular replacement.

The use of likelihood for molecular replacement was first suggested by Bricogne (CCP4 Proceedings, 1992), who provided some approximations that could be computed quickly, and an interpretation of the likelihood function in terms of current molecular replacement targets.

The likelihood target used in structure refinement is appropriate for the translation problem in molecular replacement, or even for simultaneous rotation and translation. In contrast, in a rotation search the positions of the symmetry-related molecules, and thus the relative phase of their contributions, are still unknown. The likelihood target must be built on probability distributions that take account of this extra level of ambiguity. Such distributions have been derived using techniques developed by Shmueli and coworkers (Shmueli & Weiss, Introduction to Crystallographic Statistics, IUCr Monograph 6, 1995) in the context of intensity distributions to which the central limit theorem cannot be applied.

Both likelihood functions require values for a σ_A curve as a function of resolution, which are normally estimated once one has a complete atomic model. Fortunately, reasonable values can be estimated in advance by exploiting correlations between sequence identity and coordinate deviation.

Initial tests are extremely promising. Likelihood-based molecular replacement has much better signal to noise and significantly greater accuracy, so that previously insoluble problems can be overcome.

M07.OA.003 MULTIPLE SAMPLINGS OF THE RECIPROCAL LATTICE AND MAP AVERAGING AS A SOURCE OF PHASE INFORMATION.

Kevin Cowtan, University of York

Multiple-crystal averaging has been applied with great success to the problem of phase improvement, and multiple crystal forms hold potential as a source of ab-initio phase information. In theory, if the magnitudes of the continuous molecular transform are available, then direct phasing is trivial either in real or reciprocal space. In practice, the molecular transform is obfuscated by both symmetry and coarse sampling, thus in general techniques are currently limited to phase improvement. However phasing a small molecule has been demonstrated from a single atomic position using 6 copies of the molecule across 3 crystal forms. In practice the use of frozen crystals is now a common source of slightly non-isomorphous crystal forms, which are in some cases useful as a source of phase information. Trials with simulated data demonstrate the usefulness of this approach and the limits arising from noise in the data and non-isomorphism in the crystals.

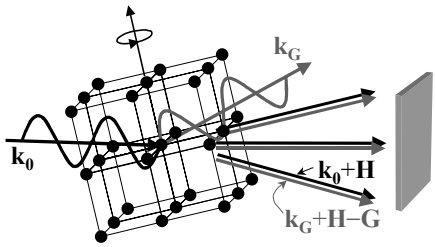
M07.OA.004 STRUCTURE DETERMINATION OF E. COLI CLPP USING 14-FOLD NON-CRYSTALLOGRAPHIC SYMMETRY AVERAGING.

Jimin Wang Department of Molecular Biophysics and Biochemistry, Yale University, New Haven, CT 06520-8114, U.S.A.

We have determined the crystal structure of E. coli ClpP at 2.2 angstroms resolution using a de novo non-crystallographic symmetry (NCS) averaging procedure. ClpP is one of five known large ATP-dependent proteolytic complexes, which regulate many cellular processes through rapid protein degradation. ClpP is a homo-tetradecameric oligomer as revealed by ultracentrifugation analysis; it has a hollow cylinderic structure with a height of 75 angstroms and inner and outer diameters of 35 and 100 angstroms as derived from small-angle x-ray scattering studies; and it has two back-to-back stacked rings of heptamers as determined by electron microscopy. Combined with these biophysical data, we were able to solve the phase problem from x-ray diffraction intensity data alone in the determination of the crystal structure. The hollow cylinderic structure was placed in the unit cell by a packing search program within 5 angstroms of accuracy, and the noncrystallographic symmetry matrices were directly derived from self-rotation function. The initial structure provided initial phases for reflections between 80 and 20 angstroms, and allowed us to extend the phases to the 2.2 angstroms resolution limit by iterative NCS averaging with matrix refinement and mask redetermination. This method should have a general application to the phasing problem in the structure determination of many biological oligomers.

M07.OA.005 TRIPLET-PHASE DATA COLLECTION WITH AN OSCILLATING CRYSTAL TECHNIQUE IN REFERENCE-BEAM GEOMETRY. Qun Shen[1], Stefan Kycia[1], and Ivan Dobrianov[2], [1]Cornell High Energy Synchrotron Source (CHESS) and [2]Department of Applied Engineering Physics, Cornell University, Ithaca, New York 14853, USA

It has been known that 3-beam x-ray diffraction can be used to measure triplet-phases of the structure factors directly from a diffraction experiment, typically using an azimuthal scan or ψ-scan technique. One serious limitation of this conventional ψ-scan technique is that 3-beam interference profiles are measured one at a time. Therefore the whole experimental procedure is rather tedious and time-consuming when many 3-beam profiles are to be measured, as usually needed in the case of macromolecular structures. To solve this problem, recently we have developed a new reference-beam diffraction method [Phys. Rev. Lett. 80, 3268 (1998)] to collect 3-beam interference data, using an oscillation camera in a Bragg-inclined geometry and an area detector such as a CCD. This technique has been shown applicable to both small molecule com-pounds and larger structures such as a protein. In addition to being able to collect a complete set of 3-beam interference data in a short time period, the reference-beam geometry offers other advantages such as a simplified polarization dependence and a single dynamical phase that is common to all 3-beam profiles collected in a data set. Once fully developed and automated, this technique may become a powerful tool for phasing crystal structures in conjunction with the direct methods. This work is supported by NSF grant DMR 97-13424 through CHESS.



07OB ENGINEERING MACROMOLECULES FOR CRYSTALLISATION

M07.OB.001 USE OF MODULES FOR RNA CRYSTALLIZATION Adrian R. Ferre-D'Amare & Jennifer A. Doudna, Department of Molecular Biophysics and Biochemistry, Yale University, New Haven CT 06520-8114, USA

The rate-limiting step in the determination of the structure of complex RNAs is often the growth of crystals. Even when crystals are successfully grown, these commonly do not diffract X-rays to high enough resolution. This could be because the molecular surface of folded RNAs is dominated by a regular array of phosphates, leading to neighboring molecules packing out of register in the crystal. In order to overcome this problem, we have developed two classes of crystallization modules, molecular moieties that are inserted into the sequences of the target molecules to provide differentiated surfaces which can make crystal contacts. The modules are placed in such a way that they do not affect the structure and function of the RNA segment of interest. The first class of modules employs the components of a long-range intramolecular RNA interaction, which are recruited to make instead a directional and stereospecific crystal contact [1]. In the second class of module, we introduce a cognate site for a sequence-specific RNA binding protein into the target RNA molecule. The complex formed between the engineered RNA and a strongly basic RNA-binding protein has not only a patch of positive charge, but also the large variety of surface functional groups of the protein available for making crystal contacts. Using this approach, we obtained crystals of an engineered hepatitis delta virus ribozyme bound to the RNA-binding domain of the U1A protein. The rhombohedral crystals diffracted X-rays to beyond 2.2 Å resolution. We prepared selenomethionyl U1A protein and co-crystallized it with the RNA to solve the structure of the complex by the MAD method [2]. Use of the crystallization modules is being extended to a variety of RNA molecules.

M07.OB.002 ENGINEERING IMPROVEMENTS IN CRYSTALS- EXPERIENCES OF RNP DOMAIN CONTAINING PROTEINS S. R. Price [1], C. Oubridge, K. Nagai [2], [1] Dept. Biochemistry and Molecular Biophysics, Columbia University, New York USA, [2] MRC Laboratory of Molecular Biology, Hills Road, Cambridge, UK

There is no substitute for good data in the solution of crystal structures. The utilisation of molecular biology techniques to overcome technical difficulties in the preparation of diffraction quality crystals has proven extremely powerful. I shall describe our experiences in the solution of two protein-RNA complex structures and how Protein- and RNA-engineering allowed the solution of these structures. RNA sequence changes proved critical to the generation of useful crystals. In addition, problems caused during heavy atom derivitisation were overcome by the judicious use of protein-engineering combined with a biochemical assay. It is highly unlikely that these structures would have been solved if these techniques had not been employed.

M07.OB.003 COVALENT TRAPPING OF A CATALYTIC HIV-1 REVERSE TRANSCRIPTASE/ SUBSTRATE COMPLEX. H. Huang and G. L. Verdine, Department of Chemistry and Chemical Biology, Harvard University, Cambridge, MA 02138, USA. R. Chopra and S. C. Harrison, Howard Hughes Medical Institute and Department of Molecular and Cellular Biology, Harvard University, Cambridge, MA 02138, USA.

A combinatorial disulfide crosslinking strategy was used to trap a complex of human immunodeficiency virus-type 1 (HIV-1) reverse transcriptase with a DNA template:primer and a deoxynucleoside triphosphate (dNTP), thereby enabling the growth of co-crystals suitable for high-resolution structural analysis. The crystals contain a fully assembled active site poised for catalysis. The crosslink itself appears to be conformationally mobile, and the surrounding region is undistorted, suggesting the crosslink is a structurally passive device that merely acts to prevent dissociation of the catalytic complex. Conformational changes that accompany formation of the catalytic complex produce distinct clusters of the residues that are altered in viruses resistant to nucleoside analog drugs. The positioning of these residues in the neighborhood of the dNTP helps to resolve some long-standing puzzles about molecular basis of resistance. The covalent trapping strategy described here may be useful with other protein-DNA complexes that have been refractory to structural analysis.

M07.OB.004 CRYSTALLOGRAPHIC STUDIES OF E. COLI RNA POLYMERASE SUBUNITS. Gongyi Zhang, Seth A. Darst, The Rockefeller University, New York, NY 10021 USA.

E.coli RNA polymerase (RNAP) contains an essential catalytic core of two alpha subunits (each 36.5 kDa), one Beta(150.6 kDa), and one beta'(155.2) subunit, each having

sequence hololog from bacteria to man. The alpha subunit, which plays a critical role by serving as the initiator for RNAP assembly, contains protein-protein interaction determinants for alpha dimerization, for the interaction of beta to form a2b subassembly, and for the interaction with beta' to form core RNAP. Limited proteolysis has shown that the alpha subunit comprises at least two domains, an N-terminal domain(NTD), which is fully competent for RNAP assembly and basal transcription in vitro, and a C-terminal domain(CTD), which is dispensable for basic assembly and transcription but interacts with the UP-element of certain promoters and is required in vivo to interact with a wide array of transcription activators. Due to crystallization problems, the alpha structure was unknown. By creating dozens of truncation and point mutations of alpha NTD, we eventually obtained one mutation that yielded good crystals for structure determination. Encouraged by these results, we made the same mutaion in the context of full length alpha. This version of alpha crystallized and the crystals diffract to 2.5 angstrom. We have applied this approach successfully to other proteins as well.

M07.OB.005 STRUCTURE OF HTLV-1 GP21 ECTODOMAIN CRYSTALLIZED AS AN ENGINEERED MALTOSE-BINDING PROTEIN CHIMERA. B. Kobe, R.J. Center, B.E. Kemp and P. Poumbourios, St. Vincent's Institute of Medical Research, 41 Victoria Parade, Fitzroy, Victoria 3065, Australia.

Human T cell leukemia virus type 1 (HTLV-1) is a retrovirus associated with adult T-cell leukaemia and tropical spastic paraparesis/HTLV-1-associated myelopathy. Envelope glycoproteins (Env) mediate the attachment and subsequent membrane fusion of virions and infected cells with target cells. The native HTLV-1 Env consists of a receptor-binding subunit (SU) gp46, and a non-covalently associated transmembrane subunit (TM) gp21, formed by a proteolytic cleavage of a polyprotein precursor gp62. Receptor binding triggers conformational changes in retroviral SU-TM complexes that result in TM-mediated fusion. While the cellular receptors for HIV-1 SU gp120, CD4 and the chemokine receptors have been extensively studied, the HTLV-1 gp46 receptor(s) are unknown.

We report the crystal structure of the HTLV-1 gp21 ectodomain (residues 338-425, gp62 numbering) at 2.5 Å resolution. We used a novel strategy for crystallisation and structure determination whereby the gp21 segment was linked to maltose-binding protein (MBP) as a crystallisation tag of known three-dimensional structure. Guided by the available biochemical data and structure predictions, the linker between MBP and gp21 was engineered to reduce flexibility, and C-terminal truncations were made to improve the quality of the crystals. The MBP domain was used to obtain the initial phases by the method of molecular replacement. The method employing MBP-chimeras may have a general application in crystallisation and structure determination.

The structure of gp21 shows an N-terminal trimeric coiled coil, a disulfide-bonded loop that stabilises a chain reversal, and a C-terminal sequence that packs against the coil in an extended anti-parallel fashion. Comparison of the gp21 structure with the structures of other retroviral TMs contrasts the conserved nature of the coiled coil-forming region and adjacent disulphide-bonded loop with the variable nature of the C-terminal ectodomain segment. The structure points to these features having evolved to enable the dual roles of retroviral TMs: conserved fusion function and an ability to anchor diverse SU structures to the virion envelope and infected cell surface. The observed structure of gp21 most likely represents the post-fusion conformation, and jointly with the experimental evidence accumulated through cell biological, biochemical, biophysical and structural studies prompts a revised model for retroviral TM-mediated membrane fusion.

07OC PHASE TRANSITIONS

M07.OC.001 DENSITY FUNCTIONAL STUDIES OF PHASE TRANSITIONS: THE FCC-BCC TRANSITION IN METALS. Karlheinz Schwarz, Institute of Physical and Theoretical Chemistry, Technische Universität Wien, A-1060 Vienna, Getreidemarkt 9/158, Austria

The importance of Density Functional Theory (DFT) is steadily increasing in chemistry and physics especially for ground state properties of large systems including transition elements. DFT provides an efficient way to approximately treat exchange and correlation effects. In the early version of DFT within the local density approximation (LDA) deviations from experimental data were found, e.g. overbinding. The use of the generalized gradient approximation (GGA) has led to a significant improvement with nearly chemical accuracy so that structural optimizations or thermo-chemical studies are often well described within DFT/GGA. These aspects rely on the total energy of the systems involved and are based on integral quantities. The Linearized-Augmented-Plane-Wave (LAPW) method as embodied in the WIEN97 code [1] is one among the most accurate schemes to solve the Kohn-Sham equations, the basis of DFT. A fcc-bcc phase transition can be modeled by a displacive transition following the Bain path [2]. A body centered tetragonal unit cell changes from fcc to bcc if the c/a ratio varies form sqrt(2) to 1. LAPW calculations provide the energy hypersurface E(V,c/a) as function of volume and c/a. Finite temperature effects can be accounted for by allowing fluctuations in both of these two variables, V and c/a. The combination of quantum mechanical DFT calculations with statistical thermodynamics (using a Ginzburg-Landau approach) provides an efficient scheme for treating phase displacive transitions.

M07.OC.002 COMPOSITIONALLY AND/OR DISPLACIVELY FLEXIBLE PHASES AND THEIR ASSOCIATED PHASE TRANSFORMATIONS. R.L.Withers, J.G.Thompson and S.Schmid Research School of Chemistry, Australian National University, Canberra, A.C.T, 0200, Australia.

The conventional concept of crystalline phases as translationally periodic objects characterized by well-defined stoichiometries, unit cells and space group symmetries (in three dimensions), and with structures which represent a unique free energy minimum in local parameter space, is a deeply entrenched idea in solid state chemistry. There have, nonetheless, always existed a significant range of compositionally and/or displacively flexible systems whose chemistry and “crystallinity” are not best expressed in this form [1-3]. The very flexibity of such systems suggests a delicate balance of forces which can be “tipped” one way or the other via slight changes in external conditions or composition. It is important not just to “solve” for the structures of any such phases in isolation but also to relate the various phases within such systems.

Structure refinement of flexible phases often necessitates a modulated structure approach [1-2]. Even when this is apparently not the case, *e.g* in the case of long period superstructures, a modulation wave approach still has distinct advantages as it enables a unified description of superficially distinct but clearly related variant phases as well as of the phase transformations that such flexible phases often undergo as a function of temperature, composition *etc*. Examples to be discussed include wide range, non-stoichiometric solid solutions [1] and displacively flexible tetrahedral framework structures [2].

M07.OC.003 FERROELASTIC PHASE TRANSITIONS. E.K.H. Salje Department of Earth Sciences Cambridge University, Downing Street Cambrdge CB2 3EQ, UK.

Ferroelastic phase transitions often generate characteristic domain pattern. Such patterns consist of twin boundaries, their junctions and complex structures which contain twin boundaries as basic elements (e.g. combs, zig-zag patterns, stripe patterns, needle and trumpet domains etc). The thicknesses of twin walls are determined by X-ray diffraction methods using dedicated 7-circle diffractometers. Typical wall thicknesses were found to be between 1nm and 7 nm (Salje 1993). It is shown that the interaction between domain walls and crystal surfaces lead to the formation of lattice instabilities including the formation of elastic 'funnels' which enable diffusion through the surface into the twin wall. Enhanced oxygen and sodium diffusion is shown in WO3 and related structures.

Almeida, Departamento De Física, Universidade Do Porto, 4150 Porto, Portugal, P. Thuery, S.C.M., C.E.A. / Saclay, 91191 Gif-Sur-Yvette, France, and A. Klöpperpieper, Fachbereich Physik, Universität Des Saarlandes, 66041 Saarbrücken, Germany

We present a structural study of the one-dimensional displacively modulated compound BCCD. The structures of two low temperature commensurate phases of the Devil's staircase-type phase diagram of BCCD, the four-fold and five-fold phases, have been determined by single-crystal neutron diffraction. In both phases, the atomic modulation functions are highly anharmonic with an almost one-third contribution of the third-order harmonic with respect to the first-order one. On the basis of four-dimensional symmetry arguments, we interpret the anharmonicity of the modulation as a soliton regime with respect to the lowest-temperature non-modulated ferroelectric phase. The physical consequences of this low temperature structural anharmonicity are discussed. The previous X-ray four-circle data of the four-fold phase, that had led to a single-harmonic model, have been re-analysed. The discrepancy with the neutron structural model that persists is explained by an irradiation effect at constant temperature : X-rays induce an unusual time-decay of the intensity of high-order satellite peaks (up to ≅ -80 % after 86 hours for third-order ones). Structural conclusions concerning the ``T_s-anomaly'' from an analysis of X-ray area-detector diffractometer data in the four-fold phase of 2 % brominated BCCD are presented.

M07.OC.005 HIGH-PRESSURE INCOMMENSURATE TO NORMAL TRANSITION IN ÅKERMANITE, $Ca_2MgSi_2O_7$. R.J. Angel, J.D.C. McConnell, C.A. McCammon, F. Seifert, Bayerisches Geoinstitut, Universität Bayreuth, D95440 Bayreuth, Germany

Insights into the structural changes accompanying the Incommensurate-Normal (IC-N) phase transition in åkermanite ($Ca_2MgSi_2O_7$) have been obtained through a combination of symmetry analysis, *in-situ* single-crystal high-pressure diffraction and *in-situ* high-pressure Mössbauer spectroscopy.

Åkermanite is tetragonal, space group $P\text{-}42_1m$ and theoretical considerations show [1] that the incommensurate modulated structure stable at room conditions is based upon the irreducible representations A_2 and B_1 of point group -42m. The IC structure is therefore two-dimensional in nature, and consists of the two structural components P-4 and $P2_12_12$. The presence of these two structural components within the crystal structure has been confirmed by *in-situ* high-pressure Mössbauer spectroscopy of Fe-doped åkermanite. The spectra consist of two distinct and sharp doublets corresponding to the two different environments for the Fe/Mg sites in the two component structures. These two absorption doublets merge to a single doublet in the high-pressure N-phase at pressures in excess of 1.8 GPa.

In-situ lattice parameter measurements at high pressure show that the N to IC transition occurs at 1.718(6) GPa. It is accompanied by a large expansion of the c-axis ($e_{33} = 1.6x10^{-3}$ at room P). Smaller spontaneous strains in the (001) plane ($e_{11} = e_{22} \sim -1.0x10^{-4}$) are attributable to the development of the orthorhombic $P2_12_12$ component structure in the IC phase. The pressure evolution of e_{33} shows that the transition is continuous with an effective critical exponent of 0.20(3), indicating that the fourth-order terms in the free energy expansion of the IC phase cancel, as required by symmetry criteria.

P07.OC.001 PHASE TRANSITIONS AND STRUCTURES BETWEEN 10 AND 293 K OF $M(I)M(III)(NH_3)_6(ClO_4)_2X_2$. A.N. Sobolev and B.N. Figgis, Department of Chemistry, University of Western Australia, Nedlands, W.A. 6907, Australia, and R.W.Henning and A.J.Schultz, IPNS, Argonne National Laboratory, IL 60439, USA, and P.A. Reynolds, Research School of Chemistry, Australian National University Canberra, ACT 0200, Australia.

Eighteen crystal structures of ten hexaammine-M(III) double salts of the title formula have been determined by X-ray diffraction where M(I), M(III) and X are NH_4, Co, Cl **(1)**; Cs, Co, Cl **(2)**; NH_4, Ru, Cl **(3)**; K, Ru, Cl **(4)**; Rb, Ru, Cl **(5)**; Cs, Ru, Cl **(6)**; Cs, Cr, Cl **(7)**; Cs, Cr, Br **(8)**; K, Cr, Cl **(9)**; K, Os, Cl **(10)**. The structures of all except **(9)** were determined at 293 K ; **(1), (4), (5)** and **(6)** have also been determined at 92 K; and those of **(5), (7), (8), (9)** and **(10)** at 10 K. At 293 K all are isomorphous, trigonal *R*-3*m*, *Z* = 3, of extremely simple and symmetrical structure. At lower temperatures most crystals undergo a subtle reversible phase change to an equally simple twinned, but atomically ordered, R-3 phase. In these twinned salts, the hexaammine-M(III) and perchlorate ions are rotated from 3 to 11 degrees about the threefold axis to remove the former mirror plane in the *R*-3*m* crystal. Thermal parameters, unit cells, transition temperatures (T_C) (determined by Differential Scanning Calorimetry) and structures vary systematically with M(I) ionic radii and M(III)-N distances. The K^+ members remain R-3m, while the larger M(I) and longer M(III)-N members undergo the greatest rotations with the highest transition temperatures. One of the latter, Cs, Co, Cl **(2)**, has been examined by neutron diffraction at 10, T_C-10, T_C+10 and 290 K. The observed twin populations, orientational order parameter and deuterium disordering indicate that a simple model involving differing

ranges of ionic orientational correlations is appropriate for all these crystals at all temperatures.

P07.OC.002 THE PHASES OF MERCURIC IODIDE. M. Hostettler, H. Birkedal, K. J. Schenk, H. P. Weber and D. Schwarzenbach, Institut de Cristallographie, Université de Lausanne, BSP Dorigny, CH-1015 Lausanne, Switzerland.

At room temperature, HgI_2 crystallizes from 2-chloro-ethanol in either or all of three modifications: the red one (α), thermodynamically stable, the yellow one, related to the high temperature phase (β), and the orange modification, metastable at all temperatures or at least in the range: 100-400K. Owing to the importance of the α-phase as an electronic material, some parts of the HgI_2 P-T phase diagram have been intensively studied in the past [1]. There are no less than 5 different phases at moderate temperatures (T < 600K) and pressures (P < 1.5GPa) [2]. The general features of the phase diagram seem to be well known, but several of the phases are only partially characterized.

Orthoscopic optical studies of the α to β transition, at 400K, are presented. There is a large hysteresis, the yellow crystal has been observed to persist upon cooling in some cases down to 360K. Different nucleation behaviours have been observed when passing through the transition in opposite directions. This indicates a reconstructive mechanism. A model describing the transition from a layered compound (α) to a molecular crystal (β) has been derived from X-ray powder diffraction patterns. The tetrahedral HgI_4 structural motif of the α-phase transforms into a HgI_2 motif with a strongly deformed octahedral Hg-coordination.

We are currently undertaking high pressure powder diffraction measurements of the barotropic α to γ phase transition. The determination of the structure of the γ-phase may shed more light on the transition mechanisms in this system.

P07.OC.003 THE PHASE TRANSFORMATION $Co_2Ge(h) \rightarrow Co_2Ge(l)$. N. Audebrand, M. Ellner and E. J. Mittemeijer. Max-Planck-Institüt für Metallforschung, Seestr. 92, D-70174 Stuttgart, Germany.

The phase transformation $Co_2Ge(h) \rightarrow Co_2Ge(l)$ could not be possible according to the published binary phase diagram Co-Ge [1]. In the present investigation, this transformation has been clearly observed by means of X-ray diffraction, metallographical and differential scanning calorimetry measurements. The (high-temperature) berthollidic phase $Co_2Ge(h)$, according to the published phase diagram stable in the composition range $0.33<x_{Ge}<0.43$, shows a defect Ni_2In structure [Pearson-Parthé symbol *hP*(6-*n*), space group $P6_3/mmc$]. Microscopical analysis, using polarized light, of the slowly cooled bulk alloy $Co_{66}Ge_{34}$ revealed multiple twinning in all grains. Such twinning can be a consequence of shape accommodation due to a polymorphic phase transformation. The Guinier pattern ($CoK\alpha_1$ radiation) of the alloy $Co_{66.6}Ge_{33.3}$ heat treated at 775 K for 5 days yielded diffraction lines of the phase $Co_2Ge(l)$: Co_2P type structure (*oP*12, *Pnma*). The refined lattice parameters of this (low temperature) phase are: a_o = 5.0504(4) Å, b_o = 3.8378(3) Å and c_o = 7.2960(5) Å [M_{20} = 109, F_{26} = 98(0.0078, 34)]. The Guinier pattern of the liquid quenched, splat-cooled, alloy $Co_{66.6}Ge_{33.3}$ showed diffraction lines of only the high-temperature phase $Co_2Ge(h)$ yielding the following refined lattice parameters: a_h = 3.9639(4) Å, c_h = 5.022(1) Å, c_h/a_h = 1,2669>√(3/2) [M_{20} = 139, F_{10} = 63(0.0047, 34)]. The ideal relationship between an orthorhombic and a hexagonal unit cells is: $a_o = c_h$; $b_o = a_h + b_h$; $c_o = -a_h + b_h$ with $c_o/b_o = \sqrt{3}$. The polymorphic phase transformation $Co_2Ge(h) \rightarrow Co_2Ge(l)$ is associated with a strong lattice distortion in the plane $(100)_o$ because c_o/b_o = 1.9011 (but the distortion a_o/c_h = 1.006 is near to the ideal value: 1). Consequently, the change of the average atomic volume $\Delta\overline{V}$ associated with the phase transformation is important, *i.e.*, 0.39 Å^3. Differential scanning calorimetric measurement showed that the phase transformation occurs at about 960 K upon heating.

P07.OC.004 ORDER PARAMETER COUPLING AND CRITICAL BEHAVIOUR OF DEBYE-WALLER FACTOR IN PEROVSKITES. H. Boysen, H. Lehnert and F. Frey, Institut für Kristallographie der Universität München, 80333 München, Germany, and P. Radaelli and Th. Hansen, ILL, 38042 Grenoble, France.

The critical behaviour of various perovskite-like compounds, $LaAlO_3$, $PbTiO_3$ and $LiNbO_3/LiTaO_3$, has been investigated by neutron powder diffraction around their phase transitions *via* detailed structure refinements including anharmonic Debye-Waller factors. The results were analysed in frame of Landau theory using the fluctuation-dissipation theorem to relate the susceptibility to the atomic displacement parameters (ADP's).

In the purely displacive case of $LaAlO_3$ ($Pm3m \leftrightarrow R\bar{3}c$) the rotations of O_6-octahedra, the spontaneous strain and $\boldsymbol{U}_{11}$(O) show the expected critical behaviour. There is, however, no exact linear-quadratic coupling between order parameter and strain: the metric becomes cubic roughly 30 K below the proper T_c. This is related to spontaneous creation of domains imposing the average cubic symmetry *via* internal stresses. In $PbTiO_3$ ($Pm3m \leftrightarrow P4mm$) there are four structural degrees of freedom (*z*-shifts of the various atoms). In the low temperature polar space group the origin is not fixed by symmetry. Analyses of the ADP's show that all $\boldsymbol{U}_{33}$'s except $\boldsymbol{U}_{33}$(Ti) are critical. Therefore, *z*(Ti) is not critical and the natural parameter to be kept fixed. Again deviations from the expected Landau behaviour are found for the spontaneous strain indicating the occurrence of stress which is further confirmed by specific peak broadenings. Anharmonic ADP's reveal a certain disorder of Pb, i.e. there is an additional order-disorder component which is also found in $LiNbO_3$ and $LiTaO_3$ ($R\bar{3}c \leftrightarrow R3c$). While this is only a secondary effect in $LiTaO_3$, there is a strong competition of both ordering mechanisms, a „superionic" and a „ferroelectric" one, in $LiNbO_3$ causing a more complex critical behaviour. This difference can be related to the actual geometries of the structures. ADP's define the centre of the O_6-octahedra as (non-critical) origins in this case. Deviations from Landau behaviour are again found in the strain indicating spontaneous re-polarisations below T_c.

P07.OC.005 PRETRANSITIONAL PHENOMENA ON THE PHASE TRANSITION OF ABO_4-TYPE FERROELASTIC COMPOUNDS. Y. Kuroiwa, S. Aoyagi and A. Sawada, Department of Physics, Okayama University, Tsushima, Okayama 700-8530, Japan, and T. Shobu, Department of Physics, Chiba University, Yayoi, Chiba 263-8522, Japan, and Y. Noda, RISM, Tohoku University, Katahira, Sendai 980-8577, Japan and S. Tsunekawa, IMR, Tohoku University, Katahira, Sendai 980-8577, Japan.

Precursor phenomena on the first-order phase transition are found in some materials. It is important to study the precursor phenomena since the phenomena are considered to be a key to solve the origin of the first-order phase transition. We have investigated precursor phenomena in ferroelastic compounds, and

found new-type precursor phenomena on the first-order phase transition of $LaNbO_4$ and $NdNbO_4$ [1, 2].

X-ray diffraction studies were performed at the home laboratory and the synchrotron radiation facility, SPring-8 (BL02B1). $LaNbO_4$ and $NdNbO_4$, which have a scheelite structure ($I4_1/a$) in the high temperature phase, transformed to a slightly distorted pseudo-scheelite structure (I2/a) at 768K and 930K, respectively. The lattice parameters changed discontinuously at the phase-transition temperature. Anomalous temperature-dependence of the profiles of Bragg reflections was observed on the phase transition. The intensities decreased remarkably and the profiles broadened such as diffuse scattering, as the phase-transition temperature was approached. In addition, anisotropic diffuse scattering was observed around the Bragg reflections. Similar phenomena on such Bragg Broadening are observed in a ferroelastic compound Na_2CO_3. In the present work, the precursor phenomena observed in $LaNbO_4$ and $NdNbO_4$ are discussed by comparison with the critical phenomena on the second-order phase transition of $BiVO_4$.

P07.OC.006 HYDROGEN ORDERING AND ELECTRON DISTRIBUTION ON THE PHASE TRANSITION OF SQUARIC ACID. Y. Noda, Research Institute for Scientific Measurements, Tohoku University, 2-1-1 Katahira, Aobaku, Sendai, 980-8577 Japan, and H. Kimura, Department of Physics, Chiba University, Yayoi, Chiba 263-8522, Japan.

Squaric acid (3,4-dihydroxy-3-cyclobutene-1,2-dione; $C_4H_2O_4$), that is abbreviated as H2SQ, undergoes antiferroelectric phase transition at 370K for H-compound and at 516K for D-compound[1]. The crystal structure was already determined by X-ray [2] and neutron diffraction[3]. The space group changes from I4/m (H-compound, Z=2, a=c=6.1340Å, b=5.3415Å, 395K) to $P2_1/m$ (Z=2, a=6.1325Å, b=5.2749Å, c=6.1431Å, β=89.96°, 300K).

We have performed precise X-ray structural analyses at 300K, 322K, 342K and 363K in the low temperature phase, and 374K, 395K in the high temperature phase to study the phase transition phenomena of this compound. From the differential Fourier analysis, we found electron distribution of hydrogen atoms in the hydrogen-bond region. Not only the hydrogen atoms, but also bonding electrons along C-C bond and C-O bond were clearly observed.

Equivalent C-C bond length in the high symmetry phase splits to a double bond C=C and a single bond C-C in the low symmetry phase. We have measured the C-C bond length as a function of temperature. By using the differential Fourier synthesis, we determined the order parameter of a hydrogen atom whose position changes from double minima to single minimum. The behaviour of the order parameter of a hydrogen atom is similar to the strain that is calculated from the temperature dependence of the monoclinic angle. The hydrogen-bond length was also measured as a function of temperature, and the lattice distortion (axis length) is entirely explained by the change of the hydrogen-bond length. These results suggest the coupling nature and the transition mechanism of H2SQ.

P07.OC.007 PHASE TRANSITIONS IN HMTA. M. Gardon, K. J. Schenk, and G. Chapuis, Institut deCristallographie, Université de Lausanne, BSP Dorigny, CH-1015Lausanne, Switzerland.

Hexamethylenetetramine azelate (HMTA) is a fascinating member of the $C_6H_{12}N_4$-$HOOC(CH_2)_nCOOH$ family (with n=7). The structures of the different phases of HMTA were investigated anddetermined by XRD techniques. HMTA undergoes three thermotropic phasetransitions at ambiant pressure. The four phases were labelled I, II,III and IV from high to low temperature. All transitions are of firstorder and reversible, except transition II→I. PhaseII is disordered while phase III and IV are ordered. The cell-doublingII→III transition has a ferroelastic character andcorresponds to a reorganisation of the COOH terminals responsible of thedisorder in phase II. Transition III→IV is ofnon-ferroelastic nature and is also associated to a doubling of theprevious cell. Optical studies of phase I at high temperature werenecessary to elucidate its nature. Orthoscopy has revealed that the II→I transition is preceded by a gradual wrinkling (over 30°C) of the (0 1 0) surface which iscleansed during the phase transformation leaving behind a neat crystalsurface. Analogy between optical and calorimetric results has beendemonstrated. We aim to emphasize at a first stage the questions whichappear when considering only the limited structural approach provided by XRD experiments. We explain how to go beyondthese frontiers and what kind of response can be given byconsidering other techniques like NMR and IRspectroscopy. Finally, results from other members of this family(n=4,...,14) are combined with the ones from HMTA in order toelaborate general features governing the thermal behavior of thesecompounds.

P07.OC.008 CHARGE, ORBITAL AND MAGNETIC ORDERING IN $Ln_{0.5}A_{0.5}MnO_3$ AND $Ca_{1-X}Bi_XMnO_3$. P.M. Woodward, J. Goldberger [1], T. Vogt, D.E. Cox [2] and K.Z. Baba-Kishi [3], [1] Department of Chemistry, Ohio State University, Columbus, OH 43210-1185, USA, [2] Physics Department, Brookhaven National Laboratory, Upton, NY 11973, USA, [3] Department of Applied Physics, The Hong Kong Polytechnic University, Hong Kong, China

Phase transitions, driven by various combinations of charge, orbital and magnetic ordering, in the systems, $Ln_{0.5}A_{0.5}MnO_3$ (Ln = La, Pr, Nd, Gd, Sm, Y; A = Ca, Sr) and $Ca_{1-x}Bi_xMnO_3$ ($0 < x < 0.3$), have been studied using high-resolution synchrotron x-ray and neutron powder diffraction techniques. The information obtained in the powder diffraction studies is supplemented with TEM and magnetic susceptibility measurements.

Despite prolonged high-temperature heat treatments (~1500° C) the $Ln_{0.5}Sr_{0.5}MnO_3$ compounds containing larger rare-earth ions (La^{3+} and Pr^{3+}) show a persistent polytypism at room temperature in the charge-delocalized state. The two structural modifications observed adopt different octahedral tilt systems, $a^0a^0c^-$ (space group *I4/mcm*) and $a^-b^0a^-$ (space group *Imma*). Variable temperature X-ray and neutron diffraction studies show that at low temperatures the tetragonal *I4/mcm* structure undergoes orbital and antiferromagnetic ordering, but no evidence for charge ordering is observed. In contrast, the orthorhombic *Imma* structure transforms to the charge-ordered, antiferromagnetic CE-type structure at low temperature. As the size of the lanthanide ion is decreased eventually *Pnma* symmetry (tilt system $a^-b^+a^-$) is observed at room temperature. The appearance Pnma symmetry corresponds to the disappearance of the charge-ordered CE-type structure at low temperature. This suggests a strong correlation between octahedral tilting and the low temperature magnetic structure.

Two distinctly different orbitally ordered states are observed at low temperature in the $Ca_{1-x}Bi_xMnO_3$ system. Structural studies show that when $x \sim 0.3$ the filled e_g orbitals are located in the *ac* plane, arranged in a zig-zag pattern similar to that observed for $LaMnO_3$ or $La_{0.5}Ca_{0.5}MnO_3$. Whereas, when $x \sim 0.2$ the occupied e_g orbitals appear to all align in the same direction. Structural refinement results for each of these ordered structures will be presented.

P07.OC.009 X-RAY STUDY OF STRUCTURE AND PHASE TRANSITIONS IN $Cs_3Sb_2I_9$ CRYSTAL. Novikova M.S. and Makarova I.P, Institute of Crystallography RAS, Leninski pr. 59, Moscow, 117333 Russia and Bagautdinov B.Sh,. Institute of Solid State Physics RAS, Chernogolovka, 142432 Russia and Blomberg M.K. University of Helsinki, FIN-00014, Finland, and Chapuis G, Universite de Lausanne, Institut de christallographie, 1015 Lausanne-Dorigny, Switzerland.

$Cs_3Sb_2I_9$ crystal belongs to a wide family of ferroelectrics $A_3B_2X_9$. Recently it was found in [1] that this compound undergoes two low temperature phase transitions (PT) at 86 and 74 K. X-ray structural study revealed that this compound crystallizes in two different modifications: hexagonal ($P6_3/mmc$, Z=2) [2],and trigonal [3] ($P\ \bar{3}m1$, Z=1). The samples that undergo PT were carefully studied on the four-circle diffractometer «Enraf-Nonius»-4F and the refinement showed that the symmetry is trigonal. The experiment was carried out in the whole sphere of the reciprocal space. Program complex JANA94 was used for refinement. The absorption correction was made by numerical integration using the shape of the crystal. Two-circle diffractometer «Siemence»-D500 and four circle diffractometer «Huber»-5042 were used for helium studies. Three modulated PT were found with the help of x-ray method. PT at 86 K is characterized by the appearance of the superstructural reflections $q_1 = 1/2c^*$ and does not change the geometry of the reciprocal space. According to x-ray data the trigonal symmetry is preserved. Below 78 K new superstructural reflections were observed with $q_2 = 1/2c^* +(1/2 +\delta)a^*$. At 72 K δ vanishes. This last PT is found to be of the first order.

P07.OC.010 EFFECT OF LASER HEATING ON STRUCTURAL STATE OF IRON-NICKEL ALLOYS. V.E. Danilchenko, B. Polchuk, Institute for Metal Physics, Academy of Sciences of Ukraine, 36 Vernadsky Blvd., 252680 Kiev, Ukraine

After laser heating of metals the specific structural state of surface layer is caused by high level of internal stresses, dispersion of phase components, by possible redistribution of alloying elements and by realisation of phase transformation in nonequilibrum conditions. In formation of complex of physical and mechanical properties of surface layer essential role is played by phase transitions, fulfilling with volume effect and supplying the distinctions in physical properties of phases.

Present work investigates the influence of laser treatment on martensitic transformation characteristics and crystalline structure of gamma- and alpha-phases in Fe-Ni alloys. Laser melting of surface of metastable austenitic Fe-Ni alloys led to the change of martensitic transformation completeness during subsequent cooling in liquid nitrogen: in binary (Fe-30%Ni) and carbonrich (Fe-24.5%Ni-0.55%C) alloys the austenite stabilisation was supervised owing to which the martensitic transformation proceeded more slowly. In alloy Fe-29%Ni-1.9%Ti-2%Al the martensitic transformation completeness was substantially increased. The austenite stabilisation in binary alloy was connected with structural factors and with increase of carbon content in gamma-solid solution at the expense of dissolution of graphite globulars during laser melting. Martensite transformation activization in Fe-Ni alloy with Ti and Al was defined by change of level of internal stresses forming during cooling of melting layer.

P07.OC.011 PHASE TRANSITIONS, ELASTIC CONSTANTS AND ELECTRON DISTRIBUTION IN KDP-FAMILY. M.T. Medetbekov[1,2], Hassel Ledbetter[3], Sudook Kim[3], Boris N. Kodess[1,2], L.A. Butman[2] , Z.K. Gubaydulin[1,2], [1]Department of Crystal Metrology, VNIIMS, 119361 Moscow, Russia, [2] ICS&E, Aurora, CO 80012, USA, [3] Materials Reliability Division NIST, Boulder, CO 80303, USA

Using single and powder X-ray diffraction at temperatures of 295, 250, 220, 210, 200, 100, and 90 K, electron paramagnetic resonance, EPR, and acoustic-resonance spectroscopy we studied $K(H_2-D_2)PO_4$-family that show order-disorder phase transformations. In solid solutions one sees unusually high "isotopic effect" for all characteristics including 90 degrees increase of T_c when 90% of Deuterium is substituted by Hydrogen. This leads to a far from equilibrium state of the system with bifurcated hydrogen bonds. The high sensitivity of such a "precritical" system to factors such as high pressure, plastic deformation and deformation fields arising due to vacancies, doped elements, irradiation and others was established. Difference Fourier synthesis and elastic-stiffness tensor C_{ij} constants at ambient temperature give evidence that KDP differs from DKDP both for electron structure and dynamic-lattice-parameters. The first 38 measured resonance frequencies are plotted versus the predicted frequencies based on two analyses: an elastic analysis and a piezoelectric analysis. For DKDP, agreement between measurement and prediction is better for the nonpiezoelectric analysis, against many literature reports for the KDP (KH_2PO_4).

The reversible phenomena was established after irradiation for both poly- and monocrystals. Relaxation of the EPR spectrum associated with birth and dissolution of color centers and changes of structural parameters after perturbation actions were more noticeable for DKDP. The data is reviewed from the point of view of "before T_c" nucleation of tetragonal phase and the fact that mobility of domain walls is significantly higher for DKDP.

P07.OC.012 PHASE TRANSITON AND SECOND HARMONIC GENERATION OF A CYCLODEXTRIN COMPLEX WITH A NONLINEAR OPTICAL CHROMOPHORE. Ali N. Rashid, R. Shoemaker, K. Kirschbaum*, J. J. Stezowski, Department of Chemistry University of Toledo, Toledo OH, Department of Chemistry University of Nebraska-Lincoln, NE 68588.

Organic molecular crystals are of great interest due to their large nonlinear optical properties and their large damage threshold. Nonlinear optics is the study of the interactions of materials with electromagnetic fields to produce new fields, which are different in phase, frequency or modulation. One manifestation of which is second harmonic generation. However, most aromatic molecular crystals pack in a centrosymetric fashion, which forbids second harmonic generation (SHG). One way to assure that crystals will be non-centrosymmetric is to introduce naturally chiral components. This study uses β-cyclodextrin (β-CD), for this purpose and reports a study of a supramolecular inclusion complex that is formally a 3:2 guest-host complex with p-nitroanaline as the guest. Crystals of the complex, prepared by slow evaporation of an aqueous solution, display C2 space group symmetry at room temperature and $P2_1$ space group symmetry at 20K. The respective lattice parameters are: {a=19.5082, b=24.4657, c=15.9775 β=109.026 for C2 and a=15.733, b=23.845, c=19.496, β=109.362 for $P2_1$}. Efforts are underway to determine the temperature and character of the phase transition. Crystal structure determinations are in progress for the complex at room temperature and at 20K. Current R-values are R1 = 0.0694 for 6110 contributing data and R1 = 0.1170 for 14272 contributing data. There is considerable disorder in the guest molecules. Current interpretation of the structural models indicates some differences in the orientation of the guest

molecules at the two temperatures. In addition to further improvement in the crystallographic models, applications of other methods such as differential scanning calorimetry, solid state NMR spectroscopy and theoretical calculations are being pursued to further characterize the system.

P07.OC.013 THE PHASE TRANSITIONS IN THE FAMILY OF A-TYPE $A_3B_2X_9$ COMPOUNDS. P.E. Tomaszewski and A. Pietraszko, Institute of Low Temperature and Structure Research, Polish Acad. Sci., POB 1410, 50-950 Wroclaw, Poland, and A.M. Yaremko, Institute of Semiconductor Physics, Ukr. Acad. Sci., 252028 Kiev, Ukraine

The anionic sublattice of more than 200 known crystals with the formula $A_3B_2X_9$ are built up of at least 3 different networks. $Rb_3Bi_2Br_9$ and $Rb_3Sb_2Br_9$ belong to the rather rare type ***A***. The structure motif composed by 6-membered $(B_2X_9^{-3})_n$ layers is realised in different space groups from trigonal prototype structure with P-3m1 symmetry even to monoclinic Pc.

Our X-ray experiments were performed using KM-4 four-circle automatic diffractometer (CCD version) of *KUMA Diffraction* to reveal the possible changes of the structure when passes through the high temperature phase transitions suggested by the existence of the domain structure observed in polarised light. DSC studies revealed transitions at 378 K for $Rb_3Sb_2Br_9$ and at 319, 325 and 456 K for $Rb_3Bi_2Br_9$. Consecutive high-temperature X-ray studies showed the disappearance of diffraction peak splitting. The disappearance of domain structure indicates on the change of crystal system at the phase transition, thus, for the ferroelastic character of the transition. The crystal structure were solved in both, high- and room-temperature, phases. For $Rb_3Sb_2Br_9$: $P2_1$ with 13.683(1), 7.778(1), 19.264(2) Å, $\beta=90.335(9)^o$ at 290 K, P-3m1 with 7.889(4), 9.667(10) Å at 440 K; for $Rb_3Bi_2Br_9$: $P2_1/c$ with 13.6059(8), 7.9222(4), 19.4169(10) Å, $\beta=90.615(4)^o$ at 290 K. The prototype structures correspond well to that of $Cs_3Bi_2Br_9$. The characteristic feature is rather high thermal motion of the terminal bromines leading even to the atom splitting in the low-temperature phases. The phase transitions in our crystals are mainly due to the rotation of the BX_3 groups leading to the deformation of 6-membered rings and inclination of pseudo-trigonal axis b. This new mechanism was not observed in the compounds with organic A where the freezing of A-ions was responsible for phase transitions. The establishing of correct symmetry (different from that of literature) open a new regard to the family of $A_3B_2X_9$ crystals with a prototype P-3m1 phase.

07OD 'IN SITU' STUDIES USING POWDER DIFFRACTION

M07.OD.001 IN-SITU STUDIES USING POWDER DIFFRACTION. P. Norby, Department of Chemistry, University of Aarhus, DK-8000 Århus C, Denmark

The need for understanding, improving and controlling the properties of advanced materials has led to an increased interest in in-situ studies, i.e. characterization of materials under real working conditions or during formation. Time resolved in-situ powder diffraction has become a very valuable and versatile tool for studying synthesis, chemical reactions and phase transitions. Examples include studies of catalytical materials at real working conditions or synthesis of microporous materials under hydrothermal conditions. Information obtainable from this type of experiments include kinetics, real time observation of structural changes and detection and identification of intermediate or precursor phases.

The talk will present results from a number of time resolved in-situ studies using synchrotron and neutron powder diffraction. Special emphasis will be put on in-situ studies of hydrothermal synthesis of microporous and layered materials, intercalation reactions and thermal transformation and decomposition of inorganic materials. Results from a combined powder diffraction and MAS NMR study of dehydration and phase transitions of a cadmium-glycine complex will be given.

The recent implementation of a facility for time resolved in-situ synchrotron X-ray powder diffraction at the European Synchrotron Radiation Facility, ESRF, will be described. The facility is situated at the Italian beamline, GILDA, and consists of a capillary based microreaction cell, a hot air heater and a Translating Imaging Plate, TIP, system for collection of time resolved powder diffraction data. Results from the first experiments will be presented.

M07.OD.002 IN SITU X-RAY ENERGY DISPERSIVE STUDIES OF INTERCALATED COMPOUNDS. Christopher Hall, Schlumberger Cambridge Research, High Cross, Madingley Road, Cambridge CB3 0EL, UK.

Synchrotron energy-dispersive X-ray diffraction is an effective means of observing mineralogical changes in dense suspensions and pastes under hydrothermal conditions. In the context of oilfield materials engineering, we have studied in detail the behaviour of swelling clays stabilised with a variety of polymers of low molecular mass. These clay/polymer complexes are well defined intercalates and their formation can be observed through changes in basal spacing. Of particular interest is the thermal stability of such complexes. We have also exploited a tomographic form of the diffraction experiment to observe thin clay membranes exposed to solutions of varying composition. This work illustrates the way in which highly penetrating synchrotron X-rays can be used to monitor processes in bulk materials in complex sample cells.

M07.OD.003 ORDER-DISORDER REACTIONS IN MINERALS FROM NEUTRON POWDER DIFFRACTION. Alessandro Pavese, Dipartimento Scienze della Terra, Universita degli Studi di Milano, Via Botticelli 23, 20133-Milano, Italy.

Most mineral families undergo cation order-disorder (OD) reactions activated by temperature/pressure (Artioli et al, 1995; Pavese et al, 1999; Redfern et al, 1997); this subject has aroused an increasing interest in research, given that determining the cation partitioning as a function of *P* and/or *T* is key to get insight into the environmental conditions experienced at formation. OD-transformations can cause space group changes (convergent cation ordering, after Carpenter et al, 1994), or leave it unaffected (non-convergent cation ordering). Neutrons have reveled an appropriate radiation to investigate cation partitioning in crystalline matter, in especial because OD-reactions oftentimes involve quasi-isoelectronic atoms, hard to be reliably distinguished by X-ray. Furthermore, being the neutron scattering lengths independent on the θ-angle allows one to combine classic Rietveld refinement techniques (providing ''effective site scattering lengths'') with advanced minimization methods, for attaining the atomic distribution. Here a set of results encompassing micas/omphacites/spinels are presented, to provide an overview about how neutron powder diffraction is a flexible technique to cope with a variety of aspects pertaining to cation partitioning in natural/synthetic minerals, at non-ambient conditions.

In case of phengitic micas (sheet minerals), OD-reactions thermally activated lead to convergent ($3T \Leftrightarrow 2M_1$, *i.e.* polytype to polytype transformation promoted by particular *P/T* ratio conditions) and to non-converget cation ordering ($3T \Leftrightarrow 3T$, $2M_1 \Leftrightarrow 2M_1$), both due to the Mg/Al and Al/Si partitioning over the octahedral (M2, M3) and tetrahedral (T1, T2) sites, respectively (Pavese et al, 1997).

Omphacites (chain minerals) undergo convergent thermally activated OD-transformations (P2/n⇔C2/c) stemming from the Mg/Al/Fe and Ca/Na readjustment over the sixfold (M1, M11) and eightfold (M2, M21) coordination sites, respectively. A two steps process underlies this OD-reactions (Pavese et al, 1999).

Spinels (AB_2O_4) have been long investigated for their non-convergent OD-transfomations that originate from mixing over the tetrahedral and octahedral sites of A and B chemical species, as a consequence both of heating and of pressure (Pavese et al, 1999).

M07.OD.004 IN-SITU KINETIC STUDY OF PORTLAND CEMENT HYDRATION. M. Bellotto, L. Bonafous, X. Launay, CTG Italcementi Group, Rue des Technodes, 78931 Guerville Cedex, France; S. L. Colston, A.C. Jupe, S.D.M. Jacques and P. Barnes, Industrial Materials Group, Department of Crystallography, Birkbeck College, Malet Street, London WC1E 7HX, UK. keywords: in-situ cement hydration, energy dispersive diffraction, synchrotron radiation powder diffraction.

The properties of a cement slurry result from a complex interplay of chemical and physical processes. With an ideal "well-behaved" paste its flow properties are maintained for a sufficient working period prior to rapid hardening to achieve the desired mechanical strength. To control such a behaviour additives are currently added to the mix of clinker and gypsum which constitutes normal Portland cement. Such additives, both mineral and polymeric, have several applications: to control the particle size distribution, to modify the liquid-phase composition and to modify the surface state of the mineral phases. A single additive, however, induces multiple effects and therefore its exact mechanism of action is difficult to elucidate. Thus, in order to develop less empirical formulation strategies, reliable kinetic data need to be acquired.

The hydration kinetics of several Portland cements (both laboratory-synthesized and industrial forms) have been monitored using velocity-imposed rheometric measurements and by synchrotron-based energy dispersive powder diffraction. In particular the effect of addition of poly-electrolytes on the nucleation and growth of the hydrates has been assessed together with the macroscopic effect on the flow characteristics. The reactions at the onset of hydration are critically dependent on the composition of the solution, both as mineral and polymeric ions. In particular the formation of ettringite from the solid tri-calcium aluminate and aqueous sulfate ions is modified by the presence of poly-electrolytes. Such a study has been made possible by use of (synchrotron) energy dispersive diffraction which is capable of collecting, in-situ, well resolved patterns from the complex multiphase pastes during hydration with time resolutions of the order of tens of seconds.

M07.OD.005 TOWARDS TIME RESOLVED NEUTRON DIFFRACTION: D20, A HIGH INTENSITY NEUTRON POWDER DIFFRACTOMETER. T. Hansen and P. Convert, Institut Laue-Langevin, BP 156, 38042 Grenoble Cédex 9, France.

The monochromatic beam of D20 has a high flux of up to $7.5 \cdot 10^7$ n·cm^{-2}·s^{-1}. Two vertically focussing monochromators give wavelengths of $\lambda = 0.9$, 1.3 or 2.4 Å. Soller collimators allow to adjust the divergence of the incident polychromatic beam. The Position Sensitive Detector (PSD) has a radius of 1.5 m and an aperture of 160° with 10 cells per degree (2θ) with *microstrip* detection electrodes. The 1600 cells are connected to 1600 amplifiers, followed by 1600 anti-coincidence logics and a fast Data Acquisition System (DAS) with parallel input, allowing counting rates up to $5 \cdot 10^4$ s^{-1} per cell.

The large stationary PSD, the high flux at sample, the choice of wavelength and resolution makes D20 a versatile instrument. It provides scientifically and experimentally a broad range of applications from numerous successive short acquisitions to follow the evolution of a sample up to long acquisitions to obtain a very high precision in intensity. Several representative experiments show these various fields: thermodiffractometry (phase transitions - crystallisation of amorphous Y-Fe-alloys, amorphisation of crystalline precursors), magnetism (magnetic structures of intermetallic $R_2T_3X_9$ and of Ag_2RuO_4), kinetics (dynamic studies of cement transformations and of battery charging), stroboscopy (orientation of flat or rod-shaped particles in moving suspensions under shear gradient - dynamic study at start and stop of flow), texture (quantitative texture analysis of composite materials), small samples (magnetic order on 3 mg sample in cryostat; preferred orientation in 1 mm slice of rat femur, 6 mg), absorbing samples (distances in natural Eu-hydrides), disordered systems (variation of mercury structure factor with density), physisorption (2D-ordered alcane monolayers on graphite).

The time-resolution of only seconds opens new opportunities for *in situ* neutron diffraction studies of solid state reactions. Therefore, tools, which will be suggested, are needed to analyse the huge amount of sequential powder diffractograms reliably and fast, and to extract the contained information completely.

P07.OD.001 IN-SITU X-RAY DIFFRACTION IMAGING OF POLYCRYSTALLINE MATERIALS. T. Wroblewski, Hamburger Synchrotronstrahlungslabor HASYLAB, Deutsches Elektronen-Synchrotron DESY, D-22603 Hamburg, Germany.

A novel method allows imaging using the radiation diffracted by polycrystalline samples [1] (and/or their fluorescence). It applies a micro-channel plate (MCP) as collimator in front of a position sensitive detector (CCD-camera) such allowing the position resolved detection of radiation from a sample area of more than 1 cm^2. The spatial resolution is proportional to the sample to detector distance (currently 12 μm for 12 *mm* distance).

The times to obtain an image displaying the radiation diffracted by a polycrystalline specimen into the direction of the MCP reach from few minutes down to less than a second allowing the observation of dynamic processes.

One example is the recrystallization of cold rolled copper during annealing [2]. The fact that the entire sample is probed simultaneously throughout the whole process enables the observation of early stages of the nucleation and growth processes without prior knowledge of where such processes occur.

It was shown that, after a certain growth period, the size of the individual crystallites remains constant. No correlation between the time of nucleation and the final size of the crystallites could be observed but the whole process can be described by the model of self organized criticality also applicable to 1/f-noise [3].

Further investigations in the field of materials process characterization like that of an electric light bulb during operation or of polymers during deformation will be presented.

P07.OD.002 *IN SITU* POWDER DIFFRACTION STUDIES OF HYDROTHERMAL SYNTHESIS OF LAYERED TITANIUM PHOSPHATES. A. M. Krogh Andersen, Department of Chemistry, Odense University, DK-5230 Odense M, Denmark and P. Norby, Department of Chemistry, University of Aarhus, DK-8000 Aarhus C, Denmark.

We have studied hydrothermal synthesis of α-$Ti(HPO_4)_2 \cdot H_2O$, using *in situ* time-resolved synchrotron powder diffraction. The starting materials for the synthesis were amorphous titanium phosphate and phosphoric acid (85 %). The samples were contained in sealed quartz capillaries. When synthesis above 100°C was performed an external pressure was applied to obtain hydrothermal conditions. A position sensitive detector was used, enabling fast data collection. Full powder patterns were obtained in 30-60 seconds. The syntheses were performed at temperatures from 50 to 200°C.

Preliminary results show that the crystallisation of α-$Ti(HPO_4)_2 \cdot H_2O$ starts at approximately 50°C and the crystallisation kinetics was followed up to 130°C. The amount of crystalline material was estimated from integrated intensities of selected reflections in the diffraction pattern. The crystallisation curves were fitted using a first order rate expression. At higher temperatures transformation of α-$Ti(HPO_4)_2 \cdot H_2O$ to β-$Ti(PO_4)(H_2PO_4)$ was observed.

P07.OD.004 In-Situ POWDER DIFFRACTION STUDIES OF DISORDER TRANSFORMATIONS IN BROWNMILLERITES. S.A. Speakman and S.T. Misture, NYS College of Ceramics at Alfred University, 2 Pine St., Alfred, NY 14802, USA

In-situ powder diffraction is used to investigate the order-disorder transformations in modified Brownmillerite materials. The affect of cation selection and doping on the anion order-disorder transformation temperature is examined using high temperature x-ray diffraction. In addition to simply determining phase transformation temperatures, in-situ XRD using position-sensitive detectors allows quantification of the reactions with time. The extent of disordering that occurs is measured in an attempt to determine if the systems fully disorder or only partially disorder. The structural changes observed using in-situ XRD are correlated to changes in the ionic conductivity of the materials.

In-situ diffraction results on barium indate and several iron-based brownmillerites demonstrate that the 'disordered' materials are not straightforward random cubic structures, even several hundred degrees above the disordering temperatures.

The diffraction study is aided by computer simulation to further understand the defect structure and stability of potentially important materials. Successful calculation of stable crystal structures of In and Fe-based Brownmillerite ceramics and subsequent experimental investigations are presented. The computational methods employed rely on ionic potentials, namely the Buckingham potential and core-shell pairs for polarizable ions. Lattice parameters and ion coordinates agree with experiment. In addition, a defect analysis using the Mott-Littleton approach has shown that Schottky pairs are expected to form, and their association energies have been calculated.

P07.OD.005 A NEW HEATING DEVICE FOR X-RAY POWDER DIFFRACTION STUDIES UNDER WATER VAPOUR PRESSURES UP TO 1000 MBAR. M. Oetzel, F.-D. Scherberich, G. Heger, *AiXtal* Institute for Crystallography, RWTH Aachen, D-52066 Aachen, Germany

Hydration and dehydration procedures in science as well as in industry are very sensitive not only on time and temperature but also on environmental water vapour pressure. Hence, in situ diffraction studies under controlled temperature and defined water vapour pressure conditions can be very helpful to study such processes.

To satisfy the diverse demands a new heating cell for a Siemens D 500 powder diffractometer has been constructed [1]. With this device it is possible to examine powder specimens under water vapour pressures up to 1000 mbar in a sample temperature range from 20°C to 1000°C. Because the environment of the sample is heated separately, examinations under constant water vapour pressures as well as under constant relative humidities can be done up to an environment temperature up to 200°C.

The presented HT unit consists of a moulded Pt or Cu block with a resistance heating. The encapsulated thermocouple is mounted between the heating and the surface of the block to ensure the best possible controlling of sample temperature. The half circle shaped cover is also resistance heated and has a double layered window made out of capton foil. The space between the foils can be floated with hot dry air to prevent water condensation at higher water vapour pressures. Humidity and air temperature in the chamber are sensor controlled.

With the above described heating device, which has already proven its performance in an application for the gypsum industry [2], a combination of time-resolved, temperature- and humidity-controlled X-ray diffraction is now applicable.

We gratefully thank the SICOWA Verfahrenstechnik für Baustoffe GmbH & Co. KG , Aachen, Germany for financial support.

P07.OD.006 TIME-RESOLVED STUDIES USING SR:INTERMETALLIC SYNTHESIS. Å.Kvick, C.Curfs, G.Vaughan [1], M.A.Rodrigues, I.G.Cano [2], X.Turillas [3], [1] ESRF,BP 220,38043 Grenoble Cedex, France, [2] Inst. de Ceramica y Vidrio,Arganda del Rey, Madrid, Spain, [3] Inst Eduardo Torroja,Madrid,Spain

The Materials Science beamline (ID11) at the ESRF has been instrumented to follow reactions in-situ on a time-scale down to ~4 millisecs using a high- speed CCD camera coupled to an image-intensifier X-ray sensitive detector with 1000*1000 pixel frames. The pixel resolution is 100 microns. This set-up has been used to follow self-propagating high-temperature syntheses (SHS) in the quarternary system Al-Ni-Ti-C in order to obtain inter-metallic ceramic composites. These products have properties that make them highly attractive for many industrial applications.They have low density,excellent oxidation resistance and high melting points (~1900K). Unfortunately poly- crystalline AlNi has poor ductility and low wear resistance due to poor creep resistance at high temperatures. These problems may be overcome by reinforcement by aluminum oxide fibres or ceramic powders. These reactions have been studied by time-resolved powder diffraction on very short time-scales. The initial powder mixtures were pressed to cylinder specimens and the reaction were started by a spark at one end of the cylinders. A highly collimated X-ray beam at high energy has been used to record diffraction patterns from a specific region of the starting pressed powder cylinders in transmission. As the reaction proceeds along the cylinder the powder patterns from the initial sample, the pre-heated region, the reaction front ,post-heated region and the final product have been recorded. The phases occurring during the processes have been identified and information on the reaction mechanisms and nucleation kinetics have been obtained.

07OE AMORPHOUS MATERIALS: SMALL ANGLE SCATTERING

M07.OE.001 X-RAY AND NEUTRON SMALL ANGLE SCATTERING WITH AMORPHOUS Si-C-N CERAMICS. P. Lamparter, S. Schempp, J. Bill and F. Aldinger, Max-Planck-Institut für Metallforschung, D-70174 Stuttgart, FRG.

Precursor-derived ceramics present a novel type of materials for high temperature applications. Amorphous Si-C-N ceramics were produced by pyrolysis of different polymers at 1050 °C. Small angle scattering revealed an inhomogeneous structure on a length scale of some ten Å. From the contrast between X-ray and neutron scattering it could be deduced that the inhomogeneities are amorphous Si_3N_4 precipitates embedded in a carbon-enriched Si-C-N matrix. A theoretical model is presented on the base of a polydisperse system of positionally correlated hard spheres which is able to describe the experimental scattering curves. Further heat treatments of the ceramics up to 1450 °C cause a coarsening of the inhomogeneous structure where the volume fraction of the Si_3N_4 precipitates does not change. The kinetics of this process is described by a Gibbs-Evett-Leake model.

M07.OE.002 STRUCTURAL TRANSFORMATIONS IN NANOSTRUCTURED MATERIALS. A.F. Craievich, Instituto de Física, CP 66318,05315-970, USP, São Paulo, SP, Brasil.

SAXS combined with the use of i) a powerful X-ray incoming beam produced by electron storage rings and ii) a cell for temperature control of the sample, offers interesting possibilities for studying *in situ* structural transformations occurring in materials which are heterogeneous at a nanometric scale. This type of study aims at the characterisation of i) the different structures formed during the transformations and ii) the kinetical aspects of the processes. This last information provides an insight into the physical and/or chemical mechanisms involved in the structural transformations. Different mechanisms are active in the several stages of the sol-gel process for material preparation, such as aggregation in liquid phase, gelation, drying and sintering. The precursors may be solutions of organic alkoxides and the final systems powdered or monolithic and nearly homogeneous materials. Since all intermediate structures along the process are heterogeneous at a nanometric scale, the whole transformation can be monitored using only SAXS. The different composite materials may be structurally very simple, e. g. nearly single-mode spherical particles, embedded in a homogeneous matrix. Alternatively, they may be very disordered and exhibit fractal structures, as is the case of a number of gels and aerogels. Several investigations on nanostructured materials, including semiconductor (PbTe, CdSe, CdSTe) and metallic (Ag) nanocrystals embedded in a glass matrix, different silica based precursor sols, gels produced by monomer aggregation and xerogels which result from drying of wet gels, will be reported. Recently published results on organic-inorganic nanostructured hybrid materials will be presented. An example in which it is shown how ASAXS provides useful information on complex systems consisting of a nanoporous matrix containing semiconductor nanocrystals will be described. The recent SAXS experiments reported in this communication were performed at the synchrotron facility of LNLS, Campinas, Brazil, and the others at LURE, Orsay, France.

M07.OE.003 MAGNETIC MICROSTRUCTURE OF NANOSTRUCTURED METALS STUDIED BY SMALL-ANGLE NEUTRON SCATTERING. J.F. Löffler, California Institute of Technology, W. M. Keck Laboratory, Pasadena, CA 91125, USA. and H.B. Braun and W. Wagner, Paul Scherrer Institut, CH-5232 Villigen PSI, Switzerland. and A. Wiedenmann, Hahn-Meitner-Institut, D-14109 Berlin, Germany. and G. Kostorz, ETH Zürich, Institut für Angewandte Physik, CH-8093 Zürich, Switzerland.

In consolidated nanostructured materials, i.e. in bulk materials with grain sizes in the nanometer range, the grain size is comparable to or even smaller than the width of a domain wall. Thus, the resulting macroscopic magnetic properties are largely determined by the grain size and the exchange interactions between adjacent grains. In Fe, for example, we find a maximum of the coercive field at a size of around 35 nm with a steep decrease towards smaller grain sizes.

In order to understand in more detail the connection between microscopic structure and macroscopic behavior, we performed magnetic small-angle neutron scattering experiments on nanostructured Fe, Co and Ni. The experiments reveal spontaneous (zero-field) magnetic correlations across the interfaces, which extend over many individual grains. The correlation length strongly depends on grain size and exhibits a minimum, which for Fe lies in the range of 35 nm. For grain sizes below this minimum length scale the correlation length sharply increases.

We explain our results on the basis of a random-anisotropy model. This model takes into account that the effective anisotropy constant results from a statistical average of the anisotropies of the magnetically coupled grains. Based on a detailed quantitative discussion of the interplay between grain size and pinning, we find that the random-anisotropy model breaks down at a length scale $\pi\delta$ with δ the bulk domain-wall width. This is in excellent agreement with our experimental results on Fe, Co and Ni.

We further investigated in detail the response of the intergranular magnetic correlations to external fields. We find that the magnetization relaxation occurs via rotation of entire domains, which confine several grains. This behavior can be explained by a modified Stoner-Wohlfarth model.

M07.OE.004 SMALL ANGLE SCATTERING STUDIES ON A PRESSURE INDUCED PHASE TRANSITION IN A TERNARY MICROEMULSION. H. Seto, D. Okuhara, Y. Kawabata, and T. Takeda, Faculty of Integrated Arts and Sciences, Hiroshima University, 1-7-1 Kagamiyama, Higashihiroshima 739-8521, Japan, and M. Nagao, Neutron Scattering Laboratory, Institute for Solid State Physics, The University of Tokyo, 106-1 Shirakata, Tokai 319-1106, Japan .

A pressure induced phase transition from droplet to lamellar / bicontinuous structure in a ternary microemulsion was investigated by means of small angle neutron scattering (SANS), X-ray scattering (SAXS) and neutron spin echo (NSE).

A mixture of surfactant AOT (dioctyl sulfosuccinate sodium salt), water and n-decane is known to form microemulsion, whose characteristic repeat distance is about 100 Å. At room temperature and ambient pressure, its structure is known to be a water-in-oil droplet in wide range of volume fractions of three ingredients. Recently, Nagao and Seto observed a pressure induced phase transition to a coexistence phase of lamellar and bicontinuous structures for some mixtures with the same water to oil ratio [1]. Although the mean repeat distance d at ambient pressure depends on a surfactant concentration, d of the lamellar was the same for all the samples observed, and the disorder parameter d/ξ, of the bicontinuous structure could be scaled with $P\text{-}P_s$, where ξ a correlation length and P_s a transition start pressure.

When a molar ratio of water to AOT is kept at 40.8, the radius of each droplet is determined to be about 50 Å, and only the droplet volume fraction ϕ is increased with decreasing decane volume fraction. In this study, a pressure dependence of the structure of the microemulsion system was investigated for various droplet concentrations $0.35 < \phi < 0.7$. Static features were clarified by means of SANS and SAXS, and dynamic features by means of NSE.

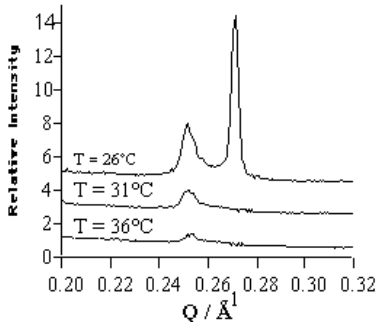
M07.OE.005 INDUCED STRUCTURAL CHANGES AT PARAFFIN-GRAPHITE INTERFACES. E.P. Gilbert, P.A. Reynolds and J.W. White, Research School of Chemistry, Australian National University, Canberra, ACT 0200, Australia.

Small-angle X-ray Scattering has been used to investigate the structures and phase behaviour of normal paraffins, with carbon number, *n*, between 10 and 20, when adsorbed on and inside the gallery structures present in exfoliated graphite. Ordering of the hydrocarbon molecules occurs at the interface and this surface crystalline structure persists at least thirty degrees above the melting temperature of the bulk crystalline phase. The surface-adsorbed structure is a lamellar arrangement different from the bulk phase. Below the bulk melting point, T_m, and for alkanes with even *n*, two distinct diffraction peaks are observed in the small-angle region, one associated with the bulk phase and the other with the surface structure. For alkanes with odd *n*, only one peak is observed below T_m; above T_m a significant reduction in peak intensity is found, indicating melting of the bulk, but a peak remains. The peak intensity at $T = T_m$ increases with *n*, indicating increasing surface stabilisation with increasing chain length. The separation between T_m and the temperature at which the diffracted intensity is greatest decreases as *n* increases and the values of the former agree well with values associated with a metastable phase transition observed previously.



SAXS patterns for *n*-octadecane adsorbed on graphite at 26, 31 and 36°C.

P07.OE.001 PHASE BEHAVIOUR OF BLENDS OF LINEAR AND BRANCHED POLYETHYLENES VIA ULTRA-SMALL-ANGLE NEUTRON SCATTERING. M. Agamalian and G.D. Wignall, Oak Ridge National Laboratory*, Oak Ridge, TN 37830-6393, USA, R.G. Alamo, Florida Agricultural and Mechanical University and Florida State University College of Engineering, Tallahassee, FL 32310, USA, L. Mandelkern, Institute of Molecular Bio-physics, Florida State University, Tallahassee, FL 32306, USA.

Small-Angle Neutron Scattering (SANS) experiments have indicated that mixture of linear (high density) and long chain branched (low density) polyethylenes (HDPE/LDPE) from a one-phase mixture in the melt [1]. However, the maximum spatial resolution of pinhole SANS camera is ~ 10^3 Å and it has been suggested [2] that such experiments do not provide unambiguous evidence for a homogenous melt. Thus the SANS data might also be interpreted as arising from a bi-phasic melt with a very large particle size (~ 3 μm), because most of the scattering from the different phases would not be resolved. We have addressed this hypothesis by means of Ultra-Small-Angle Neutron Scattering (USANS) experiments, using a newly developed Bonse-Hart USANS facility [3], which can resolve particle dimensions up to 30 μm. The experiments confirm that HDPE/LDPE blends are homogenous in the melt on the length scales probed by pinhole SANS and by USANS. Blends of linear and short-chain branched polyethylenes phase separate when the branch content is sufficiently high [4]. It is shown that USANS resolves both the size of the dispersed phase (~ 4 μm), and the forward cross-section [$d\Sigma/d\Omega(0) \sim 10^8$ cm^{-1}], which is six orders of magnitude higher than for homogenous blends.

07OF CATALYSTS AND SURFACES

M07.OF.001 FIRST-PRINCIPLES CALCULATION OF THE STRUCTURE OF OXIDE SURFACES. S.P. Bates, Department of Chemistry, Trinity College, University of Dublin, Ireland

The capability of first-principles simulation methods to predict the surface structure of oxides is demonstrated, with the examples of the low index surfaces of TiO2 and SnO2. The computational technique is based on density functional theory and the pseudopotential approximation and utilises a parallel code that can be run efficiently on multi-processor PC's, as well as large supercomputers. Particular attention is focussed on the choice of suitable calculation variables and their effect on the predicted surface structures. These accurate theoretical descriptions of the surface form the starting points of simulation of simple reactions and processes.

M07.OF.002 MELTING OF N-ALCOHOL MONOLAYERS ON GRAPHITE: EFFECT OF MOLECULAR LENGTH. K.Morishige, Department of Chemistry, Okayama University of Science, Okayama 700-0005, Japan

The structures and melting of n-alcohols(methanol to nonanol) adsorbed on graphite have been studied by x-ray diffraction.

All the monolayers of n-alcohols studied here consist of rows of molecules in a head-to-head arrangement with OH groups close to each other and zigzag chains of hydrogen bonds occur along the short axis of the unit cell. Melting behavior shows odd-even effect of carbon atom number in the range of carbon number of 2-7[1]. Two-dimensional smectic liquid crystals are formed in melting processes of the complete monolayers of odd alcohols while those of even alcohols melt directly into liquids. Octanol and nonanol show different behavior of melting, suggesting a different mechanism of melting.

M07.OF.003 INTERFACE INDUCED STRUCTURE IN CONCENTRATED SURFACTANT SOLUTIONS. S.A. Holt and J.W. White, Research School of Chemistry, Australian National University, ACT 0200, Australia.

We have demonstrated that grazing incidence diffraction studies of mesoporous films self-assembled at the air/liquid interface can be carried out in very short periods of time with image plates at synchrotron sources [1]. The structure of concentrated surfactant solutions at the air/liquid interface is also amenable to study by this method. The high flux available at third generation sources means that data can be collected over a wide range of reciprocal space in less than one minute. We have applied this method, in conjunction with specular reflectivity, to the study of concentrated solutions of cetyl trimethylammonium chloride solutions as a function of temperature and concentration. Not only are we able to observe that the surface ordering decreases with concentration (25 – 6 wt%) but that for a given concentration there exists surface phase transitions as a function of temperature.

S.A. Holt, G.J. Foran & J.W. White. L*angmuir*. Accepted for Publication (1999).

M07.OF.004 ELUCIDATING METAL SURFACE COMPOUNDS: PUTTING CRYSTAL STRUCTURAL INFORMATION TO WORK. S. G. Harris, R. O. Gould, D. A. Nation, S. Parsons, P. A. Tasker and R. E. P. Winpenny, Department of Chemistry, The University of Edinburgh, Edinburgh EH9 3JJ, UK.

It goes without saying that metals and their alloys play a huge role in our society. It is an obvious concern then that all metals, with the exception of gold, are thermodynamically unstable with respect to oxygen in acid solution, which means that the writing is on the wall for all our metallic artefacts. Although all metals exposed to the atmosphere suffer eventual degradation, the kinetics of corrosion are often slowed by passivation, such as the formation of a stable oxide layer on aluminium.

Metals can be further stabilised by application of specific organic additives, which are thought to form impervious, insoluble films. However, hampering the science of corrosion protection is the lack of information about structural compositions of such films, even after attempts to probe with surface physical experiment.

We are striving to contribute structural information to this field using molecular modelling techniques. It is known that surface films are coordination complexes and so must have analogous structural features to 'small molecule' complexes. This allows us to parallel any surface simulations with comprehensive search & analysis of relevant structural data available both locally and in the CSD [1]. In this way we have been able to shed light on surface films formed by various organic 'actives' on iron [2], copper and aluminium. A case study will be presented.

M07.OF.005 SPONTANEOUS CHIRAL SEPARATION IN LANGMUIR MONOLAYER FILMS AND CHIRAL DISORDER. I. Kuzmenko, M. Lahav and L. Leiserowitz, Department of Materials and Interfaces, the Weizmann Institute of Science, Rehovot 76100, Israel, K.Kjær, Condensed Matter Physics and Chemistry Department, Risø National Laboratory, DK-4000 Roskilde, Denmark, Jens Als-Nielsen, Niels Bohr Institute, H.C.Ørsted Laboratory, Copenhagen, Denmark

Spontaneous separation of enantiomers, discovered by Pasteur some 150 years ago, is driven by the same thermodynamic and kinetic factors both in two- and three-dimensional crystals. However, amphiphilic crystalline monolayers at an interface cannot possess a center of inversion, the most common symmetry element in bulk crystals. This fact should in principle lead to better chances for spontaneous separation in the Langmuir or Langmuir-Blodgett monomolecular films. On the other hand, the monolayers of most amphiphiles studied to date incorporate long aliphatic chains that have an intrinsic tendency to pack in a herring-bone motif requiring glide plane symmetry, thus creating a bias towards racemate formation. Moreover, 2D crystals supposedly have much higher degree of molecular and therefore enantiomeric disorder compared to bulk crystals. All these factors necessitate a careful choice of molecules to guarantee enantiomeric separation in two-dimensions.

We made use of acid-base interactions between two different chiral amphiphilic molecules (p-pentadecylmandelic acid and p-tetradecylphenylethylamine) to achieve spontaneous chiral segregation from a racemic mixture at the air-water interface, as shown by grazing incidence X-ray diffraction. The extent of possible chiral disorder for the two acid and base components is examined. We show that even in apparently crystalline monolayers the oblique lattice symmetry is insufficient evidence for spontaneous segregation of chiral molecules in two dimensions due to possible chiral disorder.

P07.OF.001 STRUCTURE, COORDINATION, AND VIBRATIONAL FREQUENCIES OF DI- AND MONOMETHYL ALUMINUM, ZINC, AND BORON DERIVATIVES ON A CHEMICALLY MODIFIED SiO_2 SURFACE. S.K. Ignatov and A.G. Razuvaev, Department of Chemistry, University of Nizhny Novgorod, pr. Gagarina 23, Nizhny Novgorod 603600, Russia, and A.A. Bagatur'yants and M.V. Alfimov, Photochemistry Center, Russian Academy of Sciences, ul. Novatorov 7a, Moscow 117421, Russia, and O. Gropen, Department of Chemistry, Faculty of Science, University of Tromsø, 9037 Tromsø, Norway

The geometrical and electronic structure of di- and monomethyl aluminum, zinc, and boron surface groups bonded to a SiO2 surface have been studied using *ab initio* clusters calculations at the HF/6-31G(d), MP2/6-31G(d), and B3LYP/6-31G(d) levels. The effects of boundary conditions and the effects of the cluster size have been examined using various cluster models. Minimal clusters $(H_3SiO)_3Si–O–Al(CH_3)_2$, $(H_3SiO)_3Si–O–ZnCH_3$, and $(H_3SiO)_3Si–O–B(CH_3)_2$ correctly describe the geometry and the main physical properties of the corresponding surface groups. Various coordination modes of the organometallic surface groups under consideration have been examined. The vibrational frequencies and IR intensities of di- and monoalkyl surface derivatives have been calculated at the B3LYP/6-31(d) level for various surface models. Experimental IR bands of silica with chemisorbed trimethylaluminum have been interpreted based on the calculated results. The observed IR bands of trimethylaluminum deposited on a preannealed SiO_2 surface at low temperatures in regions of 2800-3000, 1400-1450, and 600-950 cm^{-1} have been assigned to vibrations of monoalkyl surface species and physisorbed trimethylaluminum. The evolution of the IR spectra of the modified silica surface on heating from 300 to 1273 K are assigned to monoalkylaluminum surface derivatives. The observed IR band at 868 cm^{-1} can be assigned to the vibrations of Si-O-Al cyclic structures.

07AA PROTEIN-NUCLEIC ACID INTERACTIONS

M07.AA.001 EUKARYOTIC GENE EXPRESSION: A STRUCTURALIST'S VIEW. S. K. Burley, The Rockefeller University & Howard Hughes Medical Institute

Gene expression in eukaryotes is regulated in response to a host of developmental and environmental signals, which direct individual cells and tissues to synthesize specific subsets of proteins required for homeostasis. Over the past three decades, biochemists and molecular geneticists have made enormous contributions to our knowledge of the diverse mechanisms by which gene expression is controlled during transcription, RNA splicing, and translation. At each of these three major synthetic steps en route to the gene product, highly-complex phylogenetically-conserved macromolecular assemblies are responsible for both chemical catalysis and regulation. With recent advances in synchrotron radiation, high-speed computing, and crystalline sample preparation/preservation, structural biologists are studying large macromolecular assemblies at the level of atomic detail. These structures are having a very considerable intellectual impact. They provide elegant mechanistic explanations for much of what we know, and are changing our experimental approach to molecular biology.

M07.AA.002 HUMAN TOPOISOMERASES I: STRUCTURE, ACTION, INHIBITION AND CANCER. W.G.J. Hol [1][2], M.R. Redinbo [1], L. Stewart [1], J.J. Champoux [3], [1] Department of Biological Structure, University of Washington, Seattle, WA 98195, [2] Howard Hughes Medical Institute, Box 357370, Seattle, WA 98195, [3] Department of Microbiology, University of Washington, Seattle, WA 98195.

Human topoisomerases I are co-responsible for maintaining the proper topology of DNA in cells. DNA is involved in numerous complicated processes and as a result does frequently become overwound or underwound. This has serious repercussions for the interactions of proteins with DNA - and hence it is essential that the proper topology of DNA is maintained all the time. Topoisomerases I are able to relax DNA by transiently breaking one strand, making a covalent link with one end of the break point, allowing the DNA to relax and resealing the broken strand. A much happier DNA is the result of this careful "controlled rotation" process and topoisomerases may therefore be considered as major psychotherapists in living cells, striving for optimal happiness of a complicated and elongated patient.

The crystal structures of several complexes of human topoisomerase I with DNA could be elucidated after inspecting over a thousand crystals on six different synchrotrons. The resultant structures provide deep insight into the functioning of this sophisticated enzyme. However, the mode of action of camptothecin and other so-called "topo poisons", two of which are in use for treatment of cancer, remains an intriguing puzzle so far.

M07.AA.003 MISMATCH RECOGNITION AND REPAIR BY THE *E.COLI* G:U/T MISMATCH GLYCOSYLASE. Laurence Pearl[1], Tracey Barrett[1], Orlando Schärer[2], Renos Savva[3], Tom Barlow[4], Tom Brown[4], George Panayotou[5], Jo Jiricny[6], Gregory Verdine[2], [1]Centre for Structural Biology, Chester Beatty Laboratories, Institute of Cancer Research; [2]Dept. of Chemistry and Chemical Biology, Harvard University; [3]Dept. of Crystallography, Birkbeck College; [4]Dept. of Chemistry , University of Southampton; [5]Ludwig Institute for Cancer Research, University College London; [6]Inst. for Medical Radiobiology, Zürich.

The mismatch specific MUG/TDG family of DNA glycosylases are able to initiate the base-excision repair of G:U, G:T and G:ethenoC mismatched base-pairs in DNA. Structural and biochemical studies of the E.coli MUG enzyme have revealed the structural basis for their specificity, which depends on recognition of the widowed guanine rather than the scissile pyrimidine 'flipped-out' into the active site. Structures of the free enzyme, and complexes with abasic products and trapped substrate DNA molecules, reveals the intricate conformational changes that accompany the base-excision reaction.

M07.AA.004 B-DNA AT ATOMIC RESOLUTION: HELIX END-CAPPING AND GROOVE INTERACTION BY NI-PORPHYRIN. M. Bennett, A. Krah, M.R. Sanderson [1], E. Garman [2], R. Mckenna, S. Neidle [3]. [1] The Randall Institute. Dept. of Biomedical Sciences. King's College, 26-29 Drury Lane, London WC2B 5RL, UK. [2] Dept of Molecular Biophysics, The Rex Richards Building , South Parks Road, Oxford OX1 3QU, UK. [3] CRC Biolmolecular Sciences Unit, The Institue of Cancer Research, Sutton, Surrey, Surrey SM2 5NG, UK.

The crystal structure of a hexameric B-DNA type duplex complexed with a metalloporphyrin has been solved by a MAD experiment and refined to an R-factor of 10.5% against 0.9Å data. Special aspects of this structure include its crystal packing arrangement, disordering of the sugar-phosphate backbone, weak vertical hydrogen bonds, hydration network, end-capping of DNA helices by porphyrin, end-to-end dimerisation of DNA helices, interaction of porphyrin meso-substituents in the minor DNA helical groove and buckling of the porphyrin ring.

The structure was solved by MAD data collection of crystals grown with the bromo-derivitised DNA sequence dCCTAGG. Phases to 1.6Å with a mean figure of merit of 0.86 were calculated, the electron density map was of a high quality with atomic centres clearly present. High resolution data has also been collected and the structure refined, the use of local non-crystallogrphic symmetry restraints proved critical. The structure exhibits bond lengths with rmsd of 0.02Å with other nucleotide structures.

M07.AA.005 INTERACTIONS OF THE *TRP* RNA-BINDING ATTENUATION PROTEIN WITH COGNATE SINGLE STRANDED RNA. A.A. Antson, E.J. Dodson, G.G. Dodson, York Structural Biology Laboratory, University of York, York Y01 5DD, UK and X.-P. Chen, P. Gollnick, Department of Biological Sciences, Cooke Hall State University of New York at Buffalo, Buffalo, NY 14260, USA.

X-ray structure of *trp* RNA-binding attenuation protein (TRAP) from *B.stearothermophilus* in complex with 53-base RNA molecule provides the structural basis for the transcription regulation of *trp* (*trpEDCFBA*) operon.

In several *Bacilli* transcription of the *trp* operon is regulated by TRAP, in response to changes in the intracellular concentration of L-tryptophan [1]. The TRAP molecule is an assembly of 11 identical subunits related by rotational symmetry

[2]. During transcription, when TRAP is activated by L-tryptophan, it binds specifically to a leader region of the *trp* operon RNA transcript. The cognate RNA region is organised as eleven GAG or UAG triplets separated by two or three nucleotide spacers [3]. By binding and arresting the RNA region, TRAP disrupts the formation of an "antiterminator" hairpin structure and allows formation of an alternative, transcription termination hairpin.

We have determined the structure of TRAP in complex with $(GAGAU)_{10}GAG$ 53-base RNA at 1.9Å resolution. In the structure, each GAG triplet is bound in a pocket formed by β-strands. The circular arrangement of TRAP subunits generates a belt of 11 GAG binding sites with a diameter of about 80Å. Each RNA triplet is bound specifically with almost no direct interactions formed between the sugar-phosphate backbone and the protein. Now crystals are also available for complexes of TRAP with several different RNA sequences. These structures will help to address the specificity of TRAP/RNA interactions.

P07.AA.001 T4 ENDONUCLEASE VII, A DNA JUNCTION RESOLVASE WITH A NEW FOLD AND AN UNUSUAL DOMAIN-SWAPPED DIMER. Hans Raaijmakers, Imre Törö, Dietrich Suck [1], Olivier Vix [2], Stephan Golz, Börries Kemper [3], [1] European Molecular Biology Laboratory, Meyerhofstrasse 1, 69117 Heidelberg, Germany, [2] Synthelabo Biomoleculaire, 16 Rue d'Ankara, F67080 Strasbourg, [3] Dept. of Genetics, Univ. of Cologne, Zülpicherstr. 47, 50674 Köln, Germany.

Phage T4 endonuclease VII (Endo VII) was the first enzyme shown to resolve Holliday junctions. Unlike other resolvases, e.g. yeast CCE1 or E.coli RuvC, Endo VII recognizes a broad range of branched DNA substrates ranging from cruciform DNA to single-base mismatches.The 2x18 kDa Endo VII shows little sequence homology with other resolvases and, as a unique feature, contains one zinc ion per monomer tetrahedrally coordinated by four cysteines, which is essential for stabilizing the fold.

We have determined the crystal structures of the Ca2+ -bound wild-type and the inactive N62D mutant enzymes at 2.5Å and 2.1Å, respectively. The Endo VII monomers, which do not have a stable fold on their own, form an elongated, highly intertwined molecular dimer exhibiting extreme domain-swapping. The major dimerization element are two pairs of antiparallel helices forming a novel '4-helix cross' motif. The two other domains are each made up of the 55 N-terminal of one and 50 C-terminal aminoacids of the other monomer. The unique fold, almost completely lacking ß-sheet structure and containing a zinc ion, does not resemble any of the known junction-resolving enzymes. The S-shaped dimer has two 'binding-bays' separated by about 24Å which are lined by positively charged residues and contain near their base residues known to be essential for activity. These include Asp40 and Asn62, which both function as ligands for the bound calcium ions. A pronounced bipolar charge distribution suggests that branched DNA substrates bind to the positively charged face with the scissile phosphates interacting with the divalent cations. A model for the complex with a 4-way junction consistant with the available biochemical data will be presented.

While the overall protein architecture is the same in both wild-type and N62D mutant structures, there is a significant change in the orientation of the rigid (N- and C)-terminal domains relative to the central dimerization domain. The position of two NCS related helices in the '4-helix cross' are each shifted roughly half a helical turn relative to each other without however disrupting the hydrophobic core of the dimerization interface.

We are currently refining the mutant structure to 1.3Å resolution and are crystallizing EndoVII - DNA complexes.

P07.AA.002 STRUCTURAL BASIS OF FIDELITY BY DNA POLYMERASE I ENZYMES. G. Waksman, Y. Li, S.V. Korolev, and V. Mitaxov, Department of Biochemistry and Molecular Biophysics, Washington University School of Medicine, Saint Louis, MO63110, USA.

Eleven distinct crystal structures of the large fragment of *Thermus aquaticus* DNA polymerase I (Klentaq1) have been determined. For example, the crystal structures of two ternary complexes of Klentaq1 with a primer/template DNA and dideoxycytidine triphosphate and that of a binary complex of the same enzyme with a primer/template DNA were solved to a resolution of 2.3, 2.3 and 2.5 Å, respectively (EMBO Journal, vol 17, pp7514-7525 (1998)). One ternary complex structure differed markedly from the two other structures by a large reorientation of the tip of the fingers domain. This structure, designated "closed", represented the ternary polymerase complex caught in the act of incorporating a nucleotide. In the two other structures, the tip of the fingers domain was rotated outward by 46^{o} ("open") and this orientation of the fingers domain was similar to that of the apo form of Klentaq1 (PNAS, vol. 92, pp9264-9268 (1995)). These structures provided the first direct evidence in DNA polymerase I enzymes for a large conformational change responsible for assembling an active ternary complex. More recently, the structures of three additional ternary closed complexes with primer/template DNA and incoming dideoxyadenosine triphosphate, dideoxyguanosine triphosphate, and dideoxythymidine triphosphate have also been determined to 2.3 Å each. Together with the previous ternary closed complex structure, these structures show a snug fit of the protein around the incoming nucleotide, thereby demonstrating that the protein displays remarkable plasticity within the active site. Only in one ternary complex, that of the primer/template/ddGTP/Klentaq1 complex, a large change in side chain conformation resulting in additional hydrogen bonding interactions with the incoming base was observed. These rearrangements may constitute a structural basis for the higher rate of ddGTP incorporation compared to other dideoxynucleoside triphosphates by Klentaq1.

P07.AA.003 THE STRUCTURE OF THE WILD TYPE DTXR-DNA COMPLEX REVEALS A METAL BINDING THIRD DOMAIN. Ehmke Pohl, Dept. of Biological Structure, University of Washington, Seattle, USA, Randall K. Holmes, Dept. of Microbiology, University of Colorado, Denver, USA and Wim G.J. Hol. Dept. of Biological Structure and Biochemistry, Howard Hughes Medical Institute, University of Washington, Seattle, USA.

The diphtheria toxin repressor (DtxR) is the best characterised member of a family of iron-dependent regulator proteins also designated IdeR in gram-positive bacteria. These regulators are activated by Fe(II) and bind DNA as a homo dimer to prevent the transcription of the following genes. In Corynebacterium diphtheriae DtxR controls the expression of several proteins involved in the iron-uptake as well as its major pathogenic factor Diphtheria Toxin [1].

Here, we report the crystal structure of wild type DtxR activated by Co(II) in complex with a synthetic 21mer duplex DNA at 3.2Å resolution [2]. The structure shows two DtxR dimers on nearly opposite sides of the DNA oligonucleotide without any dimer-dimer contacts. The activation mechanism appears to involve both metal binding sites and a hinge motion of the N-terminal DNA-binding domain with respect to the dimerization domain.

Furthermore, our crystal structure reveals crucial parts of the SH3-like C-terminal domain (residues 121-226) that has been absent in previous structures [3]. In all four crystallographically independent DtxR monomers this domain contributes to metal binding at site 1 with two conserved residues. This interaction for the first time suggest an essential role of the SH3-like domain in the activation mechanism of DtxR.

P07.AA.004 STRUCTURES OF A NOVEL COMPLEX OF NUCLEIC ACID AND A CATALYTIC FRAGMENT OF REVERSE TRANSCRIPTASE. Millie M. Georgiadis, Shabir Najmudin, and Dunming Sun, Waksman Institute, Dept. of Chemistry, Rutgers University, Piscataway, NJ

We have obtained a novel complex of a catalytic fragment of Moloney murine leukemia virus reverse transcriptase (MMLV RT) with nucleic acid and determined two crystal structures at 2.3Å resolution. Reverse transcriptase, an essential retroviral enzyme, uses RNA- and DNA-directed DNA polymerase activities and an RNaseH activity to produce a double-stranded DNA copy from the single-stranded RNA genome of the retrovirus. The catalytic fragment is comprised of the fingers and palm domains of RT and retains polymerase activity. Both crystal forms include two catalytic fragment molecules and a single symmetric 8/8-mer DNA molecule in the asymmetric unit. Each catalytic fragment molecule provides a binding site for the oligonucleotide. The protein-DNA interactions include primarily hydrogen-bonding interactions with sugar atoms and base atoms in the minor groove of the DNA. These interactions should be possible for any sequence of DNA or RNA. Two conserved residues in the fingers domain of the catalytic fragment are important for DNA binding, Asp 114 and Arg 116, which form an ion-pair in the complex. We now refer to this binding site as the DXR site. Six of the hydrogen bonds found in each binding site are the same, and four of these involve the side chain atoms of Arg 116.

In order to determine the functional significance of the DXR binding site, we have substituted Ala for Asp 114 or Arg 116 in the full-length MMLV RT and characterized the enzymes. The specific activities of the enzymes were similar, but the products generated in polymerase assays were significantly shorter for the substituted enzymes. The substitutions affect processivity of the enzymes, the ability to incorporate many nucleotides prior to product dissociation, indicating that the newly identified DXR site plays a role in translocation of nucleic acid during polymerization. Our crystal structures provide the first models of a proposed intermediate step important in the mechanism of translocation.

P07.AA.005 CRYSTAL STRUCTURE OF THE REPLICATION INITIATOR PROTEIN RepE54 OF MINI-F PLASMID COMPLEXED WITH AN ITERON DNA AT 2.6Å RESOLUTION. H. Komori*, F. Matsunaga**, Y. Higuchi*, M. Ishiai**, C. Wada** and K. Miki*. *Department of Chemistry, Graduate School of Science, Kyoto University, Sakyo-ku, Kyoto 606-8502, Japan. **Institute for Virus Research, Kyoto University, Sakyo-ku, Kyoto 606-8501, Japan.

DNA replication is provoked by the binding of initiator proteins to the region of DNA replication origin. Regulation of DNA replication by initiator protein binding is one of the most important issues for ordered cell proliferation. The RepE, replication initiator protein of mini-F plasmid in Escherichia coli, exhibits two major functions. RepE exists mostly as dimer and binds to operator of *RepE* as an autogenous repressor, which is so stable that chaperones are required to facilitate their monomerization and initiate replication. One mutant, RepE54, is stable in the monomeric form without aggregations, while the wild-type protein tends to form aggregations easily making crystallization difficult. We have successfully crystallized RepE54 complexed with DNA. Here, we report for the first time the crystal structure of the prokaryotic initiator protein (RepE54) complexed with DNA. The structure was solved by the multiple isomorphous replacement method and refined to R = 21.3% at 2.6Å resolution. The crystal structure of the RepE54-DNA complex showed a new type of the DNA-binding modes. RepE54 is composed of two distinct N- and C-terminal domains which are structurally similar to each other and related by a non-crystallographic dyad, although no such similarity has been expected from its amino acid sequence. The helix-turn-helix motifs of both domains bind to the major groove of DNA with different binding affinities. The recognition helix of the C-terminal domain makes multiple specific contacts with the DNA bases, while that of the N-terminal domain has nonspecific interactions with the DNA backbones. It is also found from hypothetical model of RepE dimer bound to the operator that the N-terminal domains of dimer face with each other and then are responsible for dimerization. The structure suggests that the C-terminal domain plays the leading role in DNA binding, while the N-terminal domain has the additional role in dimerization. This functional difference of both domains is essential for the differential binding to the origin and the operator.

07BB BIOINFORMATION AND DATABASES (sponsored by NIST)

M07.BB.001 IDENTIFICATION OF STRUCTURAL NEIGHBORS AND HOMOLOGOUS CORE STRUCTURES. S. Bryant. NCBI, NIH, Bethesda, MD 20894, USA.

NCBI's 3D structure database now contains roughly 30,000 protein domain structures and 3,000,000 structure-structure alignments (1). This information is accessible at http:/www.ncbi.nlm.nih.gov/Entrez/Structure, using a WWW browser and molecular graphics viewer (2). Structure "neighbours" are detected and aligned by the VAST algorithm (Vector Alignment Search Tool) (3). VAST identifies structural similarities that are surprising in a statistical sense, those where the number of secondary structure elements that may be superimposed is greater than one would expect to see by chance. VAST also computes the most surprising atomic superposition, by comparing the RMS and length of alternative alignments to the background distribution expected by chance. These statistical definitions are useful in a search and retrieval system, where one does not wish to bias results according to subjective judgements or classifications. It may nonetheless be difficult to interpret structural similarity, since this can alternatively indicate descent from a common ancestral gene or convergence to a stable folding architecture. To assist in this interpretation we define the HCS (Homologous Core Structure) of protein families and show that a test for the presence of the HCS is effective in discrimination of homologs and "analogs" among structure neighbours. In the talk I will describe VAST, the statistical similarity thresholds it employs, and recent research in definition of homologous core structures.

M07.BB.002 ReLiBase - A DATABASE FOR ANALYSING RECEPTOR-LIGAND INTERACTIONS. Manfred Hendlich, Institute for Pharmaceutical Chemistry University of Marburg, Germany.

The dramatic increase of publicly available high resolution protein structures has resulted in an enormous amount of information about protein-ligand interactions. ReLiBase is the first database system which provides a selective and efficient access to structures of protein-ligand complexes. It has been designed to allow a wide range of queries relevant for structure based drug design. Ligands with certain topological properties and complexes with specific interactions between proteins and ligands can be identified within seconds to minutes. To enable a detailed characterisation of protein-ligand interactions a complete chemical description of protein ligands including bond orders and atom types has been added.

Recently, several new modules have been added to the ReLiBase core. This includes methods for detecting local similarities in binding sites of non-related proteins, tools for analysing and comparing water structures in binding sites and methods for analysing ligand induced conformational adaptations.

A custom-written database engine and a graphical user interfaces provide an efficient environment for the formulation of complex queries. ReLiBase is currently available to the academic community on the World Wide Web at the Protein Databank and the European Bioinformatics Institute.

M07.BB.003 CATH STRUCTURAL FAMILIES: INSIGHTS INTO PROTEIN EVOLUTION AND FUNCTION. Orengo, C.A, Bray, J., Todd, A. Pearl, F. & Thornton, J.M., Biomolecular Structure and Modelling Unit, University College, London

The rapid progress of the international genome projects has resulted in a wealth of sequence information for protein families. There are nearly 400,000 sequences known which can be grouped into ~20,000 families. Although the structural data has lagged behind the sequences, analysis suggests that with the advent of structural genomics initiatives we may soon have structural representatives for many evolutionary protein families. Since structure can provide crucial information on a protein's biological role, the next step is to accumulate and analyse functional data within these families.

At UCL, we have clustered all the well-resolved protein structures, in the PDB, into structural families. Proteins are first divided into separate domains and both sequence and structure alignment methods used to identify relationships. Data on families is stored within the CATH database (**C**lass, **A**rchitecture, **T**opology or fold and **H**omologous superfamily). To date, there are ~18,000 domains within CATH, which cluster into ~1100 homologous superfamilies and ~650 fold families.

Techniques are now being developed for assigning structural families to genome sequences. For example, we can identify probable families for >30% of proteins in Mycoplasma Genitalium (Salamov et al. 1999). Tools are also being developed for analysing available functional data within each homologous superfamily. Protein ligand interactions are identified and displayed (DOMPLOT, Todd et al. 1998) and correlations between sequence and structure motifs are captured using a new analysis program (CORA, Orengo, 1999).

M07.BB.004 IDENTIFICATION OF BIOISOSTERIC MOLECULES USING FIELD-BASED SIMILARITY SEARCHING. Peter Willett, University of Sheffield.

This paper discusses techniques for similarity searching in databases of three-dimensional chemical structures represented by steric, electrostatic and hydrophobic fields. Searches of several files of bioactive molecules demonstrate that field-based searching provides an effective way of identifying structural resemblances between molecules even in the absence of any obvious skeletal similarities. Such searches hence provide a method of database access that is complementary to existing, fragment-based methods for chemical similarity searching.

M07.BB.005 IDENTIFYING STRUCTURAL DOMAINS IN PROTEINS: IS THERE A UNIQUE SOLUTION? Shoshana J. Wodak [1,2], and Lorenz Wernisch[2], [1] Unte de Conformation de Macromolecules Biologiques, Universite Libre de Bruxelles, CP160-16, Ave. F. Roosevelt, 1050 Brusselles, Belgium. [2] EMBL Outstation, European Bioinformatics Institute, Wellcome Trust Genome Campus, Hinxton, Cambridge, CB10 1SD, UK.

The issue of subdividing protein molecules into structural and functional units has come up repeatedly over the last 25 years. In the early days the main emphasis was on identifying structural units capable of folding independently and of being stable on their own. Some attempts were made to link such units to exon/intron boundaries, and thereby with evolutionary processes. In recent years, with the number of known protein structures reaching over 10,000, the major incentive has been to devise automatic methods for identifying domains that can form the basis for a consistent protein classification.

Currently, there are over a dozen different methods for automatically assigning domains limits from the protein atomic coordinates. In general, the assignments by the different methods show only partial agreement. This has been interpreted as resulting primarily from the inherently difficulty in coping with the natural complexity of proteins, and dealt with by using consensus assignments by several methods.

We will discuss the concepts underlying the definitions of structural and functional domains, review the different types of approaches used to derive domain assignments and illustrate their application to protein structure classification protein folding and enzyme function.

P07.BB.001 THE GEOMETRY OF METAL-LIGAND INTERACTIONS RELEVANT TO PROTEINS. Marjorie M Harding, Institute of Cell and Molecular Biology, University of Edinburgh, Michael Swann Building, Edinburgh EH9 3JR, Scotland.

For a selection of metals (Ca, Mg, Mn, Fe, Cu, Zn at present) and ligands (water, carboxylate, imidazole, thiolate etc) which commonly occur in proteins geometrical data have been extracted from the Cambridge Structural Database, CSD [1] (*ca* 4500 observations, all with $R < 0.065$). Mean metal-donor atom distances are tabulated, together with sample standard deviation and range of observed values, for each metal-ligand combination. Where practicable subsets with different coordination numbers and/or oxidation state are given. Also included are interbond angles at the ligand donor atom, the orientation of carboxylate and imidazole groups and some other aspects of ligand geometry.

One objective of this work is to make the information conveniently available to protein crystallographers[2] – for use in interpretation of electron density maps, or as target distances in restrained refinement, when medium resolution diffraction data (2-3 A) must be used, also for the checking or validation of results of protein structure determination. Further, this analysis of preferred geometry and range of allowed geometry may contribute to the basic understanding of the function of different metals in metalloproteins .

Further work, in close collaboration with the Cambridge Crystallographic Data Centre, will analyse the geometry found in metalloprotein structures in the Protein Data Bank, selecting those which are more accurately determined. A pilot project[3] showed

that the mean of 146 Zn-$N_{imidazole}$ distances in 46 proteins, 2.07(11)A was not greatly different from that in 'small molecules', 2.00(2)A, although the 'spread ' of values was, as expected, much greater in the protein results.

P07.BB.003 OUR VISION FOR THE NEW PROTEIN DATA BANK. Helen M. Berman, John Westbrook, Kyle Burkhardt, Zukang Feng, Shri Jain, Rachel Kramer, Bohdan Schneider, Christine Zardecki [1], Peter Arzberger, Phil Bourne, John Badger, Helge Weissig [2], Gary Gilliland, Phoebe Fagan, Hillary Gilson, Diane Hancock, Narmada Thanki, Greg Vasquez [3], The Research Collaboratory for Structural Bioinformatics, [1] Rutgers University, Piscataway, NJ, USA, [2] San Diego Supercomputer Center, University of California, San Diego, USA, [3] National Institute of Standards and Technology, Gaithersburg, MD, USA

On October 1, 1998, the Research Collaboratory for Structural Bioinformatics (RCSB) became responsible for the management of the PDB. The RCSB members are Rutgers, the State University of New Jersey, the San Diego Supercomputer Center of the University of California, San Diego, and the National Institute of Standards and Technology.

The vision of the RCSB (http://www.rcsb.org/) is to enable new science by providing accurate, consistent, and well-annotated structure data via the application and development of modern information technology.

Data is deposited and processed by the RCSB using an integrated data processing system called ADIT (the AutoDep Input Tool). ADIT provides rapid and reliable data processing, and is also being used to revisit all existing structures in the PDB to create a more uniform archive.

The RCSB has also developed a query and reporting interface to search across the PDB archive. Searches and reports can be generated for single or multiple structures. As the quality of the data improves, the reliability of the query results will improve.

These systems and plans for extending the capabilities of the new PDB will be described.

This project is funded by the National Science Foundation, the Department of Energy, and two units of the National Institutes Of Health: the National Institute Of General Medical Sciences and the National Library Of Medicine.

07CC SHORT RANGE ORDER AND DIFFUSE SCATTERING

M07.CC.001 DIFFERENT APPROACHES TO THE PROBLEM OF DIFFUSE SCATTERING. R.I.Barabash, Metal Physics Department, National Technical University of Ukraine, apt.25, str. Proreznaya 4, Kiev, 252003, Ukraine.

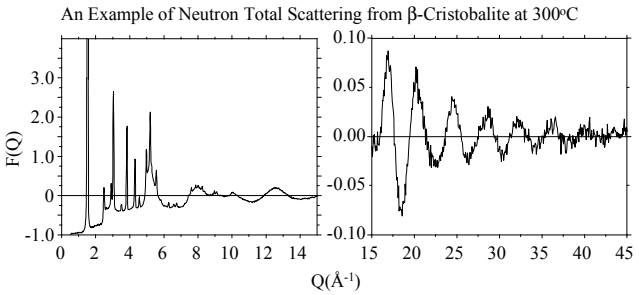
The presence of point defects or precipitates in the crystals results in the appearance of intensive diffuse scattering around matrix reciprocal lattice points. The shape of isodiffuse surface depends on the symmetry of of displacement field caused by defects. For point defects with cubic symmetry of displacement field the shape of isodiffuse surface is always double-drop. The change of such symmetry to tetragonal one results in apple or single drop shape of isodiffuse surface. Matrix anisotropy results in the distortion of isodiffuse surface of scattering but the type of it is retained.

Symmetric part of the diffuse scattering coincides with classic Huang scattering while asymmetric part is first of all connected with the difference in structure amplitudes between host (A) and impurity (C) atoms. When matrix consists of two or more host atoms (for example A and B) additional weak peaks occur due two the difference between their structure amplitudes. Impurity atoms in such matrix result in the formation of diffuse scattering around all (both weak and strong) initial peaks. The formation of clusters increases asymmetry of diffuse scattering intensity distribution. With the increase of precipitate size the character of isodiffuse surface may be changed essentially. In case of small defect concentration phenomenological description of scattering is correct, for high concentration of defects it is necessary to use microscopical analysis. The characteristics of diffuse scattering intensity distribution are related to the defect concentration and the type of displacement field around them. It gives possibility to solve the inverse task of scattering and determine the parameters of real structure for solid solutions and precipitation related crystals.

M07.CC.002 DETERMINATION OF LOCAL DISORDER IN SiO_2 AT HIGH TEMPERATURE USING TOTAL SCATTERING. David A. Keen, ISIS Facility, Rutherford Appleton Laboratory, Chilton, Didcot, Oxon OX11 0QX U.K.

At high temperatures many crystalline materials display significant structural disorder which may not be straightforward to characterise in terms of an average structure. In contrast, the Fourier transform of the total scattering is a direct measure of the instantaneous local structure. In this talk I shall describe how, using a combination of Rietveld analysis and modelling of total scattering data, a more complete picture of high temperature structural disorder can emerge.

I shall illustrate this approach with examples from the high-temperature polymorphs of silica (quartz, tridymite and cristobalite) and compare their instantaneous local structures to the structure of quenched silica glass.



M07.CC.003 DIFFUSE SCATTERING AND MICROSTRUCTURE IN CRISTOBALITE AND TRYDIMITE TYPE STRUCTURES. H. Lemmens, G. Van Tendeloo, S. Amelinckx, EMAT, University of Antwerp, Groenenborgerlaan 171, B-2020 Antwerp, Belgium.

Electron diffraction techniques, dark field imaging and high resolution electron microscopy are used to study the origin of diffuse scattering in the high temperature cristobalite phase of silica $(Si_{0.9}Ge_{0.1})O_2$. The metastable phase at lower temperatures undergoes a structural phase transition near 530 K. The low temperature α-cristobalite has $P4_12_12$ symmetry, the high temperature β-cristobalite has space group Fd3m. This high temperature symmetry however is an idealized structure and Hatch and Ghose [1] proposed this form to be a dynamic average of α-type phases. The domain structure in the β-phase is studied by electron diffraction and dark field imaging. The microstructure of the α-phase is studied by high resolution electron microscopy and different local structures are characterized such as a mixed trydimite/cristobalite layering.

Trydimite type structures like $BaAl_2O_4$ and $BaGa_2O_4$ are shown to undergo a paraelectric to ferroelectric phase transition with the formation of translation and orientation variants. These domains and their interfaces are studied by high resolution electron microscopy. Dark field imaging in diffuse spots shows curved anti phase boundaries, some of them forming closed loops. Under electron beam heating a breathing type motion of these anti phase boundaries is observed, similar to the ones observed before in anorthite by Van Tendeloo et al.[2].

M07.CC.005 DIFFUSE SCATTERING IN DECAGONAL $AL_{70}NI_{15}CO_{15}$. E. Weidner, LMU Muenchen, K. Hradil, Univ. Wuerzburg, F. Frey, T. Scholpp, LMU, Muenchen, M. De Boissieu, A. Letoublon, LTPM, St. Martin d'Heres,M. Capitan, ESRF, Grenoble, W. Morgenroth, DESY, Hamburg

Decagonal quasicrystals exhibit longrange aperiodic order in 2 dimensions and periodicity in the third, perpendicular direction. The diffraction patterns of $Al_{70}Co_{15}Ni_{15}$ show diffuse scattering of significant intensity as well as sharp Bragg peaks, indicating superorder and disorder: (1) satellite reflections, (2) diffuse *streaks*, (3) modulated diffuse layers perpendicular to the periodic direction (4) diffuse scattering near the Bragg peaks (5) diffuse maxima arranged in the shape of a pentagon (6) diffuse scattering in the center of a pentagon. For a review of various models explaining these phenomena, see [1]. High resolution measurements confirmed [2] for this phase the that the centers of the satellite pairs do not coincide with the position of the Bragg peak, but are shifted slightly, as predicted by a linear phason strain model. The average structure remains quasiperiodic as indicated by Bragg peaks at positions corresponding to an unstrainded qc. *Random phason fluctuations* cause diffuse scattering near the Bragg peaks, the integral diffuse intensity increases with the internal component of the reflection. The diffuse pentagon has been interpreted as a type II superstructure [3], this model is based on the proposition that the diffuse maxima form a regular pentagon. High-resolution measurements show that the positions agree with those predicted by the *phason strain*-model. Measurements at the ESRF have detected scattering in the center of a pentagon, at the position of a strong S1 reflection [4].

P07.CC.001 THE ORDER - DISORDER TRANSFORMATION IN $Al_{70}Ni_{15}Co_{15}$ QUASICRYSTAL. H. Abe, National Defense Academy, Yokosuka 239-8686, Japan, and T. Tamura and J. Bai, Oak Ridge National Laboratory, Tennessee 37831, USA, and D. Le Bolloc'h and S.C. Moss, University of Houston, Texas 77204, USA.

$Al_{70}Ni_{15}Co_{15}$ (ANC) alloys are well known to contain a decagonal phase. Recently many studies of ANC have been carried out in relation to an order-disorder transformation at high temperature. It is suggested that local atomic rearrangements, caused by phason softening, contribute to diffuse scattering around Bragg reflection [1]. Here we study the precise atomic short-range order (SRO) relating to this transformation. Our measurements are on a single quasicrystal of ANC at X14A in the National Synchrotron Light Source. Anomalous-x-ray scattering was used to clarify the atomic arrangements between Ni and Co, since the atomic number difference is only one. Three incident energies were selected to be 7.686, 8.098 and 8.304 keV (3λ method). We observed a large contrast difference in the diffuse scattering intensity with this method. SRO diffuse intensity are proportional to $|f_{Ni} - f_{Co}|^2$, reflecting the clear existence of SRO between Ni and Co atoms.

Y. Ishii, Phys. Rev. B**45**, 5228 (1992).

P07.CC.002 THE ANALYSIS OF DIFFUSE SCATTERING AND SHORT RANGE ORDER USING THE ATOMIC PAIR DISTRIBUTION FUNCTION. Th. Proffen and S.J.L. Billinge, Department of Physics and Astronomy, Michigan State University, East Lansing, MI 48824-1116, USA.

The analysis of diffuse scattering and the determination of the local atomic arrangements holds the key to a deeper understanding of the properties of modern materials. Since conventional structure refinement based on Bragg reflections can only reveal information about the **average** structure, the interest in methods to analyse diffuse scattering is increasing.

A convenient method to study these local arrangements is the analysis of the atomic pair distribution function (PDF) [1,2] which is obtained via Fourier Transform from powder diffraction data. The obtained PDFs are analysed via the full profile refinement based on a structural model having a size of only one or a few unit cells. The results are then compared to the long-range average values obtained via normal Rietveld [3] refinement. The potential of the PDF refinement technique will be illustrated on systems ranging from simple Ni and $In_{1-x}Ga_xAs$ to the more complex system of $La_{1-x}Ca_xMnO_3$.

The program PDFFIT used for the refinements is part of the diffuse scattering software package DISCUS [4] and is available free of charge from the authors.

P07.CC.003 ORDER, DISORDER AND SHORT RANGE ORDER IN ZIRCONIUM OXYNITRIDES. I. Kaiser, H. Boysen and F. Frey, Institut für Kristallographie, LMU, 80333 München, Germany, M. Lerch, Silicatchemie, 97070 Würzburg, Germany, T. Hansen and P. Convert, ILL, 38042 Grenoble, France, and D. Hohlwein, HMI, 14109 Berlin, Germany.

Zirconia, ZrO_2, doped with cations of lower valency is a technologically important material, e.g. with respect to its high ionic conductivity. A new alternative to create the necessary vacancies on the oxygen lattice is the doping with higher valency anions like nitrogen. Especially co-doped ternary probes have interesting properties. While for cation doped material the conductivity is affected by short range order (cluster), the N-doped samples also exhibit different long range vacancy ordering depending on the N content, and some N/O-order. Both disappear at high temperatures.

To analyse these order phenomena neutron experiments were performed at MAN1 and MAN2/FRM1, D20/ILL, and E2/HMI. The Bragg intensities were refined using the Rietveld program including anharmonic contributions to the Debye-Waller factor to determine the diffusion pathways of the anions. The modulated diffuse background, analysed with a Warren-Cowley formalism, gives information about the short range order.

All investigated phases are modifications of the fluorite structure type, with different ordering of the vacancies and concomitant relaxations of the surrounding atoms. Some anion positions show a preference of N occupation partly at variance with MAPLE calculations. The calculated diffusion pathways are similar in all systems at high temperatures, but the number of

diffusing ions is varies. The refinement of the diffuse background is based on a defect-cluster including a vacancy connected with a Zr atom, where the oxygens shift towards the vacancy and the cations away from it. The gradual disappearance of the short range order at high temperatures causes the ionic conductivity.

This work is supported by funds of the DFG under FR747/12-2.

P07.CC.004 DIFFUSE SCATTERING INTENSITIES FROM SELECTED CRYSTALLINE SAMPLES RECORDED WITH NEUTRON IMAGING PLATES. Ulrich C. Wildgruber, Physics Department, Brookhaven National Laboratory

Neutron sensitive Imaging Plates (NIP's) make it possible to collect diffracted neutrons with high spatial resolution and efficiency over large areas simultaneously. The usefulness of NIP's to map reciprocal space will be demonstrated with crystalline samples of C60, Pr2NiO4.215 and Zr0.8Nb0.2. We will show that there is a significant potential to collect diffuse intensity distributions up to q = 12.6 rec.Å.

The objective of this study is to collect diffuse intensities with NIP's at room temperature from an aged sample of Zr0.8Nb0.2 before and after heat treatment at 1273K and quenching to room temperature. The Zr-Nb system forms alloys with a bcc high temperature phase (β phase) and a hexagonal or trigonal lowtemperature phase (ω phase). The athermal ω phase is formed diffusionless by displacing atom rows parallel to [111]. The ideal heaxagonal ω phase however is formed only for small (< 2 wt %) Niobium concentrations. For Niobium concentrations in the range of 17 to 30 wt % diffuse scattering appears in the vicinity of the theoretical Bragg positions [Hall, B.A., Roberts J. A. Acta Met. **8** 575 (1960)]. The diffuse intensity increases with the amount of Niobium until the transition β -> ω is suppressed for concentrations greater than 30 wt %. The spatial distribution of the diffuse signal is basically the same in a wide temperature range from 6K to 1273K although it is sharper and significantly stronger at low temperatures [Keating, D.T. LaPlaca, S.J. J. Phys. Chem. Solids **35** 879 (1974)]. We will compare the data of this study with older neutron data collected with a single detector. The extended q-volume accessible in the case of NIP detection demands new strategies for data reduction and model refinement.

P07.CC.005 DIFFUSE SCATTERING BY RANDOM SOLID SOLUTIONS. R.I.Barabash [1], M. F.Thorpe [2], J. S. Chung [3], [1] Metal Physics Department, National Technical University of Ukraine, apt.25, str.Proreznaya 4, Kiev, 252003, Ukraine, [2] Physics & Astronomy Department, Michigan State University, East Lansing, MI 48824-1116, USA, [3] Department of Physics, Chungbuk National University, Gaeshin-dong,Cheongju-shi, 361-763, Republic of Korea

Modern simulation techniques on lattices allow the individual atomic displacements to be found and hence the associated diffuse X-ray or neutron scattering to be calculated directly. In this paper we use both the direct lattice simulations based on a lattice model of the crystalline alloy and the method of fluctuation waves in the continuum limit, to analyze the diffuse scattering by random solid solutions of a semiconductor alloy A1-xBxC. We consider both a single impurity atom in the crystal and also the case of a concentrated solid solution (with different concentrations of impurities x = 0.5; x = 0.3; x = 0.7 etc). The displacement field caused by a single impurity atom was analyzed for the alloy Ga1- xInxAs and compared with the case of a defect in an elastically isotropic medium. In the continuum limit, the substitution of the host atom by an impurity atom is accompanied by hydrostatic pressure across the surface of the impurity atom due to the size mismatch between the host and impurity. This results in the appearance of an inverse square displacement field in the matrix. The actual displacement field in Ga1-xInxAs is slightly more complicated and contains small tangential components as well as radial components. A crystalline alloy has a mean long-range order that leads to Bragg peaks and the associated diffuse scattering is divergent very close to these Bragg peaks. The shape of the diffuse scattering intensity distribution in different sections of reciprocal space is computed for the lattice, is compared with the continuum approximation. For the limiting case of a single defect in the crystal, the continuum approach agrees well with the results of direct lattice simulations. For concentrated random solid solutions where the angular and central spring constants are equal everywhere, the diffuse scattering intensity is proportional to the intensity for one defect case and scales with concentration as x (1-x). * Work supported in part by the US National Science Foundation and Department of Energy.

07DD THICK COATINGS

M07.DD.001 THE STUDY OF FILMS AND COATINGS USING GLANCING ANGLE X-RAY DIFFRACTION R J Cernik, Synchrotron Radiation Departmant, CLRC Daresbury Laboratory, Warrington WA4 4AD

Synchrotron radiation is an ideal probe for studying the structure of surfaces. Evidence for this can be found in the large number very successful studies of the structure of perfect surfaces using glancing angle X-rays. These are usually carried out in vacuum with cleaved surfaces or in-situ growth of epi layers. These are not usually suitable for industrial surfaces which have to work under realistic circumstances. For these materials deposited in thick or thin coatings two techniques have proved very valuable. These are glancing angle X-ray diffraction and reflectivity. The latter has combined specular and diffuse scattering to gain information on the lateral correlation length and surface roughness. Fringe spacing can be used to measure layered structures and diffraction is a very sensitive probe of structure as a function of depth. This presentation will cover the way in which these techniques are implimented on station 2.3 at Daresbury Laboratory for the study of a variety of coatings.

M07.DD.002 GLANCING ANGLE XRD MEASUREMENTS ON METALLURGICAL COATINGS. D. Rafaja, R. Kuzel and V. Valvoda, Faculty of Mathematics and Physics, Charles University, Ke Karlovu 5, CZ-121 16, Prague, Czech Republic.

The glancing angle X-ray diffraction (GAXRD) techniques are used to study a wide range of materials, but the application of the GAXRD in the analysis of metallurgical coatings is still dominant. The main advantage of the GAXRD is that the penetration depth of X-rays can easily be tuned up by changing the inclination of the sample with respect to the primary and diffracted beams. In particular, the penetration depth depends strongly on the angle of incidence of the primary beam, while the dependence of the penetration depth on the diffraction angle is rather weak. Thus, the GAXRD is applied to perform "layer-by-layer" measurements at constant penetration depths by keeping the angle of incidence constant in individual detector scans.

On the other hand, such a scanning of the reciprocal space is much more complex than in the symmetrical mode, as the direction of the diffraction vector changes during the measurement. Thus, the analysis of the diffraction patterns becomes more complicated, which holds especially for diffracted intensities if the coatings contain preferred oriented crystallites. Besides, intensity corrections for instrumental effects differ strongly from the intensity corrections used for symmetrical measurements.

In the contribution, the main attention will be paid to the GAXRD using the quasi-parallel beam optics. The experimental

results will illustrate the use of this technique in the depth-resolved X-ray diffraction, in the residual stress measurements and in the investigation of the anisotropic crystal deformation in cubic materials. The subjects of the experimental study are the PVD and CVD metallurgical coatings, ion-implanted CVD metallurgical coatings and thick metallurgical coatings prepared by reactive diffusion.

M07.DD.003 PROBLEMS RELATED TO THE DEPTH RESOLVED RESIDUAL STRESS ANALYSIS IN STRONGLY TEXTURED PVD-COATINGS. Ch. Genzel, Hahn-Meitner-Institut Berlin, Glienicker Str. 100, 14109 Berlin, Germany.

Hard coatings deposited by physical vapour deposition methods are widely used today to improve the mechanical properties of technical parts, for example the resistance to abrasive wear. In many cases, high compressive stresses up to some GPa develop during the coating process within the films, which contribute to the mechanical behaviour in a positive manner. In order to combine favourable mechanical properties like high hardness on the top of the coatings with a sufficient adhesiveness at its interface, efforts are made to adjust defined internal stress gradients with respect to the film thickness.

Therefore, the knowledge of both, the amount and the distribution of the residual stresses within the coatings, is of great practical interest. However, due to the small diffracting volume as well as texture, X-ray diffraction at polycrystalline coatings often leads to line profiles of rather weak intensity, and therefore, stress analysis involves a series of difficulties.

Starting from a general overview of the problems related to X-ray film stress analysis, several methods are compared concerning their suitability for the detection of non- uniform residual stress fields $\sigma(z)$. It will be shown that the choice of the appropriate method depends strongly on the material to be investigated. If the layers are strongly textured and their thickness is small compared with the penetration depth τ of the X-rays, the scattering vector method [1] offers some advantages, because the lattice strain depth profiles $\varepsilon_{\varphi\psi}(hkl,\tau)$ are obtained even for fixed positions of the scattering vector with respect to the sample reference system. Based on this measuring principle, a self consistent method will be presented, which yields the stress depth profiles $\sigma_{ij}(\tau)$ (i, j = 1, 2, 3) as well as the strain-free lattice spacing $d_0(hkl)$ even without some reference material [2].

M07.DD.004 MICROSTRUCTURE AND RESIDUAL STRESS IN PLASMA SPRAYED TBCS. M. Leoni, P. Scardi, Università di Trento, Facoltà di Ingegneria, Dipartimento di Ingegneria dei Materiali, via Mesiano, 77 - 38050 Trento, Italy.

Plasma sprayed Thermal Barrier Coatings (TBCs) find a growing number of applications for the protection of hot parts in combustion engines. Their performance and life is strongly related to the microstructure of the material and to the residual stresses generated by the deposition process, and their variation due to service (cycling).

Diffraction techniques are particularly suited to the study of two important features of these systems: phase composition and residual stress. The former is particularly relevant for zirconia TBCs, where three polymorphs (monoclinic, tetragonal and cubic) can be present in the coatings or develop after service. The knowledge (and control) of phase composition is extremely important as it strictly relates to the structural stability of the coatings. The Rietveld method, that can be used on both X-ray and neutron diffraction data, turns out as a very effective tool as it permits a non-destructive phase analysis without standards, and can also be used for routine quality control.

The measurement of residual stresses in thick ceramic coatings is one of the major steps towards the improvement of the durability of coated components. Traditional X-ray stress measurements based on the reflection geometry are not sufficient to give information on the variation of the residual stress through the coating thickness, because of the high absorption of zirconia with respect to the film thickness (millimetre range). Nevertheless, by combining these techniques with data coming from a mechanical modelling of the coating-substrate system, or some destructive stress analysis, the in-depth stress profile can be determined.

This kind of analysis, not involving a direct measurement of the inner coating region, will be shown to be consistent with true through-thickness measurements conducted by neutron diffraction, confirming the great potentiality of combining multiple measurement techniques for the analysis of complex stress states.

M07.DD.005 ABSTRACT NOT AVAILABLE. J.-L. Lebrun

07EE POLYMORPHISM IN INDUSTRY (sponsored by Dept. Pharmaceutical Sciences, Strathclyde University)

M07.EE.001 THE IMPACT OF POLYMORPHISM ON DRUG DEVELOPMENT: A REGULATOR'S VIEWPOINT. Wilson H. DeCamp, Division of New Drug Chemistry III, Food and Drug Administration

A general overview will be presented of the typical interactions between a drug company and the FDA during the development of a drug. The physical chemistry of the solid state bulk drug, especially its potential for crystallizing in multiple solid state forms, can significantly influence the development of both the synthetic process and the analytical chemistry of the drug. The drug is marketed and used as a finished drug product, which must be controlled to assure consistent quality. When the drug substance is known to be polymorphic, it can present special analytical concerns for the product. These topics will be discussed from two points of view: the type of information that should be acquired during drug development and how this information relates to issues of drug quality.

M07.EE.002 POLYMORPH CHARACTERISATION BY SOLID-STATE NMR. Robin K. Harris, Department of Chemistry, University of Durham, South Road, Durham, DH1 3LE, UK

Polymorphism is ubiquitous in many chemical industries (pharmaceutical,polymer, dyestuffs, ceramics etc.) so that techniques for distinguishing and characterising the different forms are essential for R&D, scale-up, manufacture, patent establishment and patent protection. Whilst single-crystal diffraction methods give detailed information in many cases, they fail or are inadequate in others. In recent years magic-angle spinning NMR has come to be the method of choice for many purposes. Its advantages will be stressed and examples given from several different industries. Crystallographic data, including asymmetric unit information and non-bonded interatomic distances, can be obtained. Questions of intermolecular interactions, structural disorder, molecular-level mobility and domain structure in heterogeneous systems will be emphasized. The combination of solid-state NMR information with powder diffraction data for complete structure determination is a growth

area. The future challenge is the simulation of intermolecular effects on chemical shifts a prelude to reversing this process. Naturally, solvates present similar problems and opportunities.

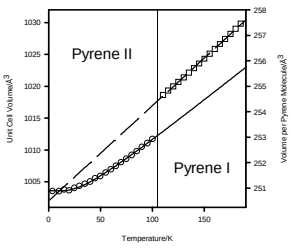
M07.EE.003 POLYMORPHISM IN PROTEIN CRYSTALS. Martin McMillan, 3-Dimensional Pharmaceuticals, Inc., Eagleview Corporate Center, 665 Stockton Drive, Exton, Pennsylvania 19341, USA

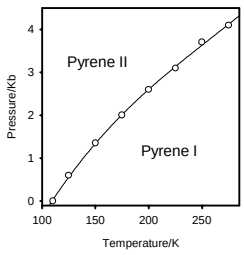
Because proteins are labile and polyvalent, the effects of pH, temperature, and additives - among many possible influences - on solubility minima are quite evident from the observation that protein molecules regularly crystallize in several polymorphic forms. In this general presentation, we will highlight a few interesting protein polymorphs and examine their packing motifs. To end, we will consider some practical aspects of polymorphism in a drug discovery setting.

M07.EE.004 SOLID STATE POLYMORPHIC TRANSFORMATIONS INDUCED BY VARIATIONS IN TEMPERATURE AND PRESSURE. K.S. Knight and K Shankland, ISIS Facility, Rutherford Appleton Laboratory, Chilton, Didcot, Oxon. OX11 0QX, UK., and N Shankland, Department of Pharmaceutical Sciences, University of Strathclyde, Strathclyde, G1 1XW, UK.

Polymorphism in industry is particularly problematic where problems arise in the advanced stages of product development. Recent problems with the HIV protease inhibitor ritonavir [1] once again underline the need for a comprehensive polymorph screen, including a search for phase transformations in the solid state. It is the surveying capability of powder diffraction which we wish to highlight here, using pyrene as an example.

We have utilised the advantages of neutron-time-of-flight techniques, namely fixed instrument geometry and total pattern integration, to rapidly determine the phase diagram of perdeuterated pyrene as a function of both temperature and pressure, Figures 1 and 2, below.





As a result of this work, we have been able to *(a)* resolve the order of the phase transition *(b)* refine the low-temperature and high-pressure structures, proving their equivalence *(c)* determine the equations of state of pyrene I at 225K and pyrene II at 95K and *(d)* evaluate the temperature dependence of the thermal expansion tensors in both polymorphs.

Recent data, currently under analysis, show the viability of cold neutrons for determining the rate of the solid-state transformation as a function of both pressure and temperature.

M07.EE.005 CRYSTAL STRUCTURE PREDICTION USING ATOM CONTACT DISTRIBUTIONS FROM THE CAMBRIDGE STRUCTURAL DATABASE. Sam Motherwell Cambridge Crystallographic Data Centre, 12 Union Rd, Cambridge CB2 1EZ, UK.

It is now well established that most molecules exhibit a range of many close-packed calculated structures all within about 2 kcal/mole of the global minimum, and thus are possible polymorphs [1]. To predict which polymorphs are more likely to be observed, one can attempt to compare the structures with the Cambridge Structural Database (CSD) which contains mostly those easily crystallisable polymorphs under normal laboratory conditions. A methodology has been developed for calculation of probable crystal structures based on the intermolecular atom-atom distances in the CSD. GA methods [2] have been used to find calculated crystal structures using rigid molecular models in common space groups. A fitness function is calculated which is a minimum when the calculated distance frequency distribution agrees best with the CSD for each atom-type in the molecule. All contacts are counted to each atom, giving a frequency distribution for a normalised distance $D = R_{ij} - R_v$, where R_{ij} is the distance between atoms i and j, and R_v is the sum of the van der Waals radii. The method makes no assumptions about energy, but seeks to reproduce the CSD frequencies characteristic of a selected set of similar molecules in the CSD. Extra fitting information can be given for patterns of close contact $D < R_v$, where a sample of chemically similar CSD molecules shows a good probability of occurrence, H-bonds being a typical example. These expectation values can be set even though we have no theoretical explanation of such patterns, and may often have kinetic reasons for formation [3].

07FF ORGANOMETALLIC AND CO-ORDINATION CHEMISTRY (sponsored by Dept. Chemistry, University of Glasgow)

M07.FF.001 COORDINATION COMPOUNDS ARE NOT ALWAYS SOLIDS. David W. H. Rankin, Paul T. Brain, Carole A. Morrison and Heather E. Robertson, Department of Chemistry, University of Edinburgh, West Mains Road, Edinburgh, EH9 3JJ, UK.

Gas-phase structures are often dramatically different from those of the same compounds in the crystalline phase - and if it can possibly be done, we should always determine both. It is the structure of the free molecule which is still obtained in most theoretical computations, and it is of crucial importance for understanding gas-phase reactions.

Coordination (and organometallic) compounds are often volatile enough to allow electron diffraction data to be collected, but the molecules are usually large and complex. However, we have developed a method in which we make use of both theoretical and experimental data. Parameters which are not well defined by the experimental data are flexibly restrained, making use of series of calculations with increasing size of basis set and increasing level of theory. The refinement optimises the fit to both sets of data, giving structures which make the best of both worlds.

The method will be illustrated by recent examples, chosen (a) to show the complexity of molecules which can now be studied in the gas phase, (b) to demonstrate the changes in structure which can occur on vaporisation / crystallisation, and (c) to explain the relevance of the gas-phase structures of some compounds to their chemistry.

M07.FF.002 THE CONTRIBUTION OF POWDER DIFFRACTION METHODS TO STRUCTURAL COORDINATION CHEMISTRY. A. Sironi Dipartimento di Chimica Strutturale e Stereochimica Inorganica Università di Milano, via Venezian 21, I 20133 Milano (Italy) and N. Masciocchi Dipartimento di Scienze Chimiche, Fisiche e Matematiche, Università dell'Insubria, sede di Como, Via Lucini 3, I 22100 Como (Italy)

In the last seven years, we have been active in the field of structural Powder Diffraction (PD) with the goal of developing a general procedure for the characterisation of moderately complex coordination and organometallic compounds using unsophisticated, widely available (but well conditioned) laboratory equipment [1].

Given that *only the lack of suitable single crystals makes PD structural studies worthwhile*, we may attempt to circumscribe the meaningful use of X-ray PD as a structural tool to *i)* insoluble, thermally unstable compounds which cannot be (re)crystallised from solution or from the melt; *ii)* metastable phases destroyed or modified upon manipulation; *iii)* twins, when the presence of double or multiple diffraction spots makes the 'single crystal' way of sampling the reciprocal lattice inefficient; *iv)* very small crystals or crystal aggregates; *v)* gas/solid, liquid/solid and solid state reactions fragmenting and misorienting the coherent domains of the starting crystals but conserving the (poly)crystalline nature of the sample.

The structural use of X-ray PD spans the whole periodic table but here we will discuss its growing importance in coordination chemistry by taking examples from our current studies on rhenium hydrido carbonyl clusters where complementarity between single crystal and PD analyses emerges.

M07.FF.003 COMBINED THEORETICAL AND STRUCTURAL DATABASE STUDIES OF BINUCLEAR TRANSITION METAL COMPLEXES. Santiago Alvarez, Departament de Química Inorgànica and Centre de Química Teòrica, Universitat de Barcelona; Diagonal 647, 08028 Barcelona, Spain.

The combination of quantum chemical calculations on model compounds and structural database analyses has allowed us to establish some trends on the structural chemistry and dynamic behavior of binuclear transition metal compounds. Calculations in which a bonding parameter is frozen and the rest of a model molecular structure is optimized mimics the effects of chemical substitutions, solvation molecules or packing forces in a crystal, thus allowing to reproduce known structural correlations or predict new ones. Furthermore, from a well planned set of calculations one should be able to identify the electronic, geometric or steric origin of such structural correlations. The cases to be discussed include (a) the conformational choice within three families of doubly bridged binuclear complexes of square planar d^8 metal ions, (b) the effect of the *umbrella* motion of the ligands on the metal-metal bond diatance in a variety of M_2L_{2n} complexes, (c) the correlation between the geometry of the coordination sphere around Cu atoms and the cleavage of the oxygen-oxygen bond in synthetic analogues of oxyhemocyanin, and (d) the continuous structural variation along the reaction path that takes from weakly associated Cu(I) linear complexes CuXL to rhombic $Cu_2X_2L_2$ dimers.

M07.FF.004 UNDERSTANDING ORGANOMETALLIC REACTIONS ON THE BASIS OF CRYSTAL STRUCTURES. K. Angermund, M. Kessler and V. R. Jensen. Max-Planck-Institut für Kohlenforschung, Kaiser-Wilhelm-Platz 1, D-45470 Mülheim an der Ruhr, Germany.

Many organometallic reactions, especially those which are of commercial interest, are very fast and highly selective catalytic processes. Crystal structure analysis on the other hand, operates on a considerably larger time scale, and usually describes the structure of catalytically inactive species, adopting conformations which are stable in the crystal field at a certain temperature. Yet, much of the necessary information for the understanding of catalytic reactions may still be contained in crystal structures of the reaction educts and products. Several methods for extracting such information will be presented during the lecture. Their degree of complexity will vary from simple "distortions" of structures [1], for which almost no energy calculations are necessary, to the concept of "accessible molecular surface" (*ams*) [2], which in some respect can be regarded as an extension of Tolman's cone angle [3], and to more complex models for true transition state structures based on theoretically (pre)calculated molecular fragments [4]. The chemical examples will cover the area of hydrovinylation, hydrogenation of CO_2 and olefin polymerisation.

M07.FF.005 NOVEL COORDINATION CHEMISTRY OF C_2^{2-} AND RELATED ANIONS. Thomas C. W. Mak and Guo-Cong Guo, Department of Chemistry, The Chinese University of Hong Kong, Shatin, New Territories, Hong Kong, China.

The literature contains scant information on the ligand behaviour of C_2^{2-} (acetylide dianion, acetylenediide), in contrast to the rich coordination chemistry of its isoelectronic analogues N_2, CO, NO^+ and CN^-. Although silver acetylide (Ag_2C_2, also known as silver carbide) was first prepared as an impure yellowish powder by Berthelot in 1866, there is as yet no single crystal X-ray structure information owing to its sensitivity to mechanical shock and low solubility in common solvents. Recently we initiated a research project to synthesize and elucidate the X-ray crystal structures of novel compounds containing silver acetylide as a component, so as to shed some light on the nature of the interaction between the acetylide dianion and silver(I) ions.

We report here the synthesis and crystal structure of the following double salts:

- $Ag_2C_2 \cdot 8AgF$, in which an acetylide dianion is completely enclosed within a Ag_9 cage of a chandelier-like assembly of ten silver atoms.[1]
- $Ag_2C_2 \cdot 2AgClO_4 \cdot 2H_2O$, in which the C_2^{2-} species acts in a μ_6-$\eta^1,\eta^1 : \eta^2,\eta^2 : \eta^2,\eta^2$ bonding mode that binds the silver cations into an unprecedented two-dimensional planar array.[2]
- $Ag_2C_2 \cdot AgNO_3$, $Ag_2C_2 \cdot 5AgNO_3$ and $Ag_2C_2 \cdot 5.5AgNO_3$, in which the C_2^{2-} dianions are fully encapsulated in the cavities of an octahedron, a monocapped trigonal prism and a monocapped octahedron, respectively.[3]

Our recent structural studies on novel coordination modes of the cyanide,[4] azide,[5] and thiocyanate[3] anions in related double salts of silver(I) will also be presented.

P07.FF.001 STRUCTURAL CHARACTERIZATION OF A SERIES OF NOVEL MONOOXOVANADIUM(V) COMPLEXES. S.-X. Liu, Dept. of Chem., Fuzhou University, Fuzhou 350002, China.

The relationships among structure, spectroscopy, and reactivity must be elucidated in order to understand fully the role of vanadium in biological systems. Thirty one novel monovanadium(v) complexes were synthesized and characterized by X-ray diffraction at room or low temperature, IR, Raman, UV, ^{1}H NMR spectra and cyclic voltammetry measurements.

There are a distorted octahedral configuration with [VO(ONO)(OO)] [1-3], [VO(ONO)(ON)] or [VO(ONO)(O)(O)] [2] type and a distorted square pyramidal configuration with [VO(ONO)(O)] or [VO(ONS)(O) type in the vanadium atoms of these monooxovanadium(V) complexes. However, most of vanadium atoms in the known vanadium hydrazone complexes have a square pyramidal [VO(ONO)(O)] coordination., only three complexes have octahedral [VO(ONO)(O)(O)] or [VO(ONO)(ON)] coordination. Some complexes reported by us represent the first structural characterization of any vanadium hydrazone complex with VO(ONO)(OO) coordination. The complex $VO(C_{15}H_{12}N_2O_3)(C_3H_7O)(H_2O)$ is the first example of a VO^{3+} complex with V-O(H_2O) bond. The order of the V-O and V-N coordination bond distances and the coordination effects of the different ligands are discussed. There are some hydrogen bonds in some of these monooxovanadium complexes, forming an infinite chain in the crystals. Therefore, some of these complexes are supermolecular complexes.

The author thanks the financial support of the Natural Science Foundation of Fujian Province of China. The author thanks the financial support from University of Durham, UK for our crystal structure determination of some complexes at low temperature.

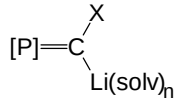
P07.FF.002 LITHIUM PHOSPHAVINYLIDENE CARBENOIDS. M. Nieger, T. Baumgartner, O. Schmidt and E. Niecke, Institut für Anorganische Chemie, Universität Bonn, D-53121 Bonn, Germany.

Carbenoids have attracted a great deal of interest because of their potential as synthetic building blocks in organic chemistry [1]. The presence of both an electronegative element and a metal at one carbon atom leads to a unique bonding situation with a 'chameleon like' ambident character of this carbon atom [2]. The carbenoide centre of phosphavinylidenes is significantly stabilized by incorporation into π-systems.



(X = F, Cl, Br)

Here, the structures of lithium phosphanylidene (X = Cl) [3] and phosphoranylidene carbenoids (X = F, Cl, Br) [4], as well as a lithiated bis-(ylene) phosphorane (X = H) [5] are presented, highlighting the first stable fluoro-lithio and the *E/Z* isomers of the chloro-lithio phosphoranyl-idene carbenoids. The structural parameters are investigated in detail. The connection between structural features and bonding in phosphavinylidene carbenoids will be discussed.

P07.FF.003 DIRECT OBSERVATION OF A SOFT MOLECULAR DEGREE OF FREEDOM IN THE SOLID STATE. U. Englert, G.E.Herberich, and J. RosenplŠnter, Institute for Inorganic Chemistry, RWTH Aachen, Prof.-Pirlet-Str. 1, 52074 Aachen, Germany.

In the boratabenzene complex $InMe(C_5H_5BMe)_2$ two six-membered rings are coordinated to In. Due to the electropositive effect of the boron its carbon neighbors in the adjacent ring positions represent preferred coordination partners for the metal center. NMR results show that the compound is dynamical in solution with effective lateral symmetry for the boratabenzene ligands, presumably due to a fast degenerate exchange of the indium coordination between the above mentioned positions of the ring. In the crystal the space group is $P2_1$ with eight molecules per unit cell, i. e. four independent molecules. Due to the presence of two heterocyclic ligands per molecule eight different metal-ligand bonding geometries may be investigated in the same solid state structure. They show a remarkable variability in terms of the shortest In-C-distances ranging from 2.395(8) to 2.523(9)Å [1]. A synopsis of all eight projections of the metal atoms on the least squares plane through an idealized ring ligand helps to understand the bonding situation: each metal projection corresponds to a snapshot of the molecule in an energetically favourable conformation. The overall picture shows that the soft structural parameter in the solid state reflects the dynamical situation in solution. Lattice energy calculations [2,3] are used to compare the experimentally established structure to hypothetical alternatives with a smaller number of independent molecular constituents per asymmetric unit.

P07.FF.004 BOND-VALENCE MODEL OF THE SEMICOORDINATION IN COPPER-OXYGEN AND COPPER-NITROGEN COMPLEXES F. Valach, Department of Chemical Physics, Faculty of Chemical Technology, Slovak University of Technology, SK-812 37 Bratislava, Slovak Republic.

The basic assumption of the bond valence model [1] is that each bond between atom *i* and *j* can be assigned a bond valence s_{ij} fulfilling the rule: $V_i = \sum_j s_{ij}$ (1) V_i is the valence of atom *i*. For

the localised bonds with the orbital interaction between neighbouring atoms the bond valence as the function of inter-nuclear distance *r* was derived in the form:

$$s = \sum_{v=1}^{\infty} \frac{\alpha_v}{r^v} \quad (2)$$

α_v are constants dependent on the nature of the bonded atoms. Existence of discontinued transition from chemical bonding to the nonbonding state in the direction of alongated bond of CuO_6 and CuO_5 chromophores limits the index v to the highest value 5 for Cu-O bond. Such supreme manifestation of coordination sphere plasticity [2] is estimated as semicoordination. The parameters α_v ($v = 1-5$) were fitted using formulae (1) and (2) for structures with Cu-O and Cu-N bonds. Mutual dependence between the bond length in copper coordination sphere with chromophores, CuO_6, CuO_5, CuN_6, and CuN_4O_2 has been derived and compared with the experimental structural correlations. Within the copper atom coordination with CuO_5 chromophore the apical Cu(II)-O bond lengths of binuclear carboxylic complexes were predicted.

P07.FF.005 THE DEVELOPMENT OF AN INDUSTRIAL CATALYST THROUGH THE USE OF CRYSTALLOGRAPHY. David J. Ager, Amihai Eisenstadt, and Scott A. Laneman, NSC Technologies, 601 East Kensington Road, Mount Prospect, IL 60056, USA, and Albert S. C. Chan, Monsanto Corporate Research, 800 Lindbergh Avenue, St. Louis, MO 63167 USA, Frank Fronczek, Louisiana State University, Boca Raton, LA 70803 USA, and Cynthia X. Day, Crystalytics Co., P.O. Box 82286, Lincoln, NE 68501 USA.

Crystallography has played an important role in the development of development of the Monsanto ruthenium-BINAP catalysts that are used for the production of intermediate for the pharmaceutical industry. The most important member of this class of catalyst is a polymer $[Ru(BINAP)Cl_2]n$ that cannot be characterised in the solid state as it is a mixture of compounds [1]. However, the discovery of this compound was found due to omission of sodium acetate in an attempt to prepare $[Ru(BINAP)(OAc)_2]$; crystallography showed that the major product was a novel ruthenium-phosphine oxide complex [2]. Other members of the catalyst class contain the $[Ru(BINAP)(acac)_2]$ moiety. Structural elucidation of these catalysts has provided insight into the factors that govern stereochemical control during asymmetric hydrogenations. Finally, during a new preparation of the BINAP ligand [3], the intermediate organometallic species was obtained as a solid and whose structure was found by crystallography. The presence of this compound showed that a different mechanism was operating for the formation of the carbon–phosphorus bond than for previous approaches.

P07.FF.006 NEUTRON DIFFRACTION STUDIES ON $(\eta^6\text{-}C_7H_8)(OH)(H)Fe\text{-}\{Sn[CH(SiMe_3)_2]_2\}_2$: A COMPOUND SUSPECTED OF HAVING A Fe-H-Sn AGOSTIC INTERACTION. Robert Bau, Jörg J. Schneider and Sax A. Mason, Department of Chemistry, University of Southern California, Los Angeles, CA 90089, U.S.A., Institut für Anorganische Chemie, Universität Essen, Essen 45117, Germany, and the Institut Laue-Langevin, Grenoble 38042, France.

The reaction of bis(toluene)iron with $Sn[CH(SiMe_3)_2]_2$ followed by hydrolysis yields the title compound, the hydroxo hydrido complex $(\eta^6\text{-}C_7H_8)(OH)(H)Fe\{Sn[CH(SiMe_3)_2]_2\}_2$ (1). Originally, ^{1}H-NMR analysis of (1) suggested the presence of a three-center "agostic"

Fe-H-Sn interaction, based on a significantly large ^2J(Sn,H,Fe) proton NMR coupling constant of 286.6 Hz. A single-crystal neutron diffraction analysis of (1), however, shows its structure to be classical, with a normal terminal Fe-H single bond [1.575(8)Å]. The Sn…H distances of 2.482(9) and 2.499(9) Å found in (1) were judged to be too long to correspond to any significant Sn…H bonding interaction. Final R factor = 7.6% for 4960 reflections collected at 20K.

P07.FF.007 CRYSTAL ENGINEERING OF MICROPOROUS 3-D METAL COORDINATION POLYMERS. Stephen S-Y. Chui, Ian D. Williams, Alvin Siu and Samuel M-F. Lo, Department of Chemistry, Hong Kong University of Science and Technology, Clear Water Bay, Hong Kong, China, A. Guy Orpen and Jonathan P.H. Charmant, School of Chemistry, University of Bristol, Cantock's Close, Bristol, BS8 1TS UK.

The engineering of new crystalline open-framework materials, which are complementary to zeolites, is of both scientific interest and considerable commercial value. Metal coordination polymers offer many attractive features in this regard due to the relative ease with which they may be chemically modified. The main issues which need to be addressed for producing potentially useful materials are a) control of framework dimensionality b) pore size engineering c) prevention of network interpenetration d) control of framework stability and e) chemical functionalization of the framework.

Using recent examples from our work we will demonstrate how framework dimensionality can be controlled through ligand multifunctionality, coordination number and minimization of ancillary ligation; pore sizes can be modified using larger polyfunctional ligands, ancillary ligand modification or use/self-assembly of cluster-type building blocks; network interpenetration can be circumvented by creating voids <50% ; and how stability can be improved though control of coordination options or through formation of ceramic hydroxide cores.

A thermally stable cubic polymer $[Cu_3(TMA)_2(H_2O)_3]n\ xH_2O$ exemplifying many of these desirable features has been prepared in excellent yield and purity by both solvothermal and RT methods. (1) It has interpentrating pores of 1nm dimension, yet is stable to removal of both the channel and ligated aqua groups and can be chemically functionalized using ligands such as pyridine. Preliminary results of the sorption properties of this and its chemical derivatives will be reported.

P07.FF.009 CRYSTALLOGRAPHIC AND SPECTROSCOPIC STUDIES OF PLATINUM(II) COMPLEXES WITH PYRIDINE DERIVATIVES. C. Tessier and F. D. Rochon. Departement de chimie, Universite du Quebec a Montreal, P.O. Box 8888, Succ. Centre-Ville, Montreal, Quebec, Canada, H3C 3P8.

The antitumor properties of *cis*-Pt-amine complexes have been known for a few decades. More recently, *trans*-$Pt(pyridine)_2Cl_2$ has shown comparable cytotoxicity with *cisplatin* towards Leukemia L1210 cells. The mixed-ligand *cis*-$Pt(NH_3)$(2-Mepyridine)Cl_2 species is a very active compound which is currently in clinical trials. We have recently started a very detailed study of complexes of the types *cis*- and *trans*-$Pt(Ypy)_2X_2$ (where Ypy =pyridine derivative and X = I, Cl, NO_3). The chloro and

iodo compounds of pyridine have been known for a long time but the nature of the Pt-pyridine bond is still unknown. Pyridine derivatives have empty π* orbitals, which can accept back-donation from the metal. The results of our study have shown how the use of crystallography, multinuclear (^{195}Pt, ^{1}H and ^{13}C) NMR and IR spectrocopy can bring interesting new information on the nature of the Pt(II)-ligand bonds especially with pyridine ligands. Six different pyridine derivatives were used and the 36 complexes were synthesized by slight variations of published methods. Thirteen compounds were studied by X-ray diffraction methods. Most structures have shown the *anti* conformation of the two pyridine ligands, while one contained the two ligands in a *syn* conformation. The relative *trans* influence of the ligands used in this project will be discussed.

08OA CRYSTALLOGRAPHY AND NMR OF RNA

M08.OA.001 ABSTRACT NOT AVAILABLE. T. Steitz

M08.OA.002 ABSTRACT NOT AVAILABLE. J.D. Puglisi

M08.OA.003 NMR STUDIES OF RNA-PROTEIN COMPLEXES AND MULTIMOLECULAR ASSEMBLIES DURING GENE EXPRESSION. Gabriele Varani - MRC Laboratory of Molecular Biology Hills Road - Cambridge CB2 2QH - UK

RNA-protein complexes play a central role in every aspect of the post-transcriptional regulation of gene expression. Our work aims at understanding the structural principles underlying RNA-protein recognition and the mechanism by which gene expression occurs and is regulated. One extreme example in RNA recognition is provided by human U1A, a protein that recognizes partially single stranded RNA in a highly specific faction. A very different example of RNA recognition is provided by is the structure of the Staufen dsRBD domain in complex with double stranded RNA, a non-sequence specific complex. The comparison with X-ray studies of related protein-RNA complexes provides an opportunity to describe the convergence and complementarity of information provided by the two techniques. At a more complex structural and biochemical level, biological regulation can be achieved not only by modulating RNA recognition, but also through RNA-dependent protein-protein interactions in the multimolecular assemblies that constitute structural and functional units during gene expression. As a paradigm to understand these processes, we are studying the 40 kDa ternary complex between two human U1A proteins and the U1A polyadenylation regulatory element RNA. Recent advances in the NMR method makes structures of this size and larger a challenging but entirely feasible goal. The ternary complex regulates expression of the U1A protein itself by interfering with the formation of the poly(A) tail in the cell nucleus. Interaction with RNA induces a conformational change in the protein that allows two U1A molecules to bind cooperatively and to interact with Poly(A)-polymerase enzyme. Thus, apparently distinct molecular recognition events are triggered by an RNA-dependent conformational change to ensure exquisite specificity in the regulation of Poly(A) polymerase activity.

M08.OA.004 FRET ANALYSIS OF U1A PRE-mRNA 3'-UTR GLOBAL STRUCTURE. David M.J. Lilley, Richard J. Grainger and David G. Norman, CRC Nucleic Acid Structure Research Group, Department of Biochemistry, University of Dundee, Dundee DD1 4HN, United Kingdom.

FRET is a valuable method for obtaining long-distance information in nucleic acids. U1A pre-mRNA contains a U1A binding element in its 3' untranslated region (UTR), comprising two asymmetric loops separated by a four basepair duplex. Using FRET we have measured the bending angle of a single UTR loop, obtaining an included bend angle of 100°. The FRET data for the complete 3'-UTR element suggest a dihedral angle between the outer helical segments of 35°. We can observe binding of U1A protein to the 3'-UTR element by a change in the fluorescence anisotropy of Cy3 attached to one of the helical ends. In parallel with the binding we observe a marked increase in FRET efficiency between fluorophores attached at the two 5' termini, indicating a significant change in global conformation induced by the binding of the protein.

M08.OA.005 STRUCTURE OF THE MATURED FORM OF THE DIMERIZATION INITIATION SITE OF HIV-1(Mal) GENOMIC RNA. P. Dumas, E. Ennifar, M. Yusupov, P. Walter, R. Marquet, B. Ehresmann, C. Ehresmann, IBMC-CNRS, 15 rue Descartes F67084 STRASBOURG

An important step of the replication cycle of retroviruses is the dimerization of its RNA genome prior to encapsidation. The Dimerization Initiation Site (DIS) is made of a hairpin closed by a loop with a self-complementary sequence of 6 nt [1]. This allows the formation of a transient 'kissing-loop complex' (Fig.1) which is thought to be matured *in vivo* by the basic viral nucleocapsid protein (NCP) into an elongated duplex [2]. We have crystallized a 23nt fragment corresponding to the DIS hairpin [3]. In some occasions, either perfectly or partially twinned crystals were obtained (space group $P3_121$). The structure was solved by the MIR method by use of bromo and iodo-uridine, as well as $Ru(NH_3)_6$, and subsequently refined at 2.3Å resolution (Rfree=21.5%). The structure obtained is a 22 bp symmetrical duplex corresponding to the matured form. It shows two non-canonical Watson-Crick-like G-A bp adjacent to two bulged adenine residues (Fig.2). The latter, lying almost on top of each other, form a striking base grip which could be a recognition signal, either *in trans* for one protein (possibly the NCP), or *in cis* for some site within the viral RNA. A network of 8 magnesium cations is clearly visible, with one being unusually chelated across the major groove by the 3'-phosphates of each bulge.

08OB LARGE UNIT CELLS: SOURCES, DETECTORS AND DATA

M08.OB.001 DESIGN OF BEAMLINES FOR MACRO-MOLECULAR CRYSTALLOGRAPHY AT 3RD GENERATION SOURCES. Gerd Rosenbaum, Argonne National Lab, Argonne, IL 60439, USA

The high flux emitted into a very narrow cone by undulators at 3rd generation storage rings makes them an ideal source for crystallography on macromolecular crystals with large unit cells. The purpose of the beamline optics is to transform the characteristics of the beam emitted by the undulator into those which are optimal for the crystallographic experiment. Generally, the optimum is a match between the sizes of the image of the source, the size of the sample and the size and spatial resolution of the detector used for recording the diffraction peaks. Strategies for beamline layout, with emphasis on suitability for small crystals with large unit cells, will be presented in general and in detail for systems using high resolution area detectors.

M08.OB.002 DATA COLLECTION FROM LARGE UNIT CELL CRYSTALS USING CCD AND LARGE IP DETECTORS ON ID14 AT THE ESRF. S. Wakatsuki, ESRF, B.P.220, 38043 Grenoble, France

The high brilliance protein crystallography beamlines at the ESRF, ID2PX and ID14/EH1-4 have made hitherto unfeasible diffraction experiments possible. These include data collection from extremely large structures (thus weakly diffracting) and very small crystals. Key factors for the success of such experiments are high brilliance, low divergence, stable optics, and large and fast detectors. X-ray beams from undulator sources on third generation synchrotron sources satisfy the first two conditions, while modern beam line design provides reliable optics which can withstand the heat load of high brilliance X-ray beam. The low divergence of the X-ray beams on ID14, on the order of 10 microradians, enables separation of diffraction spots corresponding to d-spacing of a few thousands of Ångstroms.

The choice of detectors is also of critical importance. We chose two types of detectors: fiber optics coupled CCD and image plate (IP) detectors. The point spread function of the detectors must be comparable to the physical dimensions of diffraction spots from crystals of 50 to 200 microns in size. The overall dimension, thus the number of pixels, needs to be sufficiently large in order to collect a large number of diffraction orders. For example, the 2k by 2k CCD detector on ID14/EH4 can record 500-550 diffraction orders with a duty cycle of 10 frames per minute.

Another solution for capturing as many diffraction orders as possible is to use image plates since larger active areas can be achieved more readily. We have developed a Weissenberg camera with an active area of 800 mm by 800mm for one of the experimental stations, EH3. Two image plates, 40 cm by 80 cm, are placed on a flat wall by a robot from an IP storage/erasure device standing next to the robot. The image plates are read out using an off-line IP drum scanner with 100 micron pixel size.

Recent examples of medium- to high- resolution data collection from crystals with large unit cell dimensions will be presented.

M08.OB.003 DATA PROCESSING USING DPS. C.G. van Beek and M.G. Rossmann, Department of Biological Sciences, Purdue University, W-Lafayette, IN 47907, USA.

A new set of programs is being developed for the processing of X-ray diffraction data collected on oscillating single crystals. These programs are based on extensive experience by us [1][2] and others [3], but also take into account the opportunities provided by frozen crystals and 2-D detectors such as CCD devices.

Data collected on frozen crystals of proteins, nucleic acids and other biological macromolecules often have relatively large mosaic spreads. As the mosaic spread approaches the useful oscillation range, special care has to be taken not to rely upon methods of data processing that are based on the availability of full recorded reflections.

With this in mind several programs have been developed as part of the Data Processing Suite (DPS). The auto-indexing [4] program and scaling [5] program are now in daily use; an integration program is to follow. Recent additions to the scaling program include statistics for assessing the quality of the anomalous signal of anomalous dispersion data.

These programs are freely available, for more information see: www-structure.bio.purdue.edu/~viruswww/Rossmann_home/dps/index.shtml

M08.OB.004 STRUCTURE OF REOVIRUS CORES. Stephen C. Harrison and Karin Reinisch, Howard Hughes Medical Institute and Harvard University, Cambridge MA, and Max Nibert, University of Wisconsin, Madison, WI

The structure of the core of reovirus has been determined, using crystals in space group F432, a=1249 Å, which diffract to about 3.5 Å. There are over 300 kDa in the icosahedral asymmetric unit and over 1.5 MDa in the crystallographic asymmetric unit. Data were collected using tandem image plates at the F1 beamline at CHESS. Initial phases were determined using a 28 Å resolution cryoEM reconstruction (from T. Baker, Purdue University), and phases were extended to 3.8 Å using fivefold averaging. There are two copies of the lambda1 protein in the icosahedral asymmetric unit: they have somewhat different conformations and largely non-equivalent contacts. Their packing and fold are related to VP3 of orbivirus cores (Stuart and co-workers). The lambda2 protein forms chimney-like protrusions around the fivefold axes. Each subunit appears to contain three of the enzymatic active sites required for RNA capping: one guanylyl transferase and two methylases. There are two copies of the sigma2 protein in the icosahedral asymmetric unit, plus a third copy on the icosahedral dyad (and hence present in two orientations, statistically). Sigma2 appears to serve as an adaptor for the outer layer of proteins in the complete virus particle. Further comparisons with cryoEM images of virions and infectious subviral particles yield information about rearrangements during the process of infection and about mechanisms of mRNA extrusion.

M08.OB.005 CRYSTALLOGRAPHIC STUDIES OF A T=7, dsDNA VIRUS CAPSID WITH A DIAMETER OF 650Å. J. E. Johnson[1], W. R. Wikoff[1], L. Liljas[1,3], R. L. Duda[2], and R. W. Hendrix[2] [1]Dept. Mol. Biol. The Scripps Research Institute, La Jolla, CA, 92037, USA [2]Dept. of Biol Sci., University of Pittsburgh, Pittsburgh, PA, 15260, USA [3]Biomedical Center, Department of Molecular Biology, University of Uppsala, Uppsala, Sweden

Empty capsids of the dsDNA bacteriophage HK97, a lambda-like phage, were prepared by co-expressing the capsid protein gene and a virally encoded protease in an E. coli system.

420 copies of the 42kD subunits spontaneously assemble into a capsid with a diameter of 450Å which contains about 50 copies of the protease [1]. Assembly activates proteolytic cleavage of the subunit removing 102 residues from the amino terminus and auto digestion of the protease. Maturation expansion to a 650Å diameter particle (head II) results from DNA packaging and initiates an auto catalytic cross linking between side chains of ASN356 and LYS169 and this results in an extraordinary chain linking of the hexamer and pentamer morphological units making the particles impervious to SDS treatment [2]. Here we report the 3.5Å structure of head II, which explains expansion, cross-linking and chain-mail. The particles crystallize in space group $P2_1$ a=580Å, b=625Å, c= 790Å, β=90.0° [3]. The structure was solved by phase extension with a cryoEM reconstruction serving as an initial phasing model at 30Å resolution [4]. Low resolution (200-15Å) data that allowed overlap with the resolution of the cryoEM model were collected on beam line 4-2 at SSRL [5], 5Å data were collected on beam line F1 at CHESS and data to 3.5Å resolution were collected on beam line 14BM-C at APS.

P08.OB.001 A LOOOOONG C AXIS; NOT A VIRUS, THOUGH. Yves Bourne[1], Wim P. Burmeister[2], & Pascale Marchot[3] [1]CNRS UPR 9039 Architecture et Fonction des Macromolécules Biologiques, Institut de Biologie et Microbiologie Structurale, Marseille, France. [2]Experiments Division, European Synchrotron Radiation Facility, Grenoble, France. [3]CNRS UMR 6560 Ingénierie des Protéines, IFR Jean Roche, Faculté de Médecine Nord, Marseille, France.

Crystals of mouse acetylcholinesterase, an α/β hydrolase, in complex with the peptidic inhibitor fasciculin (Fas2-mAChE complex) belong to space group $P6_522$ with cell dimension c ≥ 500 Å whether $AmSO_4$ or PEG is used as a precipitant [1, 2]. Separation of the resulting overlapping spots usually requires a very large crystal-detector distance, but the maximal resolution achieved is not sufficient to permit detailed intrepretation of the structures. High quality X-ray data were collected at the ESRF beamline ID14-EH3 equipped with i) a combination of a 2k x 2k CCD detector on a 2θ arm for fast screening of crystals and determination of the orientation matrix, ii) a Weissenberg camera with a very large active area using image plates (up to 80 x 80 cm), iii) an industrial robot for automatic exchange of the image plates, iv) an off-line image plate scanner [3]. With this set-up, we collected complete data with resolution up to 2.5 Å with a total oscillation of 36° and a 3° oscillation range, with the long c axis of the crystal being roughly aligned to the spindle axis; the crystal-to-detector distance was 590 mm. In this particular case, data collection required a single manual intervention. Five complete data sets were collected: a « native » Fas2-mAChE complex, and four ternary Fas2-mAChE-2nd inhibitor complexes obtained either by co-crystallization of the three partners or by soaking of the Fas2-mAChE crystals with the 2nd inhibitor. Details on the large image plate device, the data, and the refined structures will be presented.

P08.OB.003 FIRST RESULTS FROM A NOVEL MICROFOCUS X-RAY GENERATOR FOR X-RAY CRYSTALLOGRAPHY. Ewa Ciszak[1], Mikhail Gubarev[1], Marshall Joy[1] and Walter Gibson[2] [1]NASA/G. Marshall Space Flight Center, Huntsville, AL 35812, USA, [2]State University of New York at Albany, NY 12222, USA.

The success of the Synchrotron radiation laboratories has not reduced the need for laboratory based x-ray diffraction systems. Indeed, the success of synchrotron laboratories in study of smaller and more complex crystals has pointed out the importance of high brightness x-ray sources in close proximity to crystal growth activity, ideally located in the same laboratory.

We present here the initial performance results from a microfocus x-ray generator combined with a polycapillary concentrator, which is being developed for crystallography. The 40-Watt, 35-micron FWHM x-ray source has been optimised for use with short focal length polycapillary optics to maximise the solid angle of collection of the emitted x-rays. We present measurements of the x-ray photon flux from the microfocus source/optics combination for 0.5mm and 1mm diameter beams, the spectral characteristics of the emergent beam and compare these results with measurements taken from standard rotating anode/optics systems.

08OC HIGH PRESSURE STRUCTURES AND PHASE TRANSITIONS

M08.OC.001 HIGH PRESSURE - HIGH TEMPERATURE POWDER DIFFRACTION STUDIES OF BINARY HALIDES. S. Hull, The ISIS Facility, C.L.R.C. Rutherford Appleton Laboratory, Chilton, Didcot, Oxfordshire, OX11 0QX, United Kingdom.

The high pressure structural behaviour of the 'simple' binary halides of stoichiometry AX and AX_2 (X=F, Cl, Br and I) has long been a popular topic for both experimental and ab-initio theoretical study. The results of recent high pressure neutron and X-ray diffraction studies of these materials will be presented and compared with calculations of their structural behaviour. Particular emphasis will be placed on the following two systems.

i) The silver and copper mono-halides are interesting compounds because their bonding character is intermediate between ionic and covalent. CuCl, CuBr, CuI and AgI adopt the tetrahedrally co-ordinated zincblende structure under ambient conditions whilst AgF, AgCl and AgBr are octahedrally co-ordinated with the rocksalt arrangement. In general, the expected phase transition sequence zincblende→rocksalt→CsCl-type occurs, though many intermediate phases of lower symmetry are observed. However, in AgCl and AgBr the continuous rhombohedral transformation from zincblende to rocksalt predicted by electronic structure calculations [1] does not occur.

ii) The high temperature behaviour of di-halides with the cubic fluorite crystal structure has been widely investigated owing to the superionic behaviour associated with extensive thermally-induced dynamic anion disorder. Under pressure, many of these compounds transform to the orthorhombic cottunite structure and there has been debate within the literature concerning possible superionic behaviour within this denser arrangement. High pressure - high temperature neutron diffraction studies have been

performed to resolve this issue and shed light on the relative importance of crystal structure in promoting superionic behaviour.

M08.OC.002 STRUCTURAL SYSTEMATICS OF HEAVY ALKALINE METALS AT HIGH PRESSURES. U. Schwarz, MPI fuer Chemische Physik fester Stoffe, Pirnaer Landstr. 176, D-01257 Dresden, K. Syassen and O. Jepsen, MPI fuer Festkoerperforschung, Heisenbergstr. 1, D-70569 Stuttgart, M. Hanfland, ESRF, BP 220, F-38043 Grenoble, and K. Takemura, National Institute for Research in Inorganic Materials, Tsukuba, Japan

We investigated crystal structures and bonding properties of the heavy alkaline metals at high pressures. Recently, the orthorhombic crystal structure of the high-pressure modification Cs-V (P>11 GPa) has been determined by means of angle dispersive x-ray powder diffraction at the ESRF [1]. The characteristic feature of this Cmca-structure, which can be viewed as a distorted fcc packing, are layers of corner-sharing octahedra. Within the equatorial plane of the octahedra each atom has a fifth contact to an atom in a neighboring polyhedron which is the shortest nearest-neighbor-distance in the crystal structure. Subsequent investigations revealed that the high-pressure phases Si-VI (38 GPa < P < 50 GPa) [2] and Rb-VI (P > 48 GPa) crystallize in the same space group and show similar axial ratios and free positional parameters.

The chemical bonding of Cs-V and Si-VI was studied within the local density functional approach by means of the TB-LMTO-ASA bandstructure method. For Cs-V the calculations reveal regions of high electron density and attractors of high ELF values in the centres of the octahedra which exhibit strong similarities to a framework of condensed octahedral clusters with two electrons per polyhedron [3]. For silicon we observe Si_2-dumbbells in every second layer of the crystal structure and in the alternating layers four-bonded silicon atoms form puckered nets.

Currently, the high pressure modifications K-III and Rb-IV are under investigation. Progress regarding phase stability and crystal structure will be reported.

M08.OC.003 PHASE TRANSITION IN AX_4 TYPE MOLECULAR CRYSTALS UNDER PRESSURE. Nozomu Hamaya and Kyoko Sato, Graduate School of Humanities and Sciences, Ochanomizu University, Tokyo 112, Japan

Crystals consisting of tetrahedral molecules AX_4 (A: group IV atoms, X: halogens) exhibit a variety of structures at high pressure. Stannic iodide SnI_4 represents AX_4 type molecular crystals and undergoes successive pressure-induced phase transition from an insulator crystalline phase, to a metallic crystalline phase at 7 GPa, to an amorphous state at about 15 GPa and to a non-molecular crystalline phase at 61 GPa at room temperature. Our recent x-ray diffraction study showed that a new crystalline phase became stable at 500K and 7 GPa. Crystal structure of the non-molecular phase at 63 GPa was studied using the anomalous x-ray dispersion below the K absorption edge of Sn. Measured photon-energy dependence of the intensity of diffraction peaks suggests a formation of the disordered alloy in which both Sn and I ions are randomly located at the fcc lattice sites.

Phase transition in GeI_4 and $SnBr_4$ were also studied at high pressure. In GeI_4, the amorphous phase appeared at about 30 GPa and persisted to the maximum pressure of our study, 100 GPa, which is much higher than the recrystallization pressure of 61 GPa in SnI_4 into a non-molecular structure. This indicates that the difference in size or electronic structure of cation plays an important role in dissociation of tetrahedral molecules. A high-pressure phase of $SnBr_4$ was newly observed at 3 GPa and found to have the same crystal structure as that SnI_4 and GeI_4 exhibited at 1 atm. Structural disordering proceeded gradually above 10 GPa, but several, broad diffraction peaks still remained at 30 GPa. On the basis of those results, we will discuss structural systematics of the AX_4 type molecular crystal at high pressure.

M08.OC.004 HIGH PRESSURE PHASE TRANSITIONS IN CARBON DIOXIDE. Choong-Shik Yoo, Lawrence Livermore National Laboratory, Livermore, California 94550

Application of high-pressure strongly perturbs chemical bonds, electronic and crystal structures, thermal and mechanical properties, and reactivities of solids. These perturbations provide opportunities for synthesizing novel materials and metastable phases. At high pressures, the electron kinetic energy increases, and the intermolecular potential becomes highly repulsive in nature. Therefore, a fundamental principle of high-pressure phase transition is to soften the repulsive potential by electrons delocalizing and forming extended bonds amongst neighboring molecules. The mechanisms which often occur in molecular solids at high pressures are (i) ionization, (ii) polymerization, (iii) metallization. In this paper, we present the experimental evidences for high-pressure transitions to ionic and polymeric phases of molecular carbon dioxide occurring prior to the metallization, based on our micro-Raman and x-ray investigations.

Work performed under the auspices of the U.S. DOE by the LLNL under contract number W-7405-ENG-48. This work has been done in collaborations with V. Iota, H. Cynn, K. Visbeck, M. Nicol, D. Hauserman, S. Carlson.

M08.OC.005 THEORETICALLY SERACHING FOR NEW MATERIALS UNDER HIGH PRESSURE. Shinji Tsuneyuki, Institute for Solid State Physics, University of Tokyo, Roppongi, Tokyo 106-8666, JAPAN.

Thanks to the recent development of computational science approaches, it is often not so difficult to predict stable structures and electronic properties of unknown materials theoretically, if we could know or assume rough arrangement of the constituent atoms in the materials. One of the most useful and reliable methods for that purpose is the first-principles molecular dynamics (FPMD) method or Car-Parrinello method, in which atoms are moved according to the interatomic forces calculated at each MD step based on the density functional theory. Combined with the constant-pressure formalism in the traditional MD, it can be a powerful tool for high-pressure physicists who search for new materials or phase transitions.[1]

We report two applications of FPMD in high-pressure physics. The apparently fcc phase of SnI_4 observed very recently above 61 GPa by an X-ray measurement [2] is identified as substitutional solid solution of tin and atomic iodine. We also predict that some graphite intercalation compounds could transform into novel crystalline phases under high pressure.

M08.OC.006 SOME REMAINING ISSUES WITH THE PHASES OF IRON SULFIDE. J. B. Parise, CHiPR[§] and Geosciences, SUNY, StonyBrook, NY 11794-2100, USA, W. G. Marshall, ISIS Facility, Rutherford Appleton Laboratory, Didcot, UK, and M. I. McMahon, R. J. Nelmes, D. R. Allan, S. A. Belmonte and C. Vanpeteghem, Department of Physics and Astronomy, University of Edinburgh, Mayfield Road, Edinburgh, EH9 3JZ, UK [§] Center for High Pressure Research, an NSF funded Science and Technology Center

The sulfides containing iron are amongst the more important high-pressure planetary accessory minerals. They have also received renewed interest of late as possible platforms for the formation of amide bonds, a significant reaction in studies of the origin of life (Wächtershäuser 1988). There are conflicting details reported of the phases forming in the Fe-S binary at high-pressures and high-temperatures however (see for example Fei et al., 1995; Kusaba et al., 1998). Some of the issues raised in these reports include:

1) The existence and nature of the high temperature phase formed upon transition from troilite; 2) the thermodynamic stability of the MnP-related phase formed at pressures intermediate between those where troilite and "FeS-III" are stable; 3) the role of composition on the behavior of FeS and 4) the electronic and magnetic properties of phases in the FeS-binary and other ternary-sulfides containing iron. The low temperatures involved in many of these transitions, and resultant sluggish reaction kinetics, might explain some of the conflicts in the literature. The differences between the in situ techniques used to study these materials may also be relevant. The largest contributor, however, is probably small differences in composition and sample homogeneity. In this presentation, the results of recent in situ X-ray and neutron powder diffraction experiments addressing these issues will be discussed. The small differences in the diffraction patterns of the phases involved make the use of high-resolution powder diffraction techniques, along with combined nuclear and magnetic scattering, advisable.

P08.OC.001 POLYMERIZED STRUCTURES OF C_{60} AND C_{70} SUPERHARD PHASES. N.R. Serebryanaya, V.D. Blank and G.A. Dubitsky, S.G. Buga, Technological Institute for Superhard & New Carbon Materials, 142092 Troitsk Moscow Reg. Russia, and L.A. Chernozatonsky, Institute of Chemical Physics of RAS, 117334 Moscow, Russia, and S.N. Sulyanov, Institute of Crystallography of RAS, 117333 Moscow, Russia.

Superhard phases of C_{60} and C_{70} (their hardness is equal to the diamond one) have been found after high pressure (13 GPa)- high temperature (2100 K) treatment with use of a diffractometer Kard-6 with a flat proportional chamber on the fast delay lines [1]. C_{60}-crystal structure has been determined as a three-dimensional polymerized one with 24 single covalent bonds. It is a cubic closest-packed structure of C_{60} cages and the other fullerite-like clusters are in the octahedral cavities. C_{60} cages are deformed and the real symmetry is orthorhombic one. C_{70} crystal structure is the same but more distorted. Atom coordinates have been obtained by molecular mechanics methods. Good fit to the C_{60} profile was obtained by the Rietvild analysis program DBWS9411. The densities calculated from X-ray diffraction data accord with experimental densities measured by the flotation method.

Crystalline states remain up to 900-1000 K, then fullerite cages collapse producting different 3D-polymerized disordered structures. The cross-linked layered disordered structure is observed in the both fullerites up to 9.5 GPa and above 900 K. At P≥12.5 GPa the second type of disordered structure is observed. This structure is transient to diamond states and the diffraction pattern has one wide halo at 2.18-2.16 Å. It is the hardest phase found only for C_{60}. The P-T phase diagram of C_{60} and C_{70} is plotted with use of X-ray diffraction data.

P08.OC.002 STRUCTURAL STUDIES OF SEMICONDUCTORS AT HIGH PRESSURE AND HIGH TEMPERATURE. C. Vanpeteghem, S.A. Belmonte, M.I. McMahon, D.R. Allan and R.J. Nelmes Department of Physics and Astronomy, The University of Edinburgh, Edinburgh EH9 3JZ, UK

Our research on the high-pressure phases of III-V and II-VI semiconductors has shown that most phases are site-ordered [1], but that there are some exceptions to this such as the Imma phase of GaSb [2]. We have also identified many misinterpreted phases and one of our most surprising discoveries is the complete absence of the diatomic beta-tin structure [3], despite numerous previous reports of its existence. Rather, it appears that all systems transform into complex lower-symmetry structures, which have variable atomic coordinates that are often strongly pressure dependent. This makes the high-pressure study of semiconductors more complex, and thus more interesting, than previously thought.

The absence of the diatomic beta-tin structure is very unexpected since theoretical calculations on GaAs and GaP [4] have reported that this structure has an energy lower than that of Cmcm, the orthorombic phase actually found. Until now no site-ordered tetragonal structure, with the exception of HgO-II, has been observed in any of the III-V or II-VI systems.

We are currently developing combined high-pressure high-temperature (HP/HT) diffraction techniques to make more detailed studies of atomic ordering in these systems. Experiments on GaSb under such conditions have found a transition from the Imma structure, which is a slight orthorhombic distortion of site-disordered beta-tin, to a true tetragonal beta-tin structure. Further HP/HT studies will not only allow us to clarify the complex matter of site-ordering but will also allow us to investigate the full P-T dependence of the structural systematics of semiconductors - an area which is relatively unexplored. The most recent results of all this work will be presented.

P08.OC.003 EFFECT OF HIGH PRESSURE AND CHEMICAL SUBSTITUTION ON STRUCTURE OF TETRAVALENT METALS. V.F. Degtyareva, Institute of Solid State Physics, Russian Academy of Sciences, Chernogolovka, Moscow district, 142432 Russia, W.B. Holzapfel, FB Physik, Universität-Paderborn, 33095 Paderborn, Germany.

Pressure action and chemical substitution lead very often to similar trends with respect to structural changes. While the light group IV elements Si and Ge have a common peculiar high-pressure form with *simple hexagonal* (*hP*1) structure, this structure does not occur for Sn. However, the *hP*1 phase can be produced in Sn at normal pressure by alloying with ~10 at.% Hg or ~20 at.% In. This observation raises the question, which structural sequence will be obtained in these alloys under pressure.

High-pressure structural studies using diamond anvil cells and energy dispersive X-ray diffraction with synchrotron radiation revealed for $Sn_{.9}Hg_{.1}$ the transformation from *hP*1 to a *body-centered tetragonal* phase, *tI*2, as for pure Sn, with nearly the same axial ratio $c/a \approx 0.92$. However, for $Sn_{.8}In_{.2}$ different structural sequence *hP*1→*intermediate*→*hP*2 was found under

pressure with more similarities to pure Si. The intermediate low symmetry phase of Sn_8In_2 seems to be closely related to an orthorhombic distortion of *hP*2, different to the complex structure of Si-IV. These results demonstrate the strong dependence of the high-pressure structural sequences in Sn alloys on the special chemical substitution.

Effects of pressure on the structural behavior for metals and alloys with nearly 4 valence electrons are discussed with respect to other recent high pressure studies with observation of *hP*1 in the Al-Ge [1], Cd-Sb and Zn-Sb [2] binary alloys and of *tI*2 in the III-V compound InBi [3].

P08.OC.004 PHASE DIAGRAM OF $KNbO_3$ UP TO 30 GPa AND FROM 700 K DOWN TO 10 K. D. Gourdain, J.C. Chervin, B. Canny, Ph. Pruzan, Physique des Milieux Condensés UMR 7602, Université P & M Curie B77 75252 PARIS Cedex 05, France, M. Hanfland, ESRF, BP220, 38043 Grenoble Cedex, France.

Investigations of the phase diagram of $KNbO_3$ using x-rays diffraction and Raman scattering are reported. Experiments were performed in the diamond anvil cell up to ~ 30 GPa and from the atmospheric Curie temperature (700 K) down to 10 K.

At room pressure this compound is well known to undergo the phase transition sequence: cubic → tetragonal → orthorhombic → rhombohedral. The cubic solid is paraelectric, the other being ferroelectric. As pressure increases a lowering of the various transition temperatures was expected, and observed for $BaTiO_3$,[1,2] however the phase diagram of this type of compound is hardly known. At room temperature the vanishing of the ferroelectricity in $KNbO_3$ was observed at ~ 10 GPa using Raman scattering.[3]

Above and below ambient temperature, high pressure analysis were performed along isothermal or isobaric paths with micro Raman scattering and angular dispersive x-ray diffraction. Data were obtained on the p-T locations of the various transitions, the vibrational dynamics and the equation of state. Our preliminary results show that the different ferroelectric states are close domains in the p-T diagram: the various transition temperatures decrease linearly at low pressure, these drops become more rapid, and consequently non-linear, on further compression. The modifications of the Raman spectrum, on increasing pressure, will be presented and the values of the parameters of the equations of state will be discussed.

P08.OC.005 NEUTRON DIFFRACTION STUDIES OF THE HYDROGEN BOND UNDER HIGH PRESSURE. M. Guthrie, J. S. Loveday, R. J. Nelmes, Dept. of Physics and Astronomy, The University of Edinburgh , Mayfield Rd, EDINBURGH, EH9 3JZ, UK

The hydrogen bond is an important interaction to a wide range of science from the physics of the interiors of giant planets to the behaviour and function of biological molecules. The behaviour of hydrogen bonded materials under high pressure probes the density dependence of the O-H and H...O interactions and hence provides fundamental and widely applicable insight into the nature of the bond itself. The ability to observe the changes in structure induced by pressure is a crucial part of this understanding. For example, our early neutron diffraction study of ice VIII [Nelmes et al, Phys. Rev. Lett. **71, (**1993), 1192] provided the first accurate information on the structural pressure dependence of H-bond dimensions over a 10GPa range. This showed that the previously-held assumptions used to interpret the vibrational spectroscopy of H-bonded solids at high pressure were significantly incorrect in this case, and consequently are suspect in others.

We have now extended our studies of H-bonded materials at high pressure using the Paris-Edinburgh cell at the ISIS pulsed neutron source to explore two new aspects. It has emerged from work at ambient pressures that the H-bonds in hydroxides are significantly different from those in molecular solids. In addition, there has been a suggestion that H...H repulsive interactions may play a far more significant role in high-pressure behaviour than has been generally recognised. We will present studies of the alkali hydroxides which provide new insight into these inter-bond effects as well as new information on the O-H and H...O interactions. Successful experiments have already been performed on KOD. The results appear to question the assumed minimum H...H separation and suggest that proton repulsion is not the mechanism for the observed high-pressure phase transition in this case.

P08.OC.006 STRUCTURAL EVOLUTION OF RUTILE-TYPE AND $CaCl_2$-TYPE GERMANIUM DIOXIDE AT HIGH PRESSURE. J. Haines, J. M. Léger and C. Chateau, Laboratoire de Physico-Chimie des Matériaux, C.N.R.S., 1, place Aristide Briand 92195 Meudon cedex, France and A. S. Pereira, Instituto de Fisica and Escola de Engenharia, UFRGS, 91501-970 Porto Alegre, Brazil.

Germanium dioxide undergoes a transition from the tetragonal, rutile-type to the orthorhombic, $CaCl_2$-type phase at 26.7 GPa. The detailed structural evolution of both phases at high pressure in a diamond anvil cell has been investigated by Rietveld refinement using angle-dispersive, x-ray powder diffraction data. These data were obtained on a laboratory source equipped with x-ray capillary optics and an imaging plate. Nitrogen and 16:3:1 methanol:ethanol: H_2O were used as pressure-transmitting media and laser annealing was performed to avoid deviatoric stress. The square of the spontaneous strain $(a-b)/(a+b)$ in the orthorhombic phase was found to be a linear function of pressure and no discontinuities in the cell constants and volume were observed indicating that the transition is second-order and proper ferroelastic. Compression of the GeO_6 octahedra was found to be anisotropic with the axial Ge-O distances decreasing to a greater extent than the equatorial distances. Above the phase transition, the columns of edge-sharing octahedra tilt about their 2-fold axes parallel to **c**. The present work has enabled systematic relationships in the homologous series, SiO_2, GeO_2, SnO_2, to be identified.

P08.OC.007 STRUCTURE OF THE HIGH-PRESSURE PHASE OF Fe_2O_3. G. Kh. Rozenberg, O. Naaman, M. P. Pasternak, School of Physics and Astronomy, Tel Aviv University, 69978, Tel Aviv, Israel, D. Hausermann, T. Lebian, ESRF, BP220, F-38043 Grenoble Cedex, France

The high-pressure form of Fe_2O_3 has been the subject of extensive investigation because of its significance in earth sciences. Early shock-wave and subsequent static compression experiments have shown that at 50 GPa hematite undergoes a structural phase transformation to a considerably denser structure (the HP phase), which could be assigned either to a "distorted corundum" (Rh_2O_3 II-type) or to an orthorhombic perovskite structure. Supported by the high-pressure Mössbauer studies it

was suggested that HP phase is characterised by two kinds of iron ions of different charge [1]. This incited the authors to choose the perovskite option to the HP phase with formula ABO_3 where A and B stand for different iron charge states and which could accommodate six-fold coordination number.

To elucidate the nature of the HP phase we performed XRD studies in the angle-dispersive mode, using the TAU miniature DAC and up to 80 GPa, at the ESRF ID30 beam-line. The diffraction peaks corresponding to the HP phase are first observed at ~ 45 GPa. The diffraction patterns of the pure HP phase recorded above 70 GPa could be exactly indexed to the distorted corundum structure (Rh_2O_3-II-type) with space group *Pbna*. This structure with formula A_2O_3 can be assigned only in case of a single cation position. This is in full agreement with recent Mössbauer studies revealing a single HP Fe^{3+} spectral component at P>72 GPa [2].

The present studies ascertain that at ~50 GPa hematite undergoes a transition from a corundum α-Fe_2O_3 to a distorted corundum Rh_2O_3-II structure.

P08.OC.008 PHASE TRANSITIONS AND CRYSTAL STRUCTURES OF TWO IONIC CONDUCTORS AT HIGH PRESSURE. S. Werner[1], H. Schulz[1], B. Maximov[2], M. Sirota[2], [1]Institut für Kristallographie und Angewandte Mineralogie, Universität München, Theresienstr. 41, D-80333 München, Germany; [2]Institute of Crystallography, Academy of Science of Russia, Leninsky pr. 59, 117333 Moscow, Russia

Phase transitions and crystal structures of the two ionic conductors $Na_4TiO(PO_4)_2$ (NTP) and $Na_{4.5}Fe(O,F)(PO_4)_2$ (NFP) were investigated at pressures up to 12 GPa utilizing diamond anvil cells and single crystal diffraction techniques.

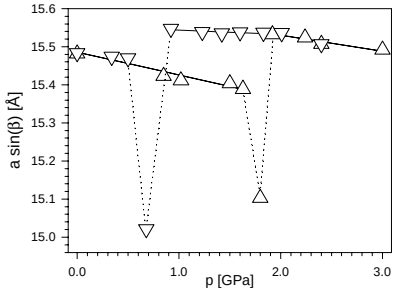

Fig.: NTP - a·sin(β) *vs.* pressure, triangles pointing up/down denote increasing/decreasing pressure.

For NTP, a phase transition is observed at a pressure of 1.8(1) GPa. At this pressure, the volume of the unit cell decreases by 2.4%. The back transformation at decreasing pressure is observed at 0.6(3)GPa, the phase transformation is characterized by a large hysteresis of 1.2 GPa. Furthermore, a marked instability of the unit cell parameters a·sin(β) and b is observed in conjunction with the phase transition (Fig.). Above 3 GPa, single crystals are destroyed, probably due to a second phase transition.

For NFP, up to 12 GPa, three phase transitions are obvious from sudden changes in the unit cell parameters a, b and c at 1.39(8), 4.5(3) and 6.0(2) GPa. No hysteresis could be detected within pressure cycles. The first and third phase transiton are also indicated by colour changes of the crystals from dark orange to pink and to violet. At six different pressures, reflection intensities were measured utilizing synchrotron radiation at HASYLAB to determine the structures of the high pressure phases.

P08.OC.009 PRESSURE DEPENDENCE OF STRUCTURE AND COMPOSITION IN THE XENON HYDRATE SYSTEM. J.L. Finney [1], C. Lobban, A. Klapproth, W.F. Kuhs [2], [1] Dept of Physics and Astronomy, University College London, Gower Street, London WC1E 6BT, UK, [2] MKI, Universität Göttingen, Goldschmidtstrasse 1, 37077 Göttingen, Germany

Clathrate hydrates are solid water structures which form a lattice of cages capable of enclosing guest molecules. These cages remain stable only through the inclusion of the guest, and would otherwise collapse. Most current research on these systems is motivated by the natural gas clathrates as a possible energy resource. In industry, clathrate formation has been a persistent and expensive annoyance in the transportation of hydrocarbons, with natural gas clathrate causing blockages in pipelines.

The actual amount of gas held within these clathrate structures in situ is uncertain, although it is thought likely that the cages are not fully occupied. It is generally assumed that the filling of the cages follows a Langmuir isotherm with increasing fugacity of the guest. Such a model is possible only by making certain assumptions (J.H. van der Waals and J.C. Platteeuw, Adv. Chem. Phys, 2, (1959), 1). First, the free energy of the water lattice should be independent of guest occupation. This is inconsistent with NMR work (J.A. Ripmeester, C.I. Ratcliffe, and J.S. Tse, J. Chem. Soc. Farad. Trans. I, 84, (1988), 3731) which indicates considerable guest-host interactions for xenon clathrate. Secondly, guest-host interactions are assumed negligible, which seems at least questionable at higher pressures and lower temperatures.

Using neutron scattering measurements on powder samples, we have refined the structures and guest occupancies for the xenon clathrate at 273K at guest pressures of 5, 7, 15, 25, and 50 bar. At all pressures investigated, the large cage is fully occupied. The occupation of the small cage varies with pressure, increasing to 92±2% at 25 bar. As pressure increases further, the small cage occupancy decreases, clearly violating Langmuir behaviour quite markedly. In addition to the guest occupancy behaviour, the detailed structures as a function of guest pressure are presented.

P08.OC.010 HIGH PRESSURE PHASE DIAGRAMS OF BINARY LANTHANIDE ALLOYS BETWEEN La, Ce, AND Pr. O. Degtyareva and W.B. Holzapfel, FB 6 Physik, Universität-Paderborn, 33095 Paderborn, Germany.

Due to the irregular behaviour of Ce under pressure in comparison with the other "regular" lanthanide metals [1], irregularities are also expected for Ce alloys under pressure. Due to the fact that La under pressure reveals a reentrant behaviour with respect to the *fcc* (*cF*4) → *distorted fcc* (*hR*8?) → *fcc* (*cF*4) transition [2] and Pr shows a special transition to an α-U (*oC*4) phase with *f* electron delocalization [3], alloys of these two elements with each other and with their neighbouring element Ce were of special interest.

In all three cases, 5 alloys with atomic ratios $0.1 \le x \le 0.9$ have been studied under pressures up to 32 GPa in diamond anvil cells (DACs) with energy dispersive X-ray diffraction (EDXD) using synchrotron radiation in HASYLAB (DESY, Hamburg).

As expected, the Ce rich alloys $Ce_{1-x}Ln_x$ with $x \le 0.2$ show the same structural sequence under pressure as pure Ce, however, the occurrence of the *oC*4 structure is suppressed with respect to the occurrence of only the (metastable?) monoclonic (*mC*4) phase up to the pressure where the transition to the ultimate *bct* (*tI* 2) phase occurs. The transitions to *tI* 2 are shifted to higher pressures with increasing of Ln content compared to the pure Ce case. In the Pr rich alloys with La transitions to the *oC*4 structure are also shifted to higher pressures. *hR*8 phase seems to persist in all the $La_{1-x}Pr_x$ alloys with $x < 0.8$ to the maximum pressure of the present experiments.

Systematics in the variations of the axial ratios with pressure and alloy concentration for different structures are discussed.

P08.OC.011 PRESSURE DEPENDENCE OF OCTAHEDRAL REGULARITY ON $Ca(OH)_2$, $Mg(OH)_2$ AND $Co(OH)_2$. T. Nagai, T. Yamanaka Department of Earth and Space Science, Graduate School of Science, Osaka University, Toyonaka, Osaka 560-0043, Japan

We have performed a synchrotron x-ray powder diffraction study of $Ca(OH)_2$, $Mg(OH)_2$ and $Co(OH)_2$ under room temperature pressurization to 10.4 GPa, to 16.0 GPa and to 15.0 GPa, respectively. We used the diamond anvil cells technique and the data were collected with an imaging plate detector at BL-18C in Photon Factory at KEK, Japan.

$Ca(OH)_2$, $Mg(OH)_2$ and $Co(OH)_2$ are isostructural with CdI_2 type and the structure has a strong anisotropy. The c-axis is much softer than the a-axis and, thus, the c/a ratio decreases with pressure. There is no remarkable discontinuity in the compression curves. The bulk modulus of $Ca(OH)_2$, $Mg(OH)_2$ and $Co(OH)_2$ were determined as 34.6 GPa, 55.5 GPa and 56.0 GPa, respectively.

Ca, Mg and Mg atoms are sitting at the special position (0, 0, 0). The atomic position of O atoms, (1/3, 2/3, z), has been successfully refined using Rietveld analysis of x-ray powder diffraction patterns. It has been reported that H disorder occurs at around 5 GPa in $Mg(OH)_2$ and this study clearly suggests that the H disorder has great influence on the compression behavior. We can discuss octahedral regularity on the basis of O-cation-O angles obtained from the structure refinements. The results indicate that CaO_6, MgO_6 and CoO_6 octahedron approach to the regular configuration with pressure and it is interesting that CaO_6 in portlandite seems to become a regular octahedron at a little below the amorphization pressure.

P08.OC.012 THE HIGH-PRESSURE CRYSTAL STRUCTURES OF THE FUNDAMENTAL ALCOHOLS AND CARBOXYLIC ACIDS. D.R. Allan [1], S.J. Clark [2], [1] Department of Physics and Astronomy, University of Edinburgh, Edinburgh, UK, [2] Department of Physics, University of Durham, Durham, UK

The structure and dynamics of molecular solids are intimately related to the interactions of the molecules, which in turn are connected to their molecular form and symmetry. In order to develop an understanding of the structural systematics of polar molecule systems it is vital that a homologous series of chemically similar compounds is studied. The monoalcohols H(CH2)nOH and the monocarboxylic acids H(CH2)nCOOH are both important, and prototypic, series of compounds which form a rich variety of crystal-structure types at low temperature. Until recently, however, relatively little was known about the high-pressure behaviour of these fundamental systems.

We have embarked on a series of studies to establish the high-pressure crystallography of the monoalcohols and monocarboxylic acids (among other systems) and we have found a surprising wealth of structures which, in each case, differ distinctly from their low-temperature forms. The results of our studies on the monoalcohols methanol and ethanol, and the monocarboxylic acids formic acid, acetic acid and propionic acid, will be presented.

P08.OC.014 HIGH-PRESSURE PHASE TRANSITION IN LEAD PHOSPHATE, $Pb_3(PO_4)_2$. R.J. Angel, Bayerisches Geoinstitut, Universität Bayreuth, D95440 Bayreuth, Germany, and U. Bismayer, Mineralogische-Petrographisches Institut, Universität Hamburg, Grindelallee 48, D20146 Hamburg, Germany.

We have studied the high-pressure behaviour of lead phosphate, $Pb_3(PO_4)_2$, at high pressures and room temperature by single-crystal X-ray diffraction. $Pb_3(PO_4)_2$ is an improper ferroelastic material that is a prototype for a large class of ferroelastics. At room conditions it displays C2/c symmetry, and at 453K transforms to a phase with global R-3m symmetry. The transition mechanism is related to a shift of the Pb atoms away from the triad of the hexagonal phase, together with a correlated tilt of the PO_4 tetrahedra. The transition is complicated by the persistence of short-range order above the transition temperature leading to domains with mobile walls in material of high chemical purity [1].

Unit-cell parameters were determined from two crystals at a number of pressures up to a maximum of 4 GPa. At pressures in excess of 1.8 GPa the unit-cell parameters become hexagonal within the experimental uncertainties, confirming an earlier report [2]. The symmetry-breaking spontaneous strains in the low-pressure monoclinic phase below 1.7 GPa vary linearly with pressure, indicating that the transition is second-order in character with a transition pressure of 1.78(1) GPa. This behaviour is in agreement with theoretical predictions and clearly shows the variation of the third order term of the free energy expansion (with its near-tricritical behaviour at high-temperatures, [3]) and is similar to the second-order behaviour observed under conditions of uniaxial stress [1].

P08.OC.015 THEORETICAL STUDIES OF THE STRUCTURES AND PROPERTIES OF HIGH PRESSURE FORMS OF PON. D.D. Klug, J.S. Tse, Steacie Institute for Molecular Sciences, National Research Council of Canada, Ottawa, Ontario, Canada K1A 0R6 and J. Haines, Laboratoire de Physico-Chemie des Matériaux, CNRS, 1 Place Aristide Briand, 92195, Meudon Cédex, France

Phosphorous Oxynitride, PON, that is isoelectronic with SiO_2 has been studied using density functional plane-wave methods in order to determine the structures and properties of possible high pressure phases. The phase transition pressures to several possible high-pressure phases are predicted. The bulk modulus and elastic constants of high-pressure phases are calculated in order to determine if these materials may be candidates for superhard solids. The physical basis for the different pressure behavior of the α-quartz and β-cristobalite structures and their physical properties is investigated.

P08.OC.016 NEW HIGH PRESSURE PHASE OF PbS. V.B.Begoulev, Yu.A.Timofeev, B.V.Vinogradov, High Pressure Physics Institute RAS, Troitsk, Moscow region, 142092, Russia

PbS is a narrow gap semiconductor crystallizing in the NaCl-type crystal structure (PbS I). Under pressure PbS undergoes transitions to orthorombic phase PbS II (TlI-tipe structure) at 2.2 GPa (T=300 K) and to cubic CsCl-tipe structure phase PbS III at about 21.5 GPa (T=300 K). It was known also that PbS III phase is superconductor.

In the present work we report the detection of a phase transition to a new high pressure phase PbS IV at 36 GPa (T=300 K). For these studies we used a high pressure cell with diamond

anvils. One of the anvils was made from synthetic polycrystalline diamond («carbonado») and had a flat working surface. The second anvil was produced from natural diamond and had a conical top trancated by a spherical surface radius of 1 mm. We used a powder of PbS (size of grain was 1-5 mkm). A thikness of a powder layers was 10-20 mkm.

New method for the detection of phase transitions and construction of P-T phase diagrams of substances has been applied to this investigation. The method is based on use of micronic ruby gauges for the measurements of pressure distribution curves. When the phase transition takes place, a «shoulder-like» feature arises on a pressure distribution curve. The observation of a change of a feature position with temperature makes it possible to construct P-T diagram of a substance investigated.

Fig.1 shows the results of pressure distribution measurements in PbS under different loads at T=300 K.

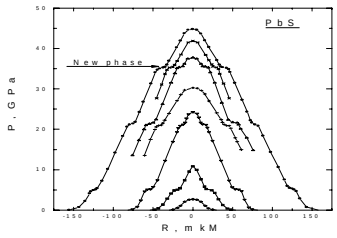

Fig.1. Pressure distribution curves in PbS under different loads at T=300 K.

When the maximum pressure in a sample of PbS was more than 4.8 GPa, a «shoulder-like» feature occured on a pressure distribution curve that corresponded to PbS I – PbS II transition. The second feature at P=21 GPa corresponds PbS II – PbS III transition. At 36 GPa a new «shoulder-like» feature occurs on a pressure distribution curve that corresponds to PbS III – PbS IV transition. We suppose that new high pressure phase PbS IV is superconductor.

P08.OC.019 HIGH-PRESSURE STRUCTURAL AND ELECTRONIC TRANSITIONS OF TRANSITION METAL OXIDES. R.J. Hemley, Q.Z. Guo, J.F. Shu, J. Badro, V.V. Struzhkin, S. Shieh, J. Z. Hu, R. E. Cohen, S. Gramsch, H.K. Mao, Geophysical Lab., Carnegie Institution, 5251 Broad Branch Rd. NW, Washington, DC 20015, USA; and C.C. Kao, NSLS, Brookhaven National Lab., Upton, NY 11973, USA.

Transition metal monoxides, MnO, FeO, CoO, and NiO in NaCl (B1) structure, have been studied in diamond cells to 150 GPa at ambient temperature. Radial diffraction employing synchrotron x-radiation is used for determination of elasticity and crystal structure. High-resolution x-ray fluorescence spectroscopy is used for identification of high-low spin states. All samples show softening in shear elastic tensor element with increasing pressure that leads to second-order, displacive phase transitions below 100 GPa. The cubic B1 symmetry is reduced to rhombohedral or lower symmetries at the transitions. The predicted high-pressure magnetic collapses based on calculations of B1 structure are shifted to higher pressures in the lower symmetry phases.

P08.OC.020 MULTIMEGABAR COMBINATORIAL STUDIES OF EQUATIONS OF STATE AND PRESSURE SCALE. H.K. Mao, J.F. Shu, J. Badro, S. Merkel, R.J. Hemley [1], G. Shen [2], C.S. Zha [3], T. LeBihan, D. Hausermann [4], [1] Geophysical Lab., Carnegie Institution, Washington, DC 20015, USA, [2] APS, Argonne National Lab., Argonne, IL 60439, USA, [3] CHESS, Cornell University, Ithaca, NY 14853, USA, [4] ESRF, BP-220, F-38043 Grenoble Cedex, FRANCE

We studied the covariance of ruby fluorescence shift and lattice parameters of 18 polycrystalline materials, V, Fe, Co, Ni, Cu, Ag. Pd, Mo, Nb, Ta, Re, Ir, Pt, Au, Pb, MgO, NaCl, and KCl, under multimegabar compressions. Each sample of 1-2 micron thick and 5-10 micron diameter were arranged in a grid in a diamond cell chamber which was filled with helium pressure medium to ensure uniform hydrostatic pressure. Each sample was probed independently with monochromatic x-ray beam of 5 X 5 micron size at ESRF ID30 Beamline. High resolution x-ray diffraction patterns were collected with FastScan image plates. A new primary pressure scale is obtained from the combination of Brillouin scattering and x-ray diffraction date of MgO. The study includes all commonly used pressure standards and yields a comprehensive, accurate, new pressure scale. In addition, it provides direct correlation of equations of state for these benchmark materials.

P08.OC.021 X-RAY STUDIES OF DISORDERED SYSTEMS AT HP-HT USING THE P-E PRESS AND A MULTICHANNEL COLLIMATOR. M. Mezouar, ESRF, B.P. 220, 38000 Grenoble, France

The determination by X-ray diffraction of the evolution at high pressure and high temperature of inter-atomic distances, and number of first neighbours of disordered systems (liquids, amorphous materials), is of great importance in various domains such as materials science or geophysics. However, many experimental problems (high background signal, chemical reactivity of liquid phases, etc.) limits this kind of study. This poster is dedicated to the recent progress realised at beamline ID30, ESRF. In particular, the development of a multichannel collimator (Sollers slits system) interfaced to a detector based on image-plates has lead to a substantial improvement of the signal to noise ratio, and allows the study of disordered systems under extreme conditions of pressure and temperature. Several examples will be presented, including the behaviour under high pressure of liquid metals of columns V and VI in the periodic table.

08OD APPLICATIONS OF LINE-BROADENING

M08.OD.001 ANALYSIS OF X - RAY DIFFRACTION LINE BROADENING IN STRUCTURALLY INHOMOGENEOUS POLYCRYSTALLINE MATERIALS. P. Klimanek, Freiberg University of Mining and Technology, Institute of Physical Metallurgy, D-09596 Freiberg/Sa., Germany

Real polycrystals (i.e. powders, coatings, or bulk materials interesting in materials science and technology) consist, in many cases, of crystallites with significantly different degree of structural perfection defining a lattice-disorder statistics. The macroscopically observable X - ray (or neutron) diffraction peaks of such structurally inhomogeneous materials are diffraction multiplets formed by superposition of the partial reflections due to the volume fractions of the lattice disorder statistics [1-4], and the reflection characteristics have the meaning of com-plicated microstructure averages depending on

- the type of the lattice-disorder statistics,
- the grain size distribution and/or the texture of the various crystallite fractions, and
- the spatial arrangement of the structurally different crystallites.

In the present paper some basic aspects of the analysis and interpretation of diffraction multi-plet profiles are discussed and illustrated by experimental results obtained with model specimens. (powders) and real bulk materials. Separation of partial reflections of diffraction multi- plets, which is particularly important in the examination of diffraction line broadening due to lattice disorder of the 2nd kind (e.g. dislocation structures, stacking

faults and micro-twins, stress-active precipitates etc., [5,6]), becomes possibly in certain limits if the lattice disorder statistics

- has only two crystallite fractions with clearly different defect structures (e.g. in partially re- crystallised materials),
- can be related to preferred spatial arrangement of the crystallites (e.g. in materials with microstructure gradients), or
- is in close connection with preferred orientations (texture components) of the grains (e.g. in plastically deformed metals and alloys)

The case of texture- related analysis of X-ray diffraction line broadening is treated in some detail for cold-rolled Cu and α-Fe [7]. The results demonstrate that analysis of X-ray (or neutron) diffraction-line broadening is a suitable tool for detailed integrated substructure characterisation even in bulk materials with complicated sample architecture.

M08.OD.002 DIFFRACTION-LINE BROADENING BY LATTICE IMPERFECTIONS; ANALYSIS THROUGH LINE-PROFILE SYNTHESIS. E.J.Mittemeijer[1,2], R.Delhez[2], Th.H.de Keijser[2], T.C.Bor[2] and L.Velterop[2], 1: Max Planck Institute for Metals Research, Seestraße 92, 70174 Stuttgart, Germany, 2: Laboratory of Materials Science, Delft University of Technology, Rotterdamseweg 137, 2628AL Delft, The Netherlands.

Lattice imperfections as dislocations and misfitting precipitates and smallness of the diffracting crystallites cause broadening of diffraction lines. The traditional methods of line-broadening analysis decompose the observed line profiles in parts of which the broadenings are dependent on ("strain broadened" part) and independent of ("size broadened" part) the order of reflection. This line-profile decomposition is subject to severe assumptions made for in particular the "strain broadened" part. As a result large errors can occur if the assumptions do not apply to the specimen concerned (*e.g.* van Berkum et al., Acta Cryst.A52, 1996, 730-747). Furthermore, the "size" and "strain" parameters obtained by such methods are often difficult to interpret. An alternative procedure is possible: line-profile synthesis on the basis of a model *appropriate for the specimen concerned*. From the comparison of calculated line profiles and the measured one the model parameters are found and thereby the characteristics of the lattice imperfections considered. Of course, this approach only works if a correct model can be constructed. The line-profile synthesis route is adopted here for two cases.

Firstly, the effect of stacking and growth faults is analysed. It follows by application of the line-profile synthesis route that some of the approximations formerly used in the derivation of analytical relations between line-profile parameters (*e.g.* profile-maximum position) and fault densities are unjustified. In certain not extreme cases even the sign of the shift of the profile maximum is predicted wrongly !

Secondly, the effect of misfitting inclusions on matrix reflections is analysed. Also in this case irregularities are found. For example the relation between the width of the strain broadened profile and the root mean square strain in the specimen is not necessarily linear, as traditionally assumed.

M08.OD.003 CRYSTALLITE SIZE DISTRIBUTIONS AND X-RAY DIFFRACTION LINE BROADENING. J.Ian.Langford, School of Physics and Astronomy, University of Birmingham, Birmingham B15 2TT, UK, and Daniel Louër, Laboratoire de Chimie du Solide et Inorganique Moléculaire (URA CNRS 1495), Université de Rennes I, 35042 Rennes cedex, France.

When the mean size of crystallites is obtained from X-ray diffraction data, it is normally assumed that diffracting domains have the same size and shape. While a Williamon-Hall plot often indicates that the latter is a reasonable assumption, on average, there is always a distribution of size. This causes the mean size obtained from integral breadths or the Warren-Averbach method to be over-estimated by an amount which depends on the nature and width of the distribution[1]. Additionally, the shape of line profiles, notably the form of their tails, is also affected profoundly. Their shape can be characterised by the parameter ϕ = FWHM/integral breadth and reflections can have any form, from approximately Gaussian (ϕ=0.939) for a narrow normal distribution of size, through Lorentzian (ϕ=0.637), to significantly super-Lorentzian (ϕ=0.5 or less) for a lognormal distribution with a large standard deviation.

From curves of the variation of ϕ with standard deviation or variance for different distributions and simulated line profiles, the corresponding quantity can be estimated for experimental reflections. This and the approximate mean size obtained in the usual way can be used as starting values for calculating line profiles for a given morphology and an assumed distribution. These parameters can then be refined by comparing the calculated and experimental diffraction patterns until the best 'fit' is obtained, to give estimates of the true mean and the standard deviation of the distribution. This procedure is demonstrated by means of data for a nanocrystalline sample of CeO_2, for which the crystallites are approximately spherical. In addition to obtaining crystallite-size distributions, the procedure automatically models line profiles meaningfully in cases where microstrain is negligible. Its implementation could thus be used to advantage in the Rietveld method for structure refinement from powder data.

M08.OD.004 THE DISLOCATION MODEL OF STRAIN ANISOTROPY. T. Ungar, Department of General Physics, Eotvos University Budapest, Pazmany Peter setany 1/A, H-1518, P.O.B 32, Budapest, Hungary

Line broadening means broadening of a Bragg reflection in the vicinity of a fundamental reciprocal lattice point. Due to reciprocity of real and reciprocal space this implies that the strain fields of defects causing this kind of broadening must have a long range character. Dislocations are the only lattice defects satisfying this criterion. On the other hand they exibit a strong contrast anisotropy as it is well known in transmission electron microscopy (TEM). In a TEM experiment the contrast of a dislocation disappears when $\boldsymbol{bg}=0$, where $\boldsymbol{b}$ is the Burgers vector of the dislocation and $\boldsymbol{g}$ is the diffraction vector. The strain part of line broadening is related to the mean square strain which, in terms of dislocations is: $\langle\varepsilon_{g,L}^2\rangle \cong \rho^* ln(R_e/L)/(2\pi^2 g^2)$, where ρ^* and R_e are the *formal* density and the effective outer cut off radius of dislocations and L is the Fourier length. The *formal* and the true dislocation densities are coupled by the contrast factors C of dislocations: $\rho^*=\rho(\pi g^2 b^2 C)/2$, which depend on the relative directions of $\boldsymbol{g}$, $\boldsymbol{b}$ and $\boldsymbol{l}$, ($\boldsymbol{l}$ being the line vector of dislocations): $C=C(\boldsymbol{g},\boldsymbol{b},\boldsymbol{l})$. The values of C can be evaluated numerically for different crystal and dislocation systems. For different dislocation systems or in a polycrystal C can be averaged and is denoted: $\overline{C}$. It has been shown recently that in cubic crystals: $\overline{C}=\overline{C}_{h00}(1-qH^2)$, where $\overline{C}_{h00}$ corresponds to $h00$, $H^2=(h^2k^2+h^2l^2+k^2l^2)/(h^2+$

$k^2 + l^2)^2$ and q is a parameter depending on the elastic constants of the crystal and can be evaluated numerically. Based on the above relations it has also been shown that the Williamson-Hall plot and the Warren-Averbach method can be rationalised for strain anisotropy by replacing g or g^2 by $gC^{1/2}$ or g^2C. The so *modified* Williamson-Hall plot and *modified* Warren-Averbach method provide reliable values for crystallite size and for strain, latter in terms of dislocation densities. Combining the *modified* plots with the scheme of the contrast factors provides a comprehensive tool to describe the microstructure of real crystals. The procedure is also apt for including it into a Rietveld refinement procedure.

M08.OD.005 DEALING WITH ANISOTROPIC PEAK BROADENING IN RIETVELD REFINEMENTS. Peter W. Stephens, Department of Physics & Astronomy, State University of New York, Stony Brook, NY 11794-3800 USA.

The use of high-resolution powder diffraction, especially at synchrotron radiation and pulsed neutron sources, places strict demands on the ability of the experimenter to correctly model the diffraction line shape. The widely used Rietveld technique treats the diffraction line width as a smooth function of *d*-spacing, whereas, for many samples of interest, the peak width depends on the diffraction indices (*hkl*) in a more complicated fashion. In this talk, I will discuss two sources of irregular dependence of peak widths on *d*-spacing.

The first is anisotropic strain broadening, which can be generally modeled as a distribution of lattice parameters within the sample [1]. I will present several applications of a recently-developed algorithm for treating this effect in whole-profile fitting techniques [2]. Examples include Na-para-hydroxy benzoate [3], $Co(N(CN)_2)_2$, $Mn(N(CN)_2)_2$, and K_4C_{60}.

The second is short-range orientational disorder of molecules within an extended crystal lattice, such as is observed in the low-temperature $P2_13$ phase of $C(Si(CH_3)_3)_4$ [4]. I will show that the Rietveld analysis of that data actually relates the observable peak width to the *phase* of the diffraction peak, a rather unusual circumstance.

P08.OD.001 DISLOCATIONS IN $LaNi_{(5-x)}M_x$ (M=Co, Mn, Al, Sn) STUDIED BY X-RAY DIFFRACTION LINE BROADENING. R. Černý, Laboratoire de Cristallographie, Université de Genève, 24, quai Ernest-Ansermet, CH-1211 Genève 4, Switzerland, and J.-M. Joubert, Laboratoire de Chimie Métallurgique des Terres Rares, CNRS - UPR 209, 2-8, rue Henri Dunant, F-94320 Thiais Cedex, France.

Real structure of $LaNi_{(5-x)}M_x$ (M = Co, Mn, Al, Sn) before and after several hydrogen absorption-desorption cycles was studied from the line broadening in powder diffraction patterns measured at the Swiss Norwegian Beam Line (BM1) at the ESRF (Grenoble). The theory of Krivoglaz and his co-workers [1] was used, and the whole line broadening and its anisotropy were explained as due to dislocations in the $LaNi_{(5-x)}M_x$ crystals. The orientation factors χ for reflections in the hexagonal crystal system and for different dislocations types were expressed analytically by Klimanek & Kuzel jr. in [2]. The effect of different substituting elements M was studied in mono- and multi-substituted alloys. The prismatic slip system (slip plane $\{0\bar{1}10\}$) with dislocations having Burgers vector $\boldsymbol{a}/3 < \bar{2}110 >$ was found to be dominating in the cycled non-substituted and Co-substituted alloys in accord with [3 and 4]. Dislocations with Burgers vector $\boldsymbol{c}$ <0001> were found in the cycled alloys substituted with Mn, Al and Sn as it was observed for non-substituted alloys in [5]. The observed dislocation densities in cycled alloys were in the order of 10^{10} cm^{-2} having low values for Al- and Sn-substituted alloys and high values for non-substituted and Co- and Mn-substituted alloys.

P08.OD.002 X-RAY LINE PROFILE ANALYSIS OF NANOCRYSTALLINE SILICON NITRIDE. J. Gubicza, T. Ungár [1], I. Mohai, J. Szépvölgyi [2], [1] Department of General Physics, Eötvös University, H-1518 Budapest P.O.B. 32, Hungary, [2] Research Laboratory of Materials and Environmental Chemistry, Chemical Research Center, Hungarian Academy of Sciences, H-1025 Budapest, Pusztaszeri ut 59-67. Hungary

Nanostructured silicon nitride powder has been produced in a thermal plasma reactor by vapor phase reaction of silicon tetrachloride and ammonia [1] and annealed at different temperatures between 1250 and 1500°C. The effect of heat-treatment on particle-size, size distribution and lattice distortion in the crystalline fraction of the powder was studied by high-resolution X-ray diffractometry. The X-ray line profiles were evaluated for particle-size and lattice distortion by the newly developed methods of the modified Williamson-Hall plot and the modified Warren-Averbach analysis [2]. It was found that the particle-size increased with increasing annealing temperature. The particle-size distribution was obtained by a recently developed numerical procedure using the size parameters provided by the modified Williamson-Hall plots of the FWHM and the integral widths and the modified Warren-Averbach method [3]. The experimental values of the average particle-size determined either by X-rays or by transmission and scanning electron microscopy or calculated from the specific surface area (obtained by the BET method) of the powder are compared with each other. The particle-size values provided by the different methods are discussed in terms of the volume fraction of the amorphous phase and agglomeration.

P08.OD.003 PRECIPITATE-RELATED STRAIN IN REACTOR-PRESSURE-VESSEL STEELS. Davor Balzar, Materials Science and Engineering Laboratory, National Institute of Standards and Technology and Department of Physics, University of Colorado, Boulder, Colorado, 80303, U. S. A. and Hassel Ledbetter, Materials Science and Engineering Laboratory, National Institute of Standards and Technology, Boulder, Colorado, 80303, U. S. A.

Diffraction-line-broadening analysis (DLBA) and small-angle neutron scattering (SANS) were used to characterize the

embrittlement of ferritic steels used in nuclear-reactor pressure vessels. It is believed that the embrittlement is caused by formation of small (1-2 nm) copper-rich precipitates (CRPs). Because the CRPs are so small, it is difficult to monitor the kinetics of their formation and growth directly. However, small CRPs are coherent with the *bcc* matrix, which causes local matrix strain and interaction with the dislocation strain fields, thus impeding dislocation mobility. As CRPs grow, at some critical size the bulk crystal structure of copper (*fcc*) is achieved, the CRPs are no longer coherent with the matrix, and the matrix strain is relieved.

We prepared a series of surrogate low-alloy ferritic-steel specimens with 1.1 mass % copper. The specimens were annealed for different times at 450 °C, which resulted in a different state of precipitation. SANS measurements showed that the precipitate size distribution broadens and shifts toward larger sizes as a function of annealing time. Mechanical hardness showed an increase with annealing time, followed by a decrease, which can be associated with the onset of the precipitates' incoherence. DLBA showed that the strain-related broadening dominated and correlated with mechanical hardness and precipitate volume fraction, as determined from the SANS measurements. A model of strain broadening will be presented to explain these results.

P08.OD.004 A NEW FUNDAMENTAL PARAMETERS APPROACH. A. Coelho and A. Kern, Bruker-AXS GmbH, Östliche Rheinbrückenstraße 50, D-76187 Karlsruhe

A new general convolution based approach to describing X-ray powder diffraction line profiles has been developed [1]. The shapes of line profiles are governed by the emission profile, instrument, and specimen aberrations. Accurate descriptions of the emission profile and instrument aberrations are a necessary prerequisite to determining the specimen aberrations. The specimen aberrations are dependent upon the geometry of the experimental conditions and the deviation of the phase(s) from ideal polycrystalline crystals. The present work aims to accurately describe the specimen aberrations arising from the geometry of the experimental conditions using single line fitting up to Rietveld methods. This includes i) the description of peak shifts and peak shapes as a function of the linear absorption coefficient of the specimen and the specimen thickness and ii) the change in peak shapes of individual phases due to differing axial divergence effects arising from preferred orientation.

An accurate description of the specimen aberrations due to the geometry of the experimental conditions, together with an accurate description of the emission profile and instrument aberrations opens the path for investigating the structurally based specimen aberrations.

P08.OD.005 STRUCTURE AND MECHANICAL PROPERTIES Ti-Al. L.A. Kommel[1], V.K Ovcharov[3], B.N. Kodess[2,3], G.P.Teterin[4], N.G. Kisel[3] , M.I. Ermolova[3]. [1] TTU, Tallin Estonia [2] ICS&E Aurora, CO, USA [3] VNIIMS Moscow, Russia; [4] MSOU, Moscow, Russia

The bimetallic valves were produced using new IFFM technique. IFFM technique is a combination of the two known methods (forging and casting) from which a new quality emerges. As a result of rapid solidification of Ti-36Al-4Nb melt, ordered TiAl and Ti_3Al phases are formed in the valve disk. Microstructure, microhardness and composition profiles across the joint demonstrate that the diffusion process reliably connects two types of alloys. The combination of pressure and rapid solidification of the melt results in materials with fine-grained structure and improved mechanical properties being produced. The diffraction pattern was determined by XRD techniques using CuK-α radiation in X-ray diffractometers. Bragg angles and the half-width of Bragg-intensity profiles of reflections of high and low order for the two intermetallic phases were measured. Hardness measurements were undertaken using 15-g, 50-g and 100-g loads using Micromet-2001 and PMT-3 testers. Analysis of X-ray pictures of valve heads exposes two major sets of Bragg reflections. Each set corresponds to γ-phase (TiAl) and α_2-phase (Ti_3Al) respectively. α_2-phase presence is in the range of 8-15% of the total content, according to the intensity analysis. The fact of presence of α_2-phase indicates that rapid solidification occurs at temperatures exceeding 1200^{o}C. The ratio of the width of γ–(004/002) and α_2-(400/200) reflections is within the limits 1.30-1.38. This reflects the fact that broadening of Bragg reflections is a result of the microscopic stresses caused by pressure and solid-state phase transformations. Note, that the calculated intensity of summarized stresses for the inlet and exhaust valves reaches the maximum magnitude on the external surface of the valve head and is equal to 169-263 MPa for steel valves. In case of the bimetallic valve (TiAl head and Ti-based alloy stem), the stress is 388 MPa.

08OE DIFFICULT STRUCTURES

M08.OE.001 STRUCTURES FROM (VERY) LOW MELTING COMPOUNDS AND THOSE WHICH FORM PLASTIC OR GLASSY PHASES. Roland Boese,* Hans-Christoph Weiss, Jordi Benet-Buchholz and Venkat R. Thalladi, Institut für Anorganische Chemie, Universität-GH Essen, Universitätsstraße 5-7, D-45117 Essen, Germany.

For a systematic investigation of the series of *n*-alkanes [1] and their α,ω-disubstituted derivatives which exhibit the so-called even/odd alternation of their melting points, we faced several problems to grow single crystals in their ordered low-temperature phases.

The *in situ* method with an automated CO_2 laser crystallization device developed in our laboratories, was applied to crystallize the *n*-alkanes from propane to *n*-nonane. The melting point of propane is 83 K and its crystal growth has been accomplished by applying liquid helium as an open gas stream cooler. This necessitated the modification of our standard low-temperature device which uses liquid nitrogen. Higher *n*-alkanes, such as *n*-nonane, crystallize in a rotatory disordered phase and the crystals shatter by further cooling into the low-temperature phase. In order to circumvent the high temperature phase, crystal growth has been performed from a solution of *n*-nonane in *n*-pentane such that the saturation point is at a temperature below the phase transition. This yielded the crystals of the ordered low-temperature phase.

Ethyleneglycol, the first member in the series of α,ω-alkane diols, solidifies in a glassy state. Attempts to induce nucleation by various techniques including ultrasonic shock waves or adding some impurities have not been fruitful. However, when we attempted to cocrystallize it with another proton acceptor, phenazine, we could grow a single crystal and determine the solid state structure.

M08.OE.002 DIFFICULT STRUCTURES: IMPROVING YOUR CHANCES WITH SYNCHROTRON RADIATION. William Clegg, Department of Chemistry, University of Newcastle upon Tyne NE1 7RU, UK and CLRC Daresbury Laboratory, Warrington WA4 4AD, UK.

Some crystal structures are difficult to solve or refine because the data are of inferior quality. Sometimes this is just a problem with the overall level of intensity scattered by very small crystals. On other occasions (or in addition to this), there may be

intrinsic structural problems, such as twinning, pseudo-symmetry, or various forms of disorder, which are reflected (not always obviously) in the quality of the diffraction data. The use of synchrotron radiation instead of a conventional laboratory X-ray source can often provide a straightforward solution to the problem of low intensity, turning difficult problems into something resembling routine studies. Furthermore, the greater intensity and higher degree of collimation of the synchrotron beam can help to resolve questions of pseudo-symmetry (such as space group ambiguities and supercells), reveal twinning evidence in the data, and provide better quality data for unravelling disorder, especially if the data are collected at reduced temperature. Unstable materials can be more readily studied with the opportunity for high-speed data collection using a modern area detector with synchrotron radiation. The wavelength tunability of synchrotron radiation adds a further tool for tackling difficult structures, particularly in the use of anomalous dispersion effects in distinguishing between some atom types.

On the other hand, synchrotron single-crystal studies may uncover problems which are not suspected from conventional X-ray data!

Examples will be given of problems solved at Daresbury Laboratory, using the new SRS single-crystal diffraction station 9.8, together with a discussion of approaches to the development and exploitation of synchrotron radiation facilities in chemical and materials crystallography.

M08.OE.003 CRUNCH: GETTING THE MAXIMUM OUT OF DETERMINANTS. R. de Gelder [1], R.A.G. de Graaff [2], [1] NSR Centre for Molecular Structure, Design and Synthesis, University of Nijmegen, Toernooiveld, 6525 ED Nijmegen, The Netherlands, [2] Leiden Institute of Chemistry, Gorlaeus Laboratories, University of Leiden, PO Box 9502, 2300 RA Leiden, The Netherlands

CRUNCH [1,2] is a system of programs aimed at solving ab initio small and medium sized structures. The program was developed to deal with cases where the usual methods fail, due to bad data, large number of atoms, etc. Phase determination is done by a unique procedure based on the concurrent maximization of Karle-Hauptman determinants. The most important steps determining the success of the method are:the use of a matrix-construction method based on considerations from graph theory the combination of interdependent matrices via the common minor strategy the application of a fast and stable phase-refinement procedur -the location of suspect phases via the analysis of symmetry relation -the extension of trial models to the complete structure by a Fourier recycling metho based on the R2-function

The overall strategy of the system will be commented upon and a brief survey will be given of the methods available to the users of CRUNCH [3].

A well known example of the succes of CRUNCH is the solution of a structure which was put on the internet by Dr. Huffman (140 non-hydrogen atoms, P1) [4]. A number of other examples for which the CRUNCH procedure proved to be very succesful will also be given.

M08.OE.004 EXPANSION OF GLOBAL VALIDATION CRITERIA TO 3-D: THE *R*-TENSOR. Sean Parkin, Biochemistry Department, Duke University Medical Centre, Durham, N.C., 27710, USA.

In difficult crystal structure determinations, objective tools to analyse and diagnose problems can be essential to the process of steering a refinement to completion. A simple, general method for expansion of common global quality criteria to include spatial information is described.

Aside from information derived from the (partial) structure itself, much of the quantitative information used in the course of a difficult refinement is in the form of global validation statistics such as various R-values, goodness-of-fit etc. Although helpful, the utility of such scalar quantities to describe the behaviour of a three-dimensional entity is obviously limited. Side-by-side comparison of observed and calculated structure factors is often a powerful way to resolve structural problems, but it is inherently subjective.

A simple method to quantify variations in a given validation statistic over the three dimensions of reciprocal space can be constructed. In it, a (3x3) matrix, the R-tensor, is constructed which allows an effective value for the statistic in question to be calculated for different points or regions of reciprocal space. A wealth of additional information over traditional scalar statistics is obtained which can help to steer refinement strategy and to assess the final product.

Details of the algorithm and some results are given. A FORTRAN77 program 'RT' is also available from the author at the e-mail address: sean@xray.duke.edu.

M08.OE.005 DIFFICULT STRUCTURES – MAKING THEM FIT FOR THE CHEMIST. Anthony Linden, Institute of Organic Chemistry, University of Zürich, Winterthurerstrasse 190, CH-8057 Zürich, Switzerland.

Difficult structures involving small molecules may be classified into two broad categories: those with difficulties that can be minimised with care, and those with inherent unavoidable properties which make the successful completion of the structural analysis a complicated process. The potential causes of difficulties encountered in each of these categories will be discussed briefly, together with suggestions on how to minimise them, make the best of unavoidably poor data, and extract the most out of an awkward refinement.

Difficult structures in the first category can frequently be overcome by carefully planning and monitoring the experiment. The key is to ensure that the best and most complete data possible has been recorded using the best crystal that can reasonably be obtained. Crystal growth sometimes requires huge doses of patience and perseverance, and poor data can often be traced to curtailed attempts in this area. Other considerations that can assist with this category include the resolution of space group or Laue symmetry ambiguities, detection of spurious intensities, recognition of twinning, and the appropriate application of absorption corrections.

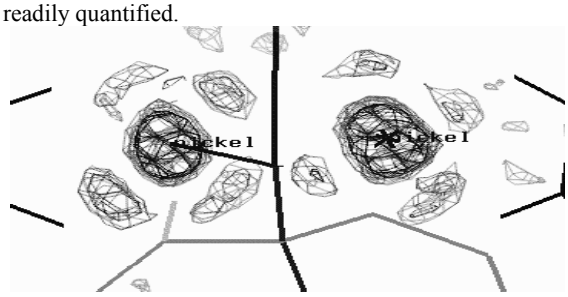
The second category of difficult structures generally involves problems with structure solution or refinement. If the structure will not solve, has the full range of structure solution options been exhausted? The power of fragment orientation routines should not be underestimated. Subtle changes in program defaults can enhance the chances of solving structures from weak data. Complicated or unsatisfactory refinements usually result from disorder, twinning, pseudo-symmetry, missed symmetry, included solvent, insufficient, weak or poor data, over-refinement, or systematic errors in the data. Refinement restraints and constraints are powerful tools for controlling ill-behaved models, but their excessive use can also lead to incorrect models or conclusions. Severely disordered solvent molecules can sometimes be treated by attempting to eliminate their contribution to the reflection data.

Once the best possible result has been obtained, how much information can be extracted from the structure analysis? The chemist needs to know how to avoid over-interpreting or misinterpreting the results. How can the results best be presented

and utilised? Above all, report clearly and concisely any non-routine procedures used to treat the difficulties.

P08.OE.001 EMPTY ORBITAL AND HYDROGEN ATOM LOCATION WITH XTALVIEW - CORRELATION WITH DENSITY FUNCTIONAL THEORY. C.J. Cardin, D.J. Cardin, P.M. Rodger and A.K. Todd, Chemistry Department, The University of Reading, Whiteknights, Reading, RG4 6AD

The use of neutral atom scattering factors for Ni in the crystal structure determination of the first acyclic metal fullerene derivative [1] produced an unexpected feature when using a difference electron density map calculated using the program XtalView to locate the single H atom on the fullerene surface. Despite a routine room temperature image plate data collection, clear negative electron density for the empty d orbitals on both nickel atoms was visible using standard software. The orientation of this LUMO was subsequently confirmed by density functional theory calculations. In another example, the structure of tetrakis(2,4,6-tri*iso*propylohenyl)diphosphine, map examination showed the presence of an unusual disorder which could otherwise not have been interpreted. Electron density maps are rarely examined by chemical crystallographers these days, but the information content of the data collected by the rotation method on area detectors is greater than statistics suggest. 'Map quality' is not readily quantified.



The synthesis of dicobalt and dinickel complexes of trimethylsilylethynyl-1,2-dihydrofullerene; Characterisation by nmr and structure of the first acyclic metal fullerene derivative: Molecular structure of [η^2-Ni-2(η-C_5H_5)$_2$- fullerene] by F. P08.OE.002 MODULAR APPROACH IN MODELING THE CRYSTAL STRUCTURE OF SOME MINERALS. G. Ferraris and Belluso E., DSMP Univ. Torino, Italy, and S.V. Soboleva, IGEM – RAS Moscow, Russia, and E.V. Sokolova, Moscow State Univ., Moscow, Russia

Typically, a group of compounds forms a polysomatic series [1] P_pQ_q if the structure of each member can be described as a linear combination of *P* and *Q* modules with composition C_p and C_q. In most cases the two building modules are slices with thickness t_p and t_q and very close periodicity in the two directions (*e.g.*, **a** and **b**) which define the contact surface; the third periodicity **c** corresponds to the stacking of the slices. Composition (*C*) and metric of the members linearly vary with the modules *P* and *Q* and a member P_pQ_q shall show: *(i)* $c \sim pt_p + qt_q$, $b \sim b_p \sim b_q$ and $a \sim a_p \sim a_q$; *(ii)* $C = pC_p + qC_q$. Actually, the modules can show substitutions and minor modifications; non planar modules can be necessary. In some cases, the above relationships can just be an inspiring starting point. The application of the modular approach in modeling a crystal structure [1] is particularly efficient when the structure of several related compounds is known; it can be necessary when other methods cannot be applied, *e.g.*, for lack of single crystal data. The procedure shall be described for the following compounds for which only TEM and powder diffraction data were available:

- nafertisite, $(Na,K,\ )_4(Fe^{2+},Fe^{3+},\ )_{10}[Ti_2O_3Si_{12}O_{34}](O,OH)_6$, related to astrophyllite, $(K,Na)_3(Fe,Mn)_7[Ti_2O_3Si_8O_{24}](O,OH)_4$, and bafertisite, $Ba_2(Fe,Mn)_4[Ti_4O_4Si_4O_{14}](O,OH)_2$;
- kalifersite, $(K,Na)_5(Fe^{3+})_7[Si_{20}O_{50}(OH)_6]\bullet 12H_2O$, related to palygorskite, $Mg_5[Si_8O_{20}(OH)_2]\bullet 8H_2O$, and sepiolite, $Mg_8[Si_{12}O_{30}(OH)_4]\bullet 2H_2O$;
- polymorph of nacaphite, $Na_2Ca[PO_4]F$, based on modules of nacaphite and arctite, $(Na_5Ca)Ca_6Ba(PO_4)_6F_3$;
- seidite-(Ce), $Na_4(Sr,Ce)_2Ti[Si_8O_{22}]F\bullet 5H_2O$, modeled by comparison with miserite, $(Ca,K,\ )_{0.5}KCa_5(RE)[Si_8O_{22}](OH)F\bullet 0.5H_2O$.

08OF ADVANCED BATTERY AND FUEL CELL MATERIALS

M08.OF.001 CRYSTAL CHEMISTRY OF HYDROTHERMALLY SYNTHESIZED INTERCALATION ELECTRODES. M. Stanley Whittingham and Peter Y. Zavalij Institute for Materials Research and Chemistry Dept, State University of New York at Binghamton, Binghamton, NY 13902-6016, USA

The unique layered structures of manganese and vanadium oxides and their derivatives are of particular interest because of their capacity to intercalate lithium and other cations between their layers that makes them promising candidates for cathode materials in secondary lithium batteries.

We have made a systematic study of the structural changes occurring when vanadium oxides are synthesized hydrothermally from aqueous media containing organic species over a wide range of pH. The coordination of the oxygen around the vanadium is found to increase from four under neutral pH conditions through square pyramidal to six in distorted octahedra at low pH values. A new vanadium dioxide phase and those containing double sheets of vanadium oxide octahedra are found to be the most electrochemically active. In contrast tetrahedral vanadium is found to be less active because of the resistance of V(IV) to take up tetrahedral coordination.

Layered manganese oxides with crystal chemistry similar to the well-known layered titanium disulfides have also been formed. Their crystal chemistry will be described, and the changes occurring on redox reaction will be outlined.

This work is being supported by the National Science Foundation (vanadium oxides) and the US Department of Energy (manganese oxides).

M08.OF.002 SYNTHESIS, NEUTRON DIFFRACTION AND MAGNETIC PROPERTIES OF CATHODE MATERIALS FOR LITHIUM BATTERIES. R. Kanno[a], R.K.B. Gover[a], A. Hirano[a], T. Kamiyama [b], and B. J. Mitchell[c], Department of Chemistry, Faculty of Science, Kobe University, Institute of Materials Science, University of Tsukuba, Intense Pulsed Neutron Source, Argonne National Laboratory.

In recent years, one particular area in Li ion battery research that has received a great deal of attention has been the layered phases $LiCoO_2$ and $LiNiO_2$. Both systems have a layered rocksalt structure, where alternating layers of Li and *M* (Ni or Co) occupy the octahedral sites of a cubic close packed oxygen array. Stoichiometric $LiNiO_2$ is difficult to prepare, due to the high temperature preparation conditions. Non-stoichiometry is associated with Li deficiency and the presence of Ni in the Li layer sites. It is thought that the Ni ions act as local pinning centres, which restricts the motion of the Li ions within the layers. In this study, the nonstoichiometry of $Li(Ni_{1-x}\text{-}Co_x)O_2$ (x=0.0, 0.2) has been controlled by varying starting material, composition and preparation temperature. X-ray and neutron Rietveld analysis has

been used to determine the composition of the materials prepared, and the electrochemical properties have been examined.

In $LiNiO_2$, the non-stoichiometry leads to a significant degradation in the charge/discharge properties, and its mechanism depends on the non-stoichiometry. Magnetic property is an another indication of the non-stoichiometry. The stoichiometric composition, y=0.00 in $Li_{1-y}Ni_{1+y}O_2$ showed a spin glass transition at 8K. The transition temperature increased with y from 0.00 to 0.05, and cluster glass behaviour was observed for the compositions, x>0.05. The behaviour is consistent with the compositions determined by X-ray and neutron Rietveld analysis.

In an attempt to improve the electrochemical properties of $LiNiO_2$, Co doped system has been widely studied. The composition y in $Li_{1-y}(Ni_{0.8}\text{-}Co_{0.2})_{1+y}O_2$ varied with the synthesis conditions, and the best samples prepared with useable capacities of the order of ~190 mAh/g have been found to be highly stoichiometric in nature by neutron diffraction. The spin glass behaviour in $Li_{1-y}(Ni_{0.8}Co_{0.2})_{1+y}O_2$ is also very sensitive to the composition changes. Relationships between the synthesis conditions, structures, charge/ discharge mechanism, and magnetic properties will be discussed.

M08.OF.003 STRUCTURE AND PROPERTIES OF LAYERED $LiNi_{1-y}M_yO_2$ PHASES. C. Delmas, Institut de Chimie de la Matière Condensée de Bordeaux-CNRS, and Ecole Nationale Supérieure de Chimie et Physique de Bordeaux, Av. Dr Schweitzer, 33608 Pessac Cedex (France).

Since $LiCoO_2$ was proposed as positive electrode material in Lithium-Ion batteries, a very strong interest has been devoted to lithium nickel oxide, which is considerably cheaper than the homologous cobalt phase. Unfortunately, the difficulty for obtaining lithium nickel oxide with a composition close to the ideal stoichiometry has inhibited for years the development of lithium-ion batteries with this positive electrode material. In fact, its true chemical formula is $Li_{1-z}Ni_{1+z}O_2$; the extra-nickel ions situated within the lithium sites play a dramatic role on the electrochemical behaviour. Recently, the preparation problems have been overcome ; nevertheless, the materials must be optimised in order to meet the requirements imposed by the applications. A considerable research activity has been devoted to studying the effects of cationic substitution for nickel. In our laboratory, the effect of cobalt, iron, aluminium and magnesium has been considered. Structural and physical characterisations will be discussed in relation with the electrochemical behaviour in lithium batteries. Special attention will be devoted to the characterisation of these materials by X- ray diffraction and also by methods which provide information at the local scale like EXAFS, NMR and Mössbauer spectroscopies.

The author wishes to thank I. Saadoune, A. Rougier, J.P. Pérès, G. Prado, C. Louchet, A. Demourgues, L. Croguennec, M. Grune, P. Gravereau, F. Weill, L. Fournés and M. Ménétrier for their contribution and CNES, SAFT, CEE (contract CT 95-0064) and Région Aquitaine for financial support.

M08.OF.004 NEUTRON DIFFRACTION STUDIES LANTHANUM GALLATE SOLID ELECTROLYTES AT HIGH TEMPERATURES. J.T.S. Irvine, University of St. Andrews, School of Chemistry, St Andrews, Fife, Scotland, UK KY16 9ST, P.R. Slater, Department of Chemistry, School of Physical Sciences, University of Surrey, Guildford, Surrey GU2 5XH and T. Ishihara and Y. Takita, Oita University, Department of Applied Chemistry, Dannoharu 700, Oita 870-11, Japan

$LaGaO_3$ doped with Sr and Mg has recently been shown to exhibit high oxide ion conductivity in both oxidising and reducing conditions and is currently being investigated as an alternative electrolyte material for use in solid oxide fuel cells. Ionic conductivity in this perovskite increases with doping, indicating that defect aggregation is not a major problem in this material.

In this study, we have investigated the structures of $LaGaO_3$ and $La_{0.9}Sr_{0.1}Ga_{0.8}Mg_{0.2}O_{3-\delta}$ by high-resolution neutron diffraction over the temperature range 25-1000°C, using the HRPD facility at the Rutherford Appleton Laboratory. On initial examination, both samples showed similar behaviour with a transition from orthorhombic (Pbnm) to rhombohedral (R3c) symmetry on heating. On more detailed examination it was observed that the doped samples were actually monoclinic (I2/a) over much of the temperature range. At the lowest temperatures the structure was pseudo-orthorhombic, changing to pseudo-rhombohedral between 250 and 500°C. Between 500 and 750°C, the monclinic distortion disappeared and the structure became rhombohedral. Significant changes are also seen in the $Ga\text{-}O_6$ octahedra on doping $LaGaO_3$ with much more distortion in the doped phase. Fundamental structural parameters such as O-O jump distance change dramatically with temperature, so it is inappropriate to consider a single activation energy for conduction in this system.

M08.OF.005 PARTIAL DISORDER IN $(Sc_yYb_{1-y})_2Ti_2O_7$ PYROCHLORE : IN-SITU NEUTRON DIFFRACTION STUDY OF A POSSIBLE OXYGEN CONDUCTOR. K. Eberman, Max-Planck-Institut für Festkörperforschung, Heisenbergstraße 1, 70569 Stuttgart, Germany; B. J. Wuensch, Massachusetts Institute of Technology, Boston, MA, 02139, USA; and J. D. Jorgensen, Materials Science Division, Argonne National Laboratory, Argonne, IL, 60439, USA.

A stability region for pyrochlores of the type $A^{3+}_2B^{4+}_2O_7$ has previously been found to include compositions having a cation radius-ratio $R_A{}^{+3}$:$R_B{}^{+4}$ between 1.54 and 1.80 for titanates [1] and between 1.40 to 1.71 for stannates [2]. In solid solutions where a larger Zr^{4+} ion is substituted on the B-site, progressive disorder has been observed near the perimeter of this stability regime for pyrochlores such as $Y_2(Zr_yTi_{1-y})_2O_7$ [3], $Y_2(Zr_ySn_{1-y})_2O_7$, and $Gd_2(Zr_yTi_{1-y})_2O_7$ [4]. This partial disordering is primarily among the anion array, which amounts to an increase in charge-carrier concentration [$V_o^{\bullet\bullet}$], and thus to an increase in ionic conductivity of up to two orders of magnitude. We are aware of only one study, other than the present, of disorder induced by substitution of a small ion on the A-site [5].

We present the analysis of neutron diffraction data taken continuously up to high-temperature (1400°C) for the entire solid solution series $(Sc_yYb_{1-y})_2Ti_2O_7$ (y = 0.00, 0.09, 0.20, 0.30, 0.40, and 0.52) together with the analysis for $Lu_2Ti_2O_7$. Preliminary results indicate that partial disorder is induced by both the chemical substitution and by increased temperature. For up to y = 0.30 the powders crystallized as single-phase pyrochlores, beyond which a second phase appears. The short hopping distances for oxygen anions among these pyrochlores of diminutive lattice parameter, together with the partial disorder among the anion array should allow for a direct interrogation of the transport mechanism in the Fourier synthesis maps.

P08.OF.001 LITHIUM LOCATION BY NEUTRON DIFFRACTION IN NASICON-TYPE α- AND α'-$LiZr_2(PO_4)_3$. M. Catti and S. Stramare, Dipartimento di Scienza dei Materiali, Università di Milano II - Bicocca, via Cozzi 53, 20126 Milano, Italy.

Within the NASICON family of ionic conductors, Li-containing compounds have not been thoroughly investigated so far from the structural point of view, mainly because lithium is a poor X-ray scatterer. On the other hand, a full knowledge of the Li^+ atomic environment is essential to understand the mechanisms of ionic mobility in these materials. With this aim, we studied $LiZr_2(PO_4)_3$ synthesized by solid state reaction at 1200 °C, which is reported to be rhombohedral $R\bar{3}c$ above 50 °C (α phase) and monoclinic C2/c at room temperature (α' phase), on the basis of conventional X-ray diffractometry [1]. Data were collected for the α and α' modifications at 150 and 25 °C, respectively, on the time-of-flight High Resolution Powder Diffractometer (HRPD) at the ISIS facility of the Rutherford Appleton Laboratory, Chilton, U.K., in the d_{hkl} range 0.7 to 2.5 Å. The α' phase turned out to be actually triclinic, consistent with recent X-ray results [2], and its Rietveld refinement converged in space group $C\bar{1}$ for 4226 data and 105 variables, with final agreement factors R_p=0.0672, wR_p=0.0929, $R(F^2)$=0.0617. A monoclinic pseudo-symmetry - x,y,1/2-z is observed for all atoms but lithium, which is disordered over two sites Li1 and Li2 with occupancies 0.71(3) and 0.29(3). Both Li1 and Li2 are in distorted tetrahedral coordinations, with <Li-O>=2.09 and 2.18 Å, respectively. Pairs of centrosymmetrical Li1 sites are located within half of the available M' holes of the NASICON structure, which are split into two independent sets by triclinic breaking of symmetry. The α structure was refined in space group $R\bar{3}c$ to R_p=0.0355, wR_p=0.0439, $R(F^2)$=0.1308, and here again Li is split into two sites Li1 and Li2 with tetrahedral surroundings. However, in this case the disorder is much higher, because all possible M' holes contain Li1 atoms with fractional occupancy, so that the larger conductivity of the α with respect to α' phase is fully accounted for.

P08.OF.002 MODELLING CONDUCTION PATHWAYS FOR SOLID ELECTROLYTES. St. Adams, MKI, Univ. Göttingen (Germany) and J. Swenson, Dep. of Appl. Physics, Chalmers Univ. of Technology, Göteborg (Sweden).

Conduction pathways for a variety of crystalline and amorphous Ag^+ ion conducting systems, including AgI-AgM_xO_y (M = B, Mo, P, V), AgI polymorphs and MAg_xI_y (M=Rb, Hg), are modelled as isosurfaces of minimum Ag bond-valence mismatch. The resulting pathway models are discussed in the light of experimental observations to elucidate relevance and limitations of the bond-valence approach. Beyond a description of the pathway topology the bond-valence pseudopotentials yield estimates of migration enthalpies and jump probabilities related to impedance and spectroscopic data.

The variation of the valence mismatch around regular silver sites closely mimics the experimental Ag probability density distribution. Bond-valence models moreover provide information on interstitial sites, for which the low occupancy precludes experimental investigations of atomic displacement parameters. In systems with complex anion disorder, structural determinations yield only an averaged picture. Thus bond-valence calculations for such systems were based on typical local co-ordinations for the mobile ions derived from complementary molecular dynamics simulations.

The simplicity of the bond-valence sum approach permits a modelling of comparatively large model systems and hence also of glassy ion conductors. Structural models of the molecular glass $(AgI)_{0.75}$ -$(Ag_2MoO_4)_{0.25}$, the network glass $(AgI)_{0.6}$-$(Ag_2O$-$2B_2O_3)_{0.4}$ and undoped borate glasses have been determined by reverse Monte Carlo (RMC) modelling based on neutron and x-ray diffraction data employing bond-valence constraints to reduce the number of unphysical Ag^+ co-ordinations. Due to the complexity of the pathways in glass systems and the snapshot character of RMC models, representative results (e.g. on the fraction of mobile ions, their local mobility, the involvement of differently co-ordinated Ag^+ in the long range ion transport, the spatial extension of pathways etc.) are derived from statistical evaluations of the percolation of Ag^+ along bond-valence sum isosurfaces.

M08.AA.004 THREADING WITH EXPLICIT MODELS FOR EVOLUTIONARY CONSERVATION OF STRUCTURE AND SEQUENCE. S.H. Bryant, A. Panchenko, A. Marchler-Bauer National Center for Biotechnology Information, National Institutes of Health, Building 38A, Room 8N805, 8600 Rockville Pike,Bethesda, MD 20894, USA

We have attempted to predict the three-dimensional structures of 19 proteins for the CASP3 experiment, each showing less than 25% sequence identity with known structures. Predictions were based on a threading method that aligns the target sequence with the conserved cores of structural templates, as identified from structure-structure alignments of the template with homologous neighbors. Alternative alignments were scored using contact potentials and a position-specific score matrix derived from sequence neighbors of the template. We find that this method identified the correct structural family for 11 of the 19 targets and predicted the remaining 8 targets to be similar to "NONE" of the templates, avoiding false positives. Threading alignments were relatively accurate for 10 of the 11 targets, including alignments for 6 of 7 identified at CASP3 as fold-recognition targets, sharing no sequence motifs with proteins of known structure. These predictions were ranked "first place" by the CASP3 assessor, and it appears that threading with family-specific models for structure and sequence conservation has improved threading prediction accuracy. A retrospective analysis of these and other CASP3 predictions clearly shows the limitations of current theading methods, however. To be detectable by threading, structural similarity must be extensive, such that 60% or more of residues may be superimposed to 2.5 Angstroms or less.

P08.AA.001 EXPLANATIONS FOR α-HELIX AND β-SHEET PROPENSITIES BASED ON CONFORMATIONAL FEATURES. P. Chakrabarti and D. Pal, Department of Biochemistry, Bose Institute, P-1/12 CIT Scheme VIIM, Calcutta 700054, India.

Since the elucidation of propensity values for amino acid residues to occur in different secondary structures by Chou and

Fasman [1], experiments have been designed to measure these. Although there is a broad agreement between different sets of values there is no universal explanation for the differences in propensity values. Extending our work on the features of the main-chain and side-chain conformations, (ϕ, ψ and χ_1) using the Brookhaven Protein Data Bank [2] we find that the α-helical propensity for a residue depends on the overall similarity in the distribution of its main-chain conformation with that of Ala, such that a stretch of residues having a high overall similarity to Ala can cooperatively form a helix. Similarly, the volume in the (ϕ, ψ, χ_1)-space occupied by a residue correlates with its β-sheet propensity. These explanations provide new insight into the folding of secondary structures, and the parameters calculated can be used for the prediction of secondary structures in proteins.

P08.AA.002 A BRUTE FORCE PATTERN RECOGNITION ALGORITHM. R.J. Morris and V.S. Lamzin, EMBL Outstation Hamburg c/o DESY, Notkestrasse 85, Geb.25A, D-22603 Hamburg, Germany, and A. Perrakis, EMBL Outstation Grenoble c/o ILL, BP 156, Avenue des Martyrs 156X, 38042 Grenoble Cedex, France.

We present a new algorithm for tracing protein/DNA chains in crystallographic electron density maps. We formulate the task of finding the best chain (or set of chains) as a linear programming problem with integer decision values. The objective function is the vector product of the binary decision variables (connection - no connection) with a connection score vector. The scores are based on known stereochemical information. For proteins the 3D distribution of C_α valence and dihedral angles - an extension to the distribution used for validation in [1] - has proven to be particularly useful. In this way we *force* the algorithm to find only well-geometrised fragments. Although this formulation belongs to the so called NP-hard class problems we have developed algorithms that deliver good results in a very efficient manner thus making the problem tractable.

The results of the automatic map interpretation are used in the form of stereochemical restraints for the ARPwARP [2,3] refinement procedure. The incorporation of iterative pattern recognition routines into ARPwARP not only resulted in a significant improvement regarding CPU time but was also in many cases vital for the refinement to proceed.

P08.AA.003 ELECTROSTATICS IN PROTEIN-PROTEIN DOCKING. M. Eisenstein, A. Heifetz, and E. Katchalski-Katzir. Departments of Chemical Services and Chemical Biology, The Weizmann Institute of Science, Rehovot 76100, Israel.

Previously we have presented an algorithm for protein-protein and protein-ligand docking, based on geometrical surface complementarity, and demonstrated its usefulness for predicting the structures of binary complexes and of supra-molecular aggregates [1-3]. Another prominent characteristic of proteins, which plays an important role in molecular recognition, is electrostatics. Yet, attempts to introduce electrostatics in our algorithm by us and by others only marginally improved the docking results [4].

The computed electrostatic interaction energies appear to be very sensitive to the exact relative position of the interacting molecules. Thus, a relative rotation of only 2 degrees may strongly affect the resultant electrostatic energy. This is a severe disadvantage in a stepwise scanning procedure as ours, which may miss the exact relative orientation of the docked molecules by a few degrees. It might be critical in docking attempts where structures of the uncomplexed proteins or model structures are used. Therefore, we looked for an alternative representation of the electrostatic characteristics of protein surfaces, which is less sensitive to the exact structural details and which can be efficiently incorporated in our docking algorithm.

Currently, we are developing a simplified "patches" representation of the electrostatic features of the docked molecules, which can be combined with an efficient scanning procedure that requires essentially the same amount of computation time as our geometrical docking. Initial results indicate that with the new representation the contribution of electrostatics to the overall surface matching score is considerably less sensitive to small orientational mis-matches and that it significantly increases the score of the correct structure and lowers the scores of many false positive solutions.

08BB PROBLEMATICS IN MACROMOLECULAR STRUCTURE (II): FITTING AND REFINEMENT (sponsored by CCP4)

M08.BB.001 ERRORS AND REPRODUCIBILITY IN ELECTRON DENSITY MAP INTERPRETATION. Sherry L. Mowbray, T. Alwyn Jones, Charlotte Helgstrand, Jill A. Sigrell, Alexander D. Cameron, Department of Molecular Biology, Swedish University of Agricultural Sciences and Uppsala University, Biomedical Centre, Box 590, S-751 24 Uppsala, Sweden.

Three investigators, with varying levels of experience, independently built the structure of *E. coli* ribokinase into an MIR map at 2.6 Å resolution, and then refined it. The refinement/rebuilding processes converged to give similar structures, although each "final" model had its own particular pattern of errors that remained. The subsequent refinement of the same structure at 1.8 Å resolution allowed an overall quality check of each of the lower-resolution models, and an analysis of which graphics-based tools were most efficient in locating these errors in general. Criteria that are useful in the application of Ramachandran, pepflip, rotamer side chain and real-space fit analyses are presented.

M08.BB.002 THROUGH PROTEIN MODEL SPACE WITH THE SPEED OF ARP/WARP. V.S. Lamzin, R.J. Morris and A. Perrakis. European Molecular Biology Laboratory, Outstations in Hamburg (Germany) and Grenoble (France).

An exponentially growing amount of challenging biological questions seeks answers through the structure determination of more and more proteins and their complexes. The number of new structural entries deposited in Protein Data Bank has been increasing over the last years and reached about 1,400 structures in 1997 alone. This puts much emphasis on the

availability of fast, reliable, objective and easy-to-use procedures for solution, building and refinement of these structural models.

We present the 'warpNtrace' method to automatically and without user intervention build and refine a protein model, starting from diffraction data extending to a resolution of higher than 2.3 Å and reasonable estimates of crystallographic phases. The method is an integral part of the ARP/wARP suite and is based on an iterative procedure describing the current electron density map as sets of unconnected atoms and then searching for protein-like patterns. The autotracing is combined with the reciprocal space refinement so that an almost complete protein model can be obtained in a fully automated way. The procedure can be applied starting from any source of phase information, experimental, computational or a combination of these. The time required for building a protein structure can be shortened from several man-days or even man-months to a few CPU hours on inexpensive workstations.

Several dozens of protein structures have already been reported to have been built and refined using 'warpNtrace'. The applications include the *Leishmania* surface protein (Leishmanolysin); a mercury derivative of 20 kDa xylanase which was solved at 2.0 Å resolution essentially *ab initio*, using SAD signal only; β-mannanase where sequence guesses from the autotraced fragments were used to design oligonucleotide primers to clone the gene; cyanase - a very large structure comprising ten monomers where the decamer is formed by a pentamer of dimers in an unusual way; GroEL apical domain where the whole procedure from the start of diffraction data collection to the completely autotraced protein structure took only 3 days.

M08.BB.003 EIGENVALUES ARE THE ANSWER, WHAT IS THE QUESTION? L.F. Ten Eyck, San Diego Supercomputer Center, University of California at San Diego, 9500 Gilman Drive, La Jolla 92093-0505, USA.

Atomic resolution protein structures have shown that essentially the same type of model describes both macromolecular and small molecule crystal structures. Incorporation of anisotropic thermal parameters, explicit hydrogen atoms, and static disorder models give similar levels of improvement in fit of the model to the observations in both cases. Adequately modelling this electron density distribution with fewer parameters is necessary at less than atomic resolution, but unfortunately is still an unsolved problem. The eigenvalue spectrum of the normal matrix for either least squares or maximum likelihood refinement is a precise and comprehensive tool for evaluating alternative parameterisations of the model. The eigenvalues and eigenvectors show the precision of parameter determination, the full multivariate correlation among all parameters and the effects of both constraints and restraints on the refined solution.

M08.BB.004 *AB INITIO* SOLUTION AND REFINEMENT OF AN 11 KDA PSEUDO-PROTEIN AGAINST MEROHEDRALLY TWINNED DATA. T.R. Schneider, J. Kärcher, E. Pohl, P. Lubini, and G.M. Sheldrick, Institute for Inorganic Chemistry, University of Göttingen, Tammanstr. 4, 37077 Göttingen, Germany

Merohedral twinning is a frequently observed (and frequently undetected but nevertheless existing) complication in both small molecule and protein crystallography. Here we describe the *ab initio* structure solution and refinement of mersacidin, a lantibiotic effective against gram-positive bacteria, based on data from a twinned crystal.

A single molecule of mersacidin contains 20 amino acids, about half of which are post-translationally modified. The compound crystallizes in the space-group $P3_2$ pretending to be $P3_221$ as a result of merohedral twinning. The asymmetric unit contains six molecules resulting in a crystallographic problem equivalent to a protein of 120 residues. At cryogenic temperatures crystals diffracted to 1.1Å on BW7B at EMBL Hamburg (100% complete, $R_m = 4.9\%$).

After very crude deconvolution of the data into contributions from the different twin domains, the program SHELXD[1] succeeded in solving the structure *ab initio*. Three quarters of the atoms were automatically located in the first electron density map. Starting from this model, refinement was performed against the original twinned data using the program SHELXL[2] employing a mixture of small molecule and protein techniques. Key steps were the introduction of tight restraints on the non-standard amino acids exploiting the local non-crystallographic symmetry and substantial phase improvement by automatic placement of dummy atoms in a way similar to ARP[3].

The current crystallographic R-value is 13.6%. The atomic model reveals an extremely tight packing including a non-crystallographic two-fold axis and a set of cleavage planes that provide a possible physical explanation for the merohedral twinning.

M08.BB.005 EFFECTS OF TLS THERMAL PARAMETERS IN MACROMOLECULAR REFINEMENT. Winn, M.D.[1], Mikhael Isupov[2] and Murshudov, G.N. [1,3], [1]CLRC Daresbury Laboratory, Warrington, WA4 4AD, UK [2]Dept of Chemistry and Biological sciences, University of Exeter, Exeter, UK [3]Chemistry Department, University of York, York, YO1 5DD, UK

Because of limited resolution, the description of the atomic model in terms of a sufficiently small number of parameters is one of the most important steps in macromolecular refinement. Translation libration screw (TLS), using only 20 parameters per rigid body, is one possibility for reducing the number of thermal parameters required. Computationally, the necessary derivatives with respect to the TLS parameters are calculated in terms of the gradients and second derivatives for individual anisotropic U values. For the latter, the FFT routine is used. This means that the procedure is fast and can be used routinely. Refinement of TLS parameters has been implemented in the program REFMAC available from CCP4 [1].

Examples of this use of TLS will be given. For a 2.0Å example with 5881 atoms, after refinement of 80 TLS parameters the free-R value dropped by 3.5%. For a 1.7Å case with 835 atoms, addition of only one set of TLS parameters improved the free-R value by 2.5%.

Refinement of these parameters in parallel with individidual positional, isotropic and anisotropic thermal parameters will also be presented. In addition, since different molecules in the unit cell might well have different overall thermal parameters, removing the TLS contribution from the individual atomic thermal parameters is expected to improve and extend the application of NCS restraints in the refinement.

P08.BB.001 IMPROVED METHODS FOR CRYSTALLOGRAPHIC ENERGY MINIMIZATION. John Badger [1] Dan Berard [2] and Sandor Szalma [2 1] , San Diego Supercomputer Center, PO Box 85608, San Diego, CA 92186, [2] Molecular Simulations Inc., 9685 Scranton Road, San Diego, CA 92121

It has generally been assumed that crystallographic refinement protocols based on simulated annealing with torsion angle dynamics have a much larger radius of convergence than protocols based on gradient-based energy minimization. We have developed a multi-stage energy minimization protocol that combines (i) the maximum likelihood targets (Pannu & Read, Acta Cryst. A52, 659, 1996), (ii) the Babinet bulk solvent scattering correction, (iii) the adopted basis Newton-Raphson (ABNR) energy minimization algorithm incorporating second derivative information.

Each of these factors improves the quality of the refinement and appears to have a larger impact on the results obtained by energy minimization than results obtained by simulated annealing. In tests (10 trials for each method) with a model containing an rms backbone error of 1.6Å; the energy minimization protocol was as effective as torsion angle dynamics for refining the model. This model appears to be on the limits of refinability since no method was able to improve the structure when the coordinate errors were increased to 2.0Å;. Analyzing the results of the multiple trials with these methods we found that there is a smaller variation in the quality of results with the energy minimization protocol than with the torsion angle dynamics protocol.

For this reason, energy minimization may be the most reliable approach for many refinements. In addition, we found that the ABNR energy minimization method refinesmodels to a lower energy than the Powell energy minimization method, avoiding numerical problems that lead to abandonment of the line search. However, for a very narrow range of difficult refinement problems (rms backbone error 1.8Å;) the more stochastic dynamics based approach was able to produce 2/10 good solutions (as well as some very poor solutions) while the solutions obtained from the energy minimization protocol were less well converged.

This refinement methodology is available in X-PLOR 98.1 from Molecular Simulations Inc.

P08.BB.002 MAXIMUM LIKELIHOOD REFINEMENT OF ADENOVIRUS TYPE 5 HEXON WITH TNT. John J. Rux and Roger M. Burnett, The Wistar Institute, 3601 Spruce Street, Philadelphia, PA 19104, USA.

Solving the adenovirus type 5 hexon (Ad5) structure was initially thought to be a straight-forward molecular replacement problem. Ad5 is the major protein component of the icosahedral adenovirus capsid. The very long chain (951 aa) forms two 8-stranded "viral" jelly-rolls at the subunit base. The trimer has highly convoluted loops making three towers visible by EM as "bumps" on the outer surface of the virus capsid. As the Ad5 sequence is closely related to that of the known Ad2 [1] (86 % aa identity), and both crystallize isomorphously, the structure solution appeared trivial.

The sequence heterogeneity between Ad2 and Ad5 occurs mainly in the loop structures. Initially, these were removed and the highly conserved base (690 aa, or 73% of structure) was used as a starting model. Various refinement and fitting attempts stalled, yielding models with Rfree values of 35-40 %. The successful approach began with a starting model containing the base plus poly-Ala loops. Refinement with TNT against a maximum likelihood (ML) target has yielded a 2.5 Å structure with R = 17.6 %, Rfree = 23.1 %, 0.004 Å RMSD bonds, and 1.444 ° RMSD angles.

The new structure reveals substantial differences from the starting model: a reverse tracing of a 65 aa loop; an up to 41 aa shift in the sequence registry for 130 aa at the N-terminus; small register shifts of 1-2 aa in other portions of the structure; and increased secondary structure. These findings explain some previously puzzling structural and experimental observations: a "missing" N-terminus; a long stretch of "buried" acidic residues; and a hypervariable sequence with conserved secondary structure.

The success of the Ad5 structure solution illustrates that current techniques such as Rfree analysis and ML refinement when applied to previously accepted models may yield much higher quality structures — and some surprises.

08CC STRUCTURES AND TECHNIQUES AT EXTREME PRESSURES AND TEMPERATURES

M08.CC.001 PHASE TRANSITIONS IN GEOPHYSICS. Raymond Jeanloz, Depts. Geology & Geophysics and Astronomy, University of California, Berkeley, CA 94720-4767, USA

Phase transitions play a key role in geophysics, both in helping to interpet the observed structure of the Earth and in order to understand the dynamics of the planet's deep interior. Crystal-structural transitions are relatively well characterized at the conditions of the mantle, and are found to exert a surprising influence on convection and large-scale heat transfer of the interior. More recent ultrahigh-pressure studies of coupled electronic and structural transitions in transition-metal oxides begin to provide an understanding of intense chemical and physical interactions between the Earth's metallic core and rocky mantle. High-pressure experiments and theory have helped lead the geophysical observations, thus revealing new insights about the long-term evolution of our planet.

M08.CC.002 SINGLE-CRYSTAL X-RAY DIFFRACTION AND SPECTROSCOPY AT MEGABAR PRESSURES. H.K. Mao, L.W. Finger, R. J. Hemley Geophysical Lab. and Center for High Pressure Research, Carnegie Institution of Washington, 5251 Broad Branch Rd. NW, Washington, DC 20015-1305, USA.

Detailed crystal structure refinement at pressures above 20 GPa has been previously obtained only with polycrystalline diffraction methods. High-pressure single-crystal x-ray diffraction, which provides far more comprehensive and accurate information on crystallography, has been limited to lower pressures and a small reciprocal space within a 90° cone of the diamond-cell axis. We have developed a special diamond cell to extend high-pressure single-crystal x-ray diffraction far beyond the previous limit. X-ray transparent gasket allows access to the full reciprocal space of the single crystal sample. Structure refinement can be performed with either monochromatic or polychromatic x-radiation. The technique also opens new areas of high-pressure single-crystal x-ray spectroscopic studies including electron and phonon dispersions and Compton scattering.

M08.CC.003 THE SHEAR STRENGTH AND ELASTIC MODULI FROM THE LATTICE-STRAINS MEASURED UNDER NON-HYDROSTATIC COMPRESSION. A. K. Singh, Materials Science Division, National Aerospace Laboratories, Bangalore 560017, India.

The stress state of the sample compressed in a diamond anvil cell (DAC) tends to be non-hydrostatic, particularly in the megabar

range. Successful attempts have been made to model the non-hydrostatic stress state of the sample and develop a theory to compute the lattice strains produced by such stresses [1-3]. A recently developed technique [4,5] permits the measurement of the lattice strains along different directions with respect to the load axis of a DAC. The analysis of these data, obtained under non-hydrostatic compression, gives the shear strength and single-crystal elastic moduli of the specimen material [6-9]. These data can be also analyzed using the present theory to derive the equation of state (pressure-volume relation) that corresponds to hydrostatic compression. The present analysis provides the only method of estimating the shear strength and elastic moduli to a few hundred gigapascals. The results of such analysis of iron data have been used recently to discuss the anomaly in the seismic wave-velocity through the earth's inner core [10].

M08.CC.004 THE AB INITIO CALCULATION OF THE STRUCTURE AND STABILITY OF IRON. G. David Price, L. Vocadlo, D. Alfe, J. Brodholt and M. J. Gillan, Departments of Geological Sciences, and Physics, University College London, Gower Street, London WC1E 6BT.

The Earth's inner core is predominantly made of metallic iron crystallizing out of the outer core which consists mainly of liquid iron with some lighter alloying element. The temperature at the outer core/inner core boundary (ICB) is unknown, but even some knowledge of the structure and melting temperature of pure iron under these conditions would provide an invaluable constraint on the ICB temperature; however, current estimates of the melting temperature of pure iron under core conditions vary by several thousand degrees. To help resolve these uncertainties, we are performing ab initio computer calculations on both the solid and liquid phase of iron under core conditions in order to determine the Gibbs free energy and temperature of the melt transition. The calculations are being performed using the projector augmented-wave method (PAW) which is a generalization of the linear augmented-plane-wave method (LAPW) and the pseudopotential method. The vibrational free energy of the solid phase are calculated using the frozen phonon technique to obtain the harmonic vibrational spectrum; an anharmonic contribution to the free energy can be obtained from ab initio molecular dynamics by thermodynamic integration from the harmonic reference system using a coupling constant method. Similarly, the free energy of the liquid can be calculated from ab initio molecular dynamics simulations by thermodynamic integration from an appropriate model reference system. We will first present our calculated results and review future developments.

M08.CC.005 STRUCTURAL STUDY OF MAGNESITE AND DIAMOND UNDER HIGH PRESSURE. G. Fiquet Laboratoire de Sciences de la Terre, UMR CNRS 8515, ENS Lyon, 46 Allée d'Italie, 69364 Lyon cedex 07, France, gfiquet@geologie.ens-lyon.fr

We report here two series of X-ray diffraction experiments that have been carried out to determine the compression properties of (1) a natural magnesite compound and (2) synthetic diamond samples of different isotopic constitutions (^{12}C and ^{13}C). Angle dispersive X-ray diffraction experiments were carried out at the high-pressure beamlines ID30 and ID09 of the ESRF (Grenoble, France). X-ray beam at wavelengths from 0.3 to 0.45 Å were used in association with imaging plates to collect data over a 2-theta interval from 4 to 25°, suitable for structural refinements.

X-ray diffraction pattern were recorded to 113 GPa on a mixture of magnesite and platinum powders, loaded in a diamond-anvil cell and annealed with an infrared YAG laser. Rietveld structural refinements show that the principal structural change with increasing pressure is a very large compression of the MgO_6 octahedra on the cost of a slight expansion of the CO_3 groups. Above 60 GPa however, MgO_6 octahedra almost stop compressing and the overall compression is in turn accomodated by a compression of the CO_3 groups.

Several runs were carried out in a diamond-anvil cell on synthetic diamond powders of different isotopic compositions (^{12}C and ^{13}C). A mixture of methanol-ethanol-water 16 :4 :1 in volume was used up to 15 GPa to provide hydrostatic pressures around the samples , whereas nitrogen or argon were used to 20 GPa. Le Bail profile refinements were applied to the diffraction patterns, in order to obtain reliable high-pressure cell parameters for diamond as well for the pressure transmitting media. Preliminary results indicate very similar compression properties for both compounds, in disagreement with ultrasonics and Brillouin scattering experiments which reported up to 17% increase in the bulk modulus of ^{13}C diamond with respect to ^{12}C diamond.

M08.CC.006 CHEMISTRY OF LIGHT MOLECULES AT HIGH PRESSURE AND TEMPERATURE. Guido L. Chiarotti, International School for advanced Studies, Via Beirut 2, I-34100, Trieste, Italy

The combined effect of high Pressure (P) and Temperature (T) may alter significantly the chemical properties of molecular systems because high-P reduces the molecular dissociation barriers and high-T helps in overcoming them. In this talk I shall review our recent works on the study of chemical reactions at high PT, using first principles computer simulations. In particular I shall discuss the high PT induced methane dissociation [1], the superionic and metallic behaviour of water and ammonia at high PT [2], the transformation of molecular carbon dioxide (CO_2) into nonmolecular carbonate phases similar to alpha-quartz SiO_2. The simulation predicts this transformation to occur above 40 GPa, with a more facile transformation for T higher than 1800 K [3].

P08.CC.001 THE "ETH DIAMOND-ANVIL CELL" DESIGN FOR SINGLE-CRYSTAL XRD AT NON-AMBIENT PT CONDITIONS. R. Miletich, H. Reifler, and M. Kunz, Laboratory for Crystallography, ETH Zentrum, CH-8092 Zürich, Switzerland

Diamond anvil cells (DAC's) provide the capability of generating large stable pressures. Angle-dispersive diffraction on single crystals aiming for high-precision diffraction data requires modifications to the DAC design in order to optimize application on a four-circle diffractometer.

Our new design is based on the BGI-type DAC [1]. It is a modular DAC system which allows a room-temperature (RT) high-pressure (HP) module to be replaced by a high-temperature (HT) part. The principle design based on (1) the mechanism for adjusting the parallelism of the opposing diamond culets, (2) the

stability as achieved by four guide pins, and two pairs of left- and righthanded bolts, and (3) the large opening angle of 90° has been transfered to the new ETH-DAC, which in overall gains from both less weight and smaller size relative to the original BGI design.

Modification of the exchangeable RTHP module include a spring-loaded mounting system of the diamond anvils on the beryllium seats, which allows a quick replacing of the anvils. The anvil shape has been modified to achieve both larger table sizes and a smaller anvil height. The HPHT module, which is based on single-crystal diamond backing plates instead of the Be seats, allows external heating by a resistance furnace in an Ar-H_2 atmosphere. The design of the new cell and first results of application will be presented.

P08.CC.002 IRON AT EARTH'S CORE CONDITIONS: AN AB-INITIO SIMULATION STUDY. G.L. Chiarotti, A. Laio, S. Scandolo [1], S. Bernard [2], E. Tosatti [1,3], [1] International School for Advanced Studies, Via Beirut 4, I-34014 Trieste, Italy, [2] Commissariat a l'Energie Atomique, DRIF ,BP 12, F-91680 Bruyeres le Chatel, France, [3] International Centre for Theoretical Physics, I-34014 Trieste, Italy

We present a theoretical description of iron at earth's core pressure and temperature conditions as obtained by a combination of first-principles and classical molecular dynamics simulations.We calculate the melting temperature, the density, and the elastic properties of solid and liquid iron at inner-core boundary conditions. Geophysical implications on the structure of the earth's core are discussed.

P08.CC.003 LATTICE STRAINS UNDER NON-HYDROSTATIC COMPRESSION: A DISCUSSION OF THE ASSUMPTIONS IN THE THEORY. A. K. Singh, Materials Science Division, National Aerospace Laboratories, Bangalore 560 017, India.

The recently derived general equations for the lattice strains [1-3] produced by non-hydrostatic compression in an opposed-anvil setup explain quantitatively the orientation dependence of the lattice strains measured by a newly developed technique [4,5]. The analyses using these equations of the lattice-strain data under non-hydrostatic compression give the shear strength, single-crystal elastic moduli, and the equation of state corresponding to a hydrostatic compression [6-9]. While deriving these equations, the following assumptions regarding the experimental conditions are made. (1) The anvils are assumed to be perfectly rigid and parallel. (2) The incident beam and the line-of-sight of the energy dispersive detector are assumed to pass through the geometric center of the sample. (3) The sample is assumed to be an aggregate of randomly oriented crystallites. (4) The yield stress of the crystallites in a polycrystalline sample is assumed to be independent of the crystallite-orientation with respect to the load direction. In practice, departures from these assumptions are expected. The changes in the lattice-strain equations arising from these departures are considered in this presentation.

P08.CC.004 X-RAY IN SITU STUDIES OF SOME REFRACTORY OXIDES, CARBIDES, METALS AND ALLOYS AT HIGH P-T CONDITIONS. N.A.Dubrovinskaia, L.S.Dubrovinsky, S.K.Saxena Department of Earth Sciences, Uppsala University

Despite the importance of refractory ceramics, metals and alloys for industrial applications (for example, the Co-Ti-C, Co-W-C and Fe-Al-C systems), basic knowledge of the individual phases, phase relationships, and their thermodynamic properties is still incomplete. Thermal expansion and compressibility data are rather sparse.

Very reliable data can be obtained by in situ X-ray experiments. We obtain powder X-ray diffraction data with a Siemens X-ray system consisting of a Smart CCD Area Detector and a direct-drive rotating anode as X-ray generator. With the capillary optic (X-ray optical stage, model CS-SRA/P-HP) installed, a high- intensity focus of X-rays is produced at the sample position, and its width is controlled by the choice of field aperture.

For the compressibility study we use the DXR-GMW diamond anvil cell (DAC) (Diacell Products, UK). In this cell a high pressure is applied to a sample by forcing two diamond anvils together along a common axis by means of a metal membrane assembly driven by a gas pressure. To increase pressure, one needs not therefore to remove the cell from the stage during an experiment. It means that additional alignment procedures are not required, and accurate data can be obtained. Both diamond anvils are mounted on beryllium plates, which are transparent for X-rays. In thermal expansion studies we heat a sample internally.

Using our in-house facilities we obtained new X-ray in situ data on thermal expansion of refractory metals (Cr, Ta) and thermal expansion, phase relations and compressibility of alloys and compounds in Fe-Al-C, Co-Ti-C , and Co-W-C systems.

For example, we found a rapid increase of thermal expansion for chromium Cr at temperatures higher than 1200 K, which confirmed a theoretically calculated large increase of entropy due to a contribution from magnetic fluctuations (Smag). From a direct in situ measurement of volume dependence of pressure for Co6W6C, its isothermal bulk modulus (K300,0) was found to be higher than that of diamond (444(3) GPa). A phase transition from cubic to rhombohedral structure was observed for TiC at pressure higher than 20 GPa. First time the isothermal bulk modulus was found from direct measurements for both phases.

P08.CC.005 STRUCTURAL STUDIES OF OXYGEN AT HIGH PRESSURE BY THE SINGLE-CRYSTAL TECHNIQUE. G.Weck, Service de Physique de la matière condensée, CEA/DIF/DPTA, 91680, Bruyeres-le Chatel, France

We have performed energy dispersive X-ray diffraction experiments on a oxygen single-crystal in helium up to 115 GPa. From 22.5 GPa to 96 GPa the diffraction line (7 different classes) are well indexed in the A2/m monoclinic lattice proposed by Johnson et al for the ε-phase. Between 96 and 110 GPa, a displacive phase transition (discontinuous change in angle and energy of diffraction) is observed that keep the single crystal. At 110 GPa the resting line do no more fit with the monoclinic cell and a triclinic cell is proposed for the metallic phase. The d-spacing variation with pressure for two experiments is presented in the figure below. Particularly, the separation between the (02-2) and (022) d-values at 110 GPa confirm a triclinic deformation.

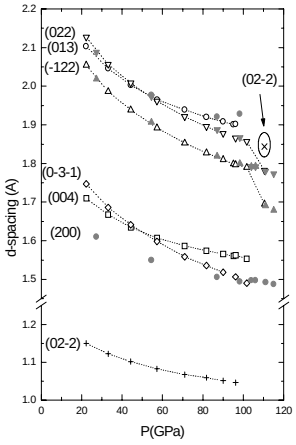

Fig 1: Pressure dependence of d-spacing. Symbols with dotted lines represents the first experimental data, the full symbols are for the second experiment.

P08.CC.006 COMPARATIVE CRYSTAL CHEMISTRY OF SOME SILICATES AT VERY HIGH PRESSURES. L. Zhang, Institute of Mineralogy, University of Marburg, 35032 Marburg, Germany

The fact that divalent iron (Fe) and magnesium (Mg) can form complete solid solutions in many silicates is attributed to their similar bonding properties. Indeed, bulk moduli (K) for Fe and Mg endmember were very close. Although bulk moduli of Fe endmember seem systematically larger than their Mg counterparts, it was impossible from experimental data available to decipher their high pressure behaviour. From KV = constant [1,2] a higher compressibility of Fe endmember at high pressures would be predicted.

Recent refinements on intensity and lattice parameter data from single crystal diffraction on silicate minerals ($Mg_3Al_2(SiO_4)_3$, $Fe_3Al_2(SiO_4)_3$, $Mn_3Al_2(SiO_4)_3$, $Ca_3Al_2(SiO_4)_3$, $Ca_3Fe_2(SiO_4)_3$, (Mg_2SiO_4, Fe_2SiO_4, Mn_2SiO_4, Co_2SiO_4, $CaMgSi_2O_6$, $CaFeSi_2O_6$) at pressures up to 33 GPa [3,4,5] provide new insights into the role of bonding properties of individual cation in the polyhedral compression. Precise measurements of the lattice parameters by multi-loading the crystals in one pressure cell allow direct determination of the differential compressibility $\Delta\beta = \beta_a - \beta_b$ between two crystals at high pressures. The results show that Mg endmembers are systematically more compressible than its Fe counterparts. This is manifested uniquely in the different compressibilities of Mg and Fe polyhedra that is clearly related with their different bonding properties, whereas the polyhedral coordination and crystal structure type appear to be of marginal significance.

The above results demonstrate that the assumption of similar chemical bonding of Fe and Mg for silicates is inappropriate. The new results helps to understand the compression mechanism and indicate that the bulk modulus of Fe endmember in a solid solution is higher than that of the Mg endmember.

In situ x-ray diffraction experiments were carried out to observe graphite to diamond transition under high pressures and high temperatures. Experiments were carried out under the P-T conditions up to 13GPa and 2100°C using a large volume press installed on BL04 beamline at the SPring-8. Three different materials, Ni, $K_2Mg(CO_3)_2$, and $MgCO_3$ were used as diamond formation catalysts and results were compared.

When Ni was used as a catalyst, diamond was always formed just at its melting temperature. On the other hand, using $K_2Mg(CO_3)_2$ as a catalyst, diamond did not appear at the temperature where catalyst started to melt. In order to synthesize diamond using this catalyst, higher temperature than its melting point was needed. Pressure dependence of two important temperatures, melting temperature of catalysts and diamond formation temperature, were obtained. For $MgCO_3$ experiment, this catalyst did not melt until 2100°C at 9.3GPa. However, at around 1800°C, which was far below the melting temperature, clear cubic diamond peaks appeared. This data indicates that graphite- diamond transition occurred without melting of the catalyst and that solid $MgCO_3$ can play a role of diamond formation catalysts.

P08.CC.008 SOME ASPECTS HOW TO PREPARE AND TO CARRY OUT A HIGH TEMPERATURE MEASUREMENT. M.Ermrich, X-ray Laboratory Dr. Ermrich, Westring 80, D-64354 Reinheim, Germany

High temperature X-ray diffraction investigations have got a significant place in every ‘up-to-date’ laboratory. The basic conditions to get diagrams with high resolution over the whole angle region in a short time are delivered by various types of high temperature attachments, which are adaptable to use the advantages of the different geometries of the goniometers, and the availability of linear and area detectors. But it is necessary to consider some aspects to prepare and to carry out a successful experiment.

Geometry: Powders, foils, compact materials and / or thin films require different geometries, e.g. capillary, transmission or reflection mode with all their advantages and disadvantages. The well-known difficulties of diffraction, preferred orientation, absorption effects, small amounts, penetration depth ... get especially critical.

Calibration: Finding out optimal calibration substances for the wanted temperature region (using their transition temperatures, melting points and / or thermal expansion coefficients), a well defined gas flow, an optimized temperature measurement, known temperature gradients - facts, which are indispensable for the experiment.

Heating element: It has to satisfy different requirements like no reaction with the sample or the inert gas, homogeneous heating ‘without’ temperature gradients, sample adapted sizes or movements, easy and stable adjustment.

These main points of view will be discussed together with both the present possibilities and experiences. Some examples will be given.

08DD NON-STRUCTURAL APPLICATIONS OF RIETVELD ANALYSIS

M08.DD.001 RIETVELD QUANTITATIVE PHASE ANALYSIS (RQPA). Julius Schneider, Institute of Crystallography and Applied Mineralogy, Universität München, Theresienstraβe 41, D-80333 München, Germany

Powder diffraction is one of the few techniques which is truly phase sensitive. It has proved to be an ideal tool for quantitative phase analysis (QPA) in such diverse fields as mineralogy, geology, solid state chemistry, materials science, pharmacy , archeology etc. Based on the pioneering work of Rietveld (1969) on precise quantitative analysis of whole powder patterns, Hill & Howard (1987) derived a simple relation between the weight fractions of individual components in multiphase mixtures and their corresponding scale factors in the Rietveld refinement. This offers a standardless method of QPA, as the role of the experimentally determined phase pure standards is taken over by the known atomic structure models of the phases. The ready availability of computer programs and of structure model data bases (ICSD, CDB) greatly eases the practical use of RQPA. It's great flexibility relies on the variability of structural as well as instrumental parameters allowing ready adaptation of the generated powder patterns to the number of phases, to changes in chemical composition, in unit cell dimensions,in profile shape or profile widths, to instrumental conditions etc. Generating "ideal" multiphase powder patterns, the detection and computational correction of systematic errors like preferred orientation, etc. is greatly facilitated. Modified methods allow inclusion of non-diffraction methods or on-line operations in plants. Examples include phase transitions at elevated temperatures.

Rietveld H. M. (1969), J. Appl. Cryst. 2, 65-71

M08.DD.002 APPLICATION OF NEW WEIGHT FUNCTION TO THE WHOLE-PATTERN L.S. FITTING FOR QUANTITATIVE PHASE ANALYSIS. S. Hayashi and H. Toraya, Ceramics Research Laboratory, Nagoya Institute of Technology, Tajimi 507-0071, Japan

In the quantitative phase analysis (QPA), whole-powder-pattern fitting (WPPF) techniques such as for Rietveld refinement or whole-powder-pattern decomposition (WPPD) have some advantages over single-line methods: 1) feasibility of analyzing complex powder pattern and 2) averaging effects for random and systematic errors and resultant improvement in accuracy and precision. The strong peaks, which can be largely shifted by preferred orientation and/or particle statistics, in the low angle region are, however, very influential on the accuracy in the QPA. Therefore, in our previous study [1], these strong peaks must be excluded from the least-squares refinement of scale factors by shortening the 2qs-range for WPPF. However, such a handling of the intensity data is sample-dependent and less general. Recently, the new weigh function with a form $w=1/Y^e$ (e>1) was introduced into the minimization function in Rietveld refinement [2]. It gives heavier weights on weak peaks and lessens the influence of strong peaks, and the uniform distribution of weighted errors thus obtained resulted in the improvement of the accuracy in structural parameters. The new weight function was expected to resolve the problem of strong peaks in the QPA using WPPF. In the present study, it was tested in the QPA using Rietveld refinement and the WPPD method. The accuracy in the QPA was significantly improved by the new weight function, even if the strong peaks were included in the least-squares refinement.

M08.DD.003 PROFILE MODELLING IN THE RIETVELD METHOD BASED ON THE LATTICE DEFECT STRUCTURE. P. Scardi, M. Leoni, Università di Trento, Facoltà di Ingegneria, Dipartimento di Ingegneria dei Materiali, via Mesiano, 77 - 38050 Trento, Italy.

Recent developments in the Rietveld method give a growing importance to the refinement of materials microstructure together with their structure. The reason is twofold: a proper modelling of microstructure-related features in the diffraction pattern usually results in a better fitting of the experimental data, which means a better quality of the refined structural data; on the other hand, a valuable information, typically of interest for materials science studies, can be obtained. So far, advancements were mostly addressed to the first point (better structure data), while the use of the Rietveld method for the study of microstructure is still an active research topic, and the potentialities of this approach are still to be revealed. This is particularly true for what concerns profile modelling, where conventional algorithms have a more or less phenomenological basis. The purpose of the present work is to show how a modelling of the line and plane defect structure can be introduced in the Rietveld method, and more generally within a whole pattern fitting procedure [1].

This new approach has considerable advantages over conventional methods of line profile analysis, as it permits a simultaneous modelling of lattice defects and scattering domain structure using the whole information (or a large portion) of the diffraction pattern. Different types of defect can be considered together, in terms of average domain size, dislocation density and cut-off radius, as well as stacking fault and twinning probabilities.

The model, which is based on the Fourier modelling of line profiles, was developed for fcc materials, but can be extended to other symmetries with suitable changes. A further point of interest to materials science is the relation that can be established between line profile parameters and elastic properties of the studied phases: when dislocations play an important role, the line broadening anisotropy can be directly related to the elastic anisotropy of the materials.

M08.DD.004 DETERMINATION OF MACROSCOPIC ELASTIC AND PLASTIC STRAIN BY RIETVELD ANALYSIS OF DIFFRACTION SPECTRA. M.R. Daymond, ISIS Facility, CLRC Rutherford Appleton Lab., OX11 0QX, UK, M.A.M. Bourke & R.B. Von Dreele, Los Alamos National Lab., NM 87545, USA, A.M. Korsunsky, Dept. of Mechanical Engineering, Uni. of Newcastle, NE1 7RU, UK.

The variation of macrostrain deep within engineering components is frequently determined using neutron diffraction. It is often desirable to minimise the sampling volume in order to maximise the spatial resolution, though this increases the required measurement time. At reactors, macrostrain behaviour is inferred from a single lattice reflection (deemed to be representative of the bulk response). At a pulsed source, a complete diffraction pattern is recorded and accordingly it is natural to fit the entire diffraction spectra using a Rietveld refinement, maximising use of the available information. This means that an idealised crystal structure is fit to the measured distorted crystal structure, which includes deviation of the measured lattice reflections from the ideal due to hkl dependent elasto-plastic strain anisotropy.

Elastic macrostrains calculated from lattice parameter changes in Rietveld refinements (without accounting for hkl dependent anisotropy) are comparable to the bulk elastic response

and also to the response obtained from a single lattice reflection typically used by practitioners at a steady state source.

By incorporating a description of the *elastic* strain anisotropy expected into the Rietveld code, an empirical but quantitative evaluation of *plastic* strain history is possible. Examples of this approach in cubic and hexagonal metals and in composite materials will be given.

M08.DD.005 EFFECT OF DATA QUALITY ON QUANTITATIVE PHASE ANALYSIS (QPA) USING THE RIETVELD METHOD. N.V.Y. Scarlett, I.C. Madsen and T. Lwin, CSIRO Minerals, Box 312, Clayton South, Victoria 3169, Australia

Quantitative phase analysis using the Rietveld method has become a valuable tool in modern X-ray diffraction. XRD is a recognised research tool and has been successfully employed in the developmental stages of many industrial processes but is now becoming increasingly important as a means of process control either in quality control laboratories or on-line in a plant.

In on-line applications, the optimisation of data collection regimes is of critical importance if rapid turn-around, and hence timely process control, is to be achieved. This paper examines the effect of data quality on the quantification of phases in well characterised suites of minerals.

A range of data collection regimes has been systematically investigated with a view to determining the minimum data required for acceptable quantitative phase analysis. Data has been collected with ranges in (i) step width from 0.01 to 0.3º 2θ, (ii) step counting times from 0.0125 to 4 sec/step and (iii) upper scan limits from 33 to 148º 2θ.

The data has been analysed using Rietveld based methods with two distinctly different analytical approaches (i) refinement of only pattern background and individual scale factors for each phase, and (ii) refinement of unit cell dimensions, overall thermal parameters, peak width and shape in addition to the background and scale factors.

Results to date indicate that, for structurally well-defined materials requiring minimal parameter refinement (i.e. the first set of analysis conditions), phase quantification via the Rietveld method is remarkably robust. In fact, the analysis for the major phases remains stable under all data collection conditions. Evidence of refinement instability is only apparent in the quantification of minor phases (approx 1wt%) with diminishing data quality.

P08.DD.001 QUANTITATIVE PHASE ANALYSIS USING THE REFERENCE INTENSITIES OR THE WHOLE XRD PATTERN. B. Grzeta, Rudjer Boskovic Institute, POB 1016, 10001 Zagreb, Croatia.

A new procedure for quantitative X-ray diffraction phase analysis based on the matrix-flushing principle [1] is proposed. The method involves preparation of (*i*) a mixture of examined multicomponent system and corundum at the one-to-one weight ratio, and (*ii*) a mixture of a pure component, the weight fraction of which is to be determined - say *X*, and corundum at the one-to-one weight ratio. There follow two approaches of X-ray diffraction analysis procedure. In the first one the intensities of the strongest diffraction line of the component *X* and of corundum are to be measured for both mixtures (*i*) and (*ii*). The weight fraction of the component *X* is related to the ratios of integrated intensities of the strongest lines of that component and corundum for the mixture (*i*) and mixture (*ii*). The second approach uses the whole XRD powder patterns of the mixtures (*i*) and (*ii*), and involves the whole-powder-pattern decomposition of these patterns. The weight fraction of the component *X* is then related to the ratios of the sum of all diffracted intensities for the component *X* and the sum of all diffracted intensities for corundum, in both mixtures (*i*) and (*ii*) respectively. Examples were worked out using the fitting programs *PROFIT* and *WPPF* [2]. For quick result the first analysis approach gives satisfactory accuracy, but for more accurate result the latter one is better.The author expresses gratitude to Professor H. Toraya for kindly providing his computer programs.

P08.DD.002 FINAL OUTCOMES OF THE IUCR CPD ROUND ROBIN ON QUANTITATIVE PHASE ANALYSIS. I.C. Madsen, CSIRO Minerals, Box 312, Clayton South, Victoria 3169, Australia

Since 1997 the IUCr Commission on Powder Diffraction has been sponsoring a round robin on quantitative phase analysis (QPA). The round robin focuses on the analysis of powder diffraction data specifically for the derivation of phase abundances.

The general goals of the round robin include (i) the documentation of methods & strategies used in QPA, (ii) assessment of levels of accuracy & precision achievable in QPA, (iii) identification of specific problems in QPA and the development of recommended analytical procedures and (iv) the creation of a set of standard samples for future reference.

The samples used the study consist of mixtures of major and minor components covering a wide range of analytical complexity. Initial samples are synthetic mixtures of crystallographically 'simple' materials and should present little problem to the analyst. Additional samples introduce problems such as preferred orientation, microabsorption and amorphous content to assess the degree to which these problems affect QPA. Several very complex materials have also been included in the sample suite including a natural granodiorite, synthetic bauxite and a mixture of pharmaceutical phases. These last three samples represent a significant analytical challenge as they exhibit preferred orientation, microabsorption and grain size effects in addition to severe peak overlap.

This presentation will include summaries of statistical analysis of participant returns for all samples in the study along with the identification of some of the problems encountered by participants.

08EE INTERFACIAL STRUCTURES

M08.EE.001 CHARACTERIZATION OF BIOMIMETIC BILAYER MEMBRANES USING NEUTRON REFLECTIVITY. S. Krueger and C.F. Majkrzak, NIST Center for Neutron Research, NIST, Gaithersburg, MD 20899, and C.W. Meuse and A.L. Plant, Biotechnology Division, NIST, Gaithersburg, MD 20899.

Neutron reflectivity is being used to characterize the structure of novel synthetic alkanethiol and phospholipid biomimetic systems, or hybrid bilayer membranes (HBMs), which are formed on gold-coated single crystal silicon substrates, and which are in contact with aqueous solution. The biomimetic characteristics of the HBMs make them not only an important tool for understanding and characterizing membrane protein structure and function but also commercially significant for a number of applications including biosensors, tissue engineering, and bioelectronics and biocatalysis. Parameters of interest in the neutron reflectivity experiments include thickness of the bilayer and its individual components, hydration of the head groups, and depth of penetration of peptides into the bilayer. Structural changes in the bilayer due to the presence of peptides are also being investigated.

Measurements have been made on HBMs consisting of a monolayer of octadecanethiol and a monolayer of d_{54}-DMPC, and on HBMs with a monolayer of thiahexaethyleneoxide octadecane, which contains a hydrophilic ethyleneoxide "spacer" moiety that replaces the octadecanethiol layer. Data were obtained at 28^{o}C, where the DMPC layer is in the fluid phase, both in the absence and in the presence of the membrane-active peptide, melittin, in the solution. Neutron scattering length density (SLD) profiles of the lipid structure perpendicular to the plane of the bilayer have been obtained from the reflectivity measurements. The reflectivity data and resultant SLD profiles will be discussed in terms of structural models for the HBMs and the location of melittin in the bilayer. A progress report on measurements of new HBM matrices designed to accommodate transmembrane proteins will also be presented.

M08.EE.002 STRUCTURAL CONFORMATION OF GLOBULAR PROTEINS ADSORBED AT DIFFERENT INTERFACES. [1] J.R. Lu, T.J. Su [2], R.K. Thomas [3], J. Penfold [1], Department of Chemistry, University of Surrey, Guildford GU2 5XH, UK, [2] Department of Physical & Theoretical Chemistry, South Parks Road, Oxford OX1 3QZ, UK, [3] ISIS Neutron Facilities, Rutherford Appleton Laboratory, Chilton, Didcot, OX11 0QX, UK

We have studied the adsorption of a number of model globular proteins at the air-solution and solid-solution interfaces using specular neutron reflection. The high depth resolution of neutron reflection together with the use of deuterium labelling to the solvent and to the solid surface makes the technique sensitive to the distribution of the in situ protein layers along the surface normal direction. The accurate determination of the protein layer distribution together with the known dimension of globular proteins allows us to infer the preferred conformation of the adsorbed protein molecules at different interfaces. We have investigated the effect of solution pH and ionic strength on the adsorpion of poteins at several different interfaces and found that for all the interfaces studied the level of adsorption is dominated by the extent of electrostatic repulsion within the adsorbed protein layers and is little affected by the interaction between the protein and the substrate surface. At a given surface the preferred structural conformation of globular proteins is also dictated by the lateral repulsion. The effect of surface hydrophobicity on the adsorption of globular proteins was also investigated and the surface hydrophobicity was varied by chemically grafting a monolayer of long chain alkane with different functional groups on the outer surface. It was found that the least adsorption occurs at the intermediate surface hydrophobicity. The nature of the surface properties on the extent of denaturation of the protein molecules will also be discussed.

M08.EE.003 POLYMER BRUSHES AT THE AIR-LIQUID INTERFACE STUDIED BY NEUTRON REFLECTION AND SURFACE TENSION MEASUREMENTS. M.S. Kent, Sandia National Laboratories, Albuquerque, NM., J. Majewski, G. S. Smith, Los Alamos National Laboratories, Los Alamos, NM., L. T. Lee, Lab. Leon Brillouin, CEN-Saclay, 91191 Gif-sur-Yvette Cedex, France, S. Satija, NIST Center For Neutron Research, National Institute of Standards and Technology, Gaithersburg, MD., F. Rondelez, Laboratoire P.S.I. Institut Curie-Section de Physique et Chimie, 11 rue Pierre et Marie Curie, 75005 Paris, France

Polymer brushes are layers of polymer chains in which only one end of each long chain molecule is anchored to the surface. Such tethered chain structures have been investigated for their potential to deliver unique properties to surfaces, because they occur in various microphases of block copolymers, and because they provide an interesting system to examine the balance of ethalpic and entropic contributions to free energy. In this work, Langmuir monolayers of PDMS-PS diblock copolymers on organic liquids are used as a model polymer brush system. The PDMS block adsorbs at the air surface while the PS block dangles into the subphase liquid. With this model system the air surface can be made either repulsive, neutral, or attractive for the tethered chain segments by choosing a subphase liquid which has a surface tension which is lower, equal to, or greater than that of PS, respectively. The segmental profile of the dangling PS block is determined by neutron reflection as a function of the molecular characteristics of the copolymers and the solution conditions. We emphasize quantitative comparisons with analytical profile forms and scaling predictions. Simultaneous with the study of the profile form, the free energy of the chains is examined through the surface tension.

M08.EE.004 NEUTRON REFLECTIVITY MEASUREMENTS OF POLYMER INTERDIFFUSION IN REAL TIME. D.G. Bucknall, ISIS Facility, RAL, Oxon, OX11 0QX and S.A. Butler and J.S. Higgins, Dept of Chem Eng, Imperial College, London, SW7 2BY

Neutron reflection (NR) studies of diffusion in thin solid polymer films has until recently only generally been applied to high molecular weight amorphous polymer systems. Measurements are usually taken at room temperature well below the Tg's of the polymers so that the interfacial structure is frozen in. However there is also much interest in small molecule diffusion into high molecular weight polymers. In this case the normal approach to NR measurements may not be applicable since small molecule diffusion may still occur at room temperature on time scales less than the typical NR measurement times of a few hours.

Using the SURF reflectometer at the ISIS Facility of the Rutherford Appleton Laboratory and specially designed reflectivity sample cells it is possible to study the interdiffusion between polymers and small molecules such as oligomers in real time. To demonstrate the technique the real-time diffusion between hydrogenated and deuterated polystyrene (PS) has been measured at 115C taking reflectivity profiles every 6 minutes in a limited window of reciprocal space. The interfacial width obtained from such data shows a change in time dependence as predicted from theory and a diffusion coefficient has been calculated. The interdiffusion between oligomers and high molecular polymers have also been studied using NR, again in real time with reflectivity profiles taken every 20-60 seconds. Even with the limited data sets the interfacial width and profile has been determined as a function of time. This has shown the interface to be highly asymmetric with an interface position which moves with time. These data have been compared to theoretical predictions for non-Fickian diffusion.

M08.EE.005 ON THE STRUCTURE OF THIN WETTING FILMS. A. Doerr, W. Press, M. Tolan, J.P. Schlomka, T. Seydel, W. Prange, Institut für Experimentelle und Angewandte Physik der Universität Kiel, D-24098 Kiel, Germany

Properties of thin wetting films have been studied by X-ray reflection techniques and grazing incidence diffraction. Films of several organic liquids had thicknesses ranging between 2 nm and 25 nm. Reflection measurements reveal, that the densities vary considerably near the substrate (Si/SiO2). The actual values depend on the packing properties [2] of the molecules: the density is enhanced for the more globular cyclohexane molecule and lowered for the more elongated perfluorohexane and hexane [2,3]. In the analysis, inversion techniques, which themselves are an interesting object of study [2,4], have been used. The profile at the interface liquid-gas, on the other hand, is determined by thermally

activated capillary waves [5,6]. A direct prove results from the diffuse scattering.

Also, first depth-profiled measurements of the liquid structure factor and thus of the local structure on an atomic scale are presented. A very direct access to the competition between surface tension (more generally: interaction within the liquid) and substrate-liquid interaction is provided by the scattering from wetting films on gratings with a shallow lateral structures.

08FF STRUCTURE-PROPERTY RELATION-SHIPS IN CHIRAL COMPOUNDS

M08.FF.001 ABSOLUTE STRUCTURE AND ABSOLUTE CONFIGURATION. H. D. Flack and G. Bernardinelli, Laboratoire de Cristallographie, University of Geneva, Switzerland

Fundamental notions concerning absolute structure and absolute configuration, and their determination from single-crystal diffraction measurements, are presented and reviewed. A compendium of terms with definitions useful in this field is provided. For absolute structure and its determination, the separate but interacting influences of the structure, the macroscopic reorientation ambiguities of the crystal (crystal polarity) and the inversion-distinguishing power of an X-ray diffraction experiment with dispersive scatterers are examined. Important experimental and algorithmic details of the current methods used for absolute-structure determination are provided. Characterisation of the crystals for absolute-structure determination and the molecules for absolute configuration determination are treated. Attention is given to the analysis of absolute structure and absolute configuration in twinned crystals. Formal proofs of the invariance properties of crystal polarity and of the analysis of absolute structure in twinned crystals are provided.

M08.FF.002 CHIRALITY RECOGNITION IN SOLID AND SOLUTION STATES. R. Kuroda, Department of Life Sciences, Graduate School of Arts and Sciences, The University of Tokyo, Komaba, Meguro, Tokyo 153–8902, Japan.

Three cases will be described where chiral – achiral molecular interactions are involved in chirality induction and/or recognition. First, a racemic solution of the chiral compound 7 bromo–1,4,8–triphenyl–2,3–benzo[3,3,0] octa2,4,7–trien–6–one (1) produces an inclusion compound with various achiral solvents. Depending on the type of solvent, the inclusion compound contains either one of the enantiomers or both of the host compound 1 [1]. For example, α-picoline, toluene and CBr_4 optically resolve the host compound to produce crystals of a 1:1 adduct with one of the enantiomers, whereas their respective analogues γ-picoline,benzene and $CHBr_4$ produce an adduct with racemic host. To understand the chiral discriminations, crystal structures of several racemates and conglomerates have been determined and compared. The racemic crystal of 1 on its own (without any guest) exhibits polymorphism. Interestingly, when one type of crystal is placed under picoline vapour, molecules in the crystal rearrange themselves to form microcrystals of another crystal structure[2]. Thus, crystals obtained from solution and those under vapour have different structures.

In the second case, for the first time 1,2–chloroethane was trapped and observed in a chiral near–eclipsed form [3] and 1–chloropropane in the truly eclipsed form [4] at room temperature in a 1:1 inclusion complex with an optically active host molecule. Finally, induced chirality in a prochiral compound in the solid–state was successfully employed in an enantio selective photoreaction[5], where solid–state CD provided valuable information [5,6].

M08.FF.003 INTERACTIONS IN OPTICALLY NONLINEAR CHIRAL CRYSTALS AS SEEN BY IR AND RAMAN SPECTROSCOPY. M.M. Szostak, Institute of Physical and Theoretical Chemistry, Wroclaw University of Technology, 50-370 Wroclaw, Poland.

Monoclinic sucrose crystals reveal second harmonic generation [1] which origin seems to be connected with pronounced anharmonicity of CH_2 and OH stretching vibrations, especially of those with transition moment directions perpendicular to optical axis a^*. The most anharmonic OH oscillator participate in the strongest hydrogen bonding which forms and infinite chain with spiral arrangement[2,3]. In optically nonlinear crystal of 4-isopropylphenol (4-IP) it is a hydrogen bonded helix which constitutes the unique channel for intermolecular charge transfer [4].

As the cooperativity in a certain type of bent H...O hydrogen bondings leads to a charge separation [5], it is possible that the Zerbi model of vibrational contribution to optical nonlinearity [6] applies also to the sucrose and 4-IP crystals.On the basis of IR and Raman relative intensities of bands a hypothesis is proposed that in chiral crystals a proton transfer between two positions in a bent hydrogen bond corresponds to the bond alteration in the two-state model of Zerbi.

M08.FF.004 INVESTIGATING THE STRUCTURAL GROUNDS OF CHIRAL RESOLUTION THROUGH CO-CRYSTALLISATION. Zs. Böcskei, K. Simon, Z. Kovári, T. Gérczei, P. Huszthy, A. Mravik, D. Kozma, E. Fogassy, Chinoin Pharmaceuticals Eötvös University and The Technical University of Budapest, Hungary

Diastereomeric salt formation is the most widely applied technique for chiral resolution. In the past few years several new methods were elaborated[1-5] at the Technical University of Budapest which generalise the basic principle of the classic method. Metal co-ordination mediated optical resolutions were successfully applied to separate racemic acids[2,4], esters[1] and alcohols[3] using different salts of the cheap resolving agent O,O'-dibenzoyl-tartaric acid (DBTA). The crystal structures of these

compounds assisted in the better understanding of the structural principles governing the resolution processes. In other instances the resolution of alcohols was achievable through molecular complex formation with DBTA without the metal mediator[5]. The crystal structures revealed a large number of isostructural molecular complexes with a constant framework of DBTA layers connected by the guest hydroxyls. The structures were used in the interpretation of the different degrees of resolution achieved by the method. In one case we also studied the most elegant, although perhaps the most expensive method for chiral resolution: the application of a tailor-made chiral crown host.

Finally, the structure of a solid solution type diastereomeric salt of an isoquinoline derivative will be presented to illustrate the limitations of the method of diastereomeric salt formation. We explain the failure of the resolution on the basis of the structure.

M08.FF.005 FROM ACHIRAL BUILDING BLOCKS TO CHIRAL ARCHITECTURES. Mike Zaworotko, Kumar S. Biradha and Konstantin V. Domasevitch, Department of Chemistry, The University of Winnipeg, 515 Portage Avenue, Winnipeg, Manitoba, R3B 2E9, Canada

That solid state architecture profoundly influences bulk physical properties and therefore function of solids has provided impetus for recent activity in the field of *crystal engineering*. The nature of crystal engineering means that chemists can design new crystal structures without the need to develop new molecular structures. This presentation will focus upon the development of new classes of chiral solid that are built from the simplest of achiral building blocks. We shall present two basic classes of compound which are chiral for very different reasons: (i) helical supramolecular structures which are built from either centrosymmetric or non-centrosymmetric building blocks and are sustained by either hydrogen bonds (cf. urea) or metal-ligand bonds[1]; (ii) chiral supramolecular adducts which induce chirality where it would otherwise not occur e.g. in centrosymmetric host frameworks (chiral adducts of benzene guest molecules are illustrated alongside). We shall discuss a number of metal-organic structures that represent (i) and (ii). Particular emphasis will be placed upon interpretation of the results in the broader context of crystal engineering.

P08.FF.001 LYSINE REPLACING HISTIDINE IN THE ACID-BASE CATALYSIS OF D-LACTATE DEHYDROGENASE. A. Razeto and V. L. Lamzin, EMBL c/o DESY Notkestrasse 85 D-22603 Hamburg, K. S. Wilson, Dept. of Chemistry, York University Heslington YO1 5DD UK, S. Kochhar, Nestle` Research Centre, Vers-chez-les-Blanc, P.O. Box 44, CH-100 Lausanne 26, Switzerland.

NAD-dependent D-Ldh and L-Ldh catalyse the same chemical reaction, differing only in the chirality of the product (or substrate), D- and L-lactate respectively. Even though the two enzymes belong to structurally different families, site-directed mutagenesis, kinetic and structural studies indicate that the same residues are involved in substrate binding and catalysis: His-296, Glu-264, Arg-235 (numbering according to the D-Ldh L. bulgaricus sequence) [1, 2]. His-296 has for a long time been considered as the acid-base group playing a key role in the catalysis. However recent studies have shown that mutation of this histidine to lysine does not result in a significant change in k_{cat} and K_m. This thus suggested that either the histidine is not indispensable in catalysis or its function in the mechanism can well be performed with lysine. In order to better understand the reasons underlying this phenomenon, crystallographic studies have been carried out. Diffraction data for the crystal of the H296K mutant of *L. bulgaricus* D-Ldh have been collected on X11 beamline (EMBL/DESY) to 1.9 Å resolution. Two D-Ldh dimers are present in the asymmetric unit. The structure has been solved by molecular replacement and is currently being refined. The electron density maps have already confirmed replacement of histidine by lysine in the enzyme active site. Full analysis will be presented after refinement of the structure is complete.

P08.FF.002 STRUCTURAL RATIONALE FOR THE SPONTANEOUS RESOLUTION OF DL-ALLO-ISOLEUCINE. Bjørn Dalhus and Carl Henrik Görbitz, Department of Chemistry, University of Oslo, PO Box 1033 Blindern, N-0315 Oslo, Norway.

The spontaneous resolution of the racemate DL-allo-isoleucine is rationalized on the basis of an analysis of interatomic distances in the crystal structures of DL-isoleucine and the DL-isoleucine:DL-allo-isoleucine 1:1 mixture.

There is a systematic distribution of the four stereoisomers in the DL-isoleucine:DL-allo-isoleucine crystal. A detailed analysis of interatomic distances between alternative positions for the disordered side-chain atoms unveil two different molecular chains in the crystal. Each such chain accommodates a single diastereomeric pair (L-isoleucine:D-allo-isolecine or D-isoleucine:L-allo-isoleucine) only. The crystal is built up by a stacking of such chains in two dimensions, and three different packing modes for the two types of chains are discussed.

P08.FF.003 RESOLUTION OF RACEMIC ALCOHOLS VIA DIASTEREOMERIC SALT FORMATION. Heidi A. Ernst, Sine Larsen, Centre for Crystallographic Studies, University of Copenhagen, Denmark.

Diastereomeric salt formation and subsequent fractional crystallisation is a classical method widely used for separation of racemic acids with optically active bases and vice versa. To make use of this method for resolution of racemic alcohols the alcohol must be converted into a derivative capable of salt formation. A common approach is reaction of the racemic alcohol with phthalic acid anhydride or succinic acid anhydride forming the racemic

mono esters. The efficiency of the following resolution depends strongly on the difference in solubility of the diastereomeric salts. Information about intermolecular interactions of importance for this chiral discrimination can be obtained by crystal structure analysis of diastereomeric salts.

We have prepared the phthalic acid mono esters of racemic 2-butanol, 2-pentanol and 2-hexanol. The subsequent resolution was carried out using the alkaloid brucine as resolving agent. At present the less soluble salts have been isolated in pure form. The crystal structures of brucinium-2-pentyl-phthalic-acid-mono-ester-ethyl-acetate-solvate and brucinium-2-hexyl-phthalic-acid-mono-ester-acetone-solvate and in addition those of the racemic 2-butyl-phthalic-acid-mono-ester and 2-pentyl-phthalic-acid-mono-ester have been determined. These structures are analysed in terms of packing mode and specific intermolecular interactions between the chiral molecules to elucidate the structural basis for chiral discrimination in the process of resolution via diastereomeric salt formation.

09OA ENDOCYTOSIS AND EXOCYTOSIS

M09.OA.001 ABSTRACT NOT AVAILABLE. W.I. Weis

M09.OA.002 X-RAY CRYSTAL STRUCTURE OF THE SNARE COMPLEX AND THE CRYSTAL STRUCTURE OF SYNAPTOTAGMIN C2AB. R. Bryan Sutton and Axel T. Brunger, Howard Hughes Medical Institute and Department of Molecular Biophysics and Biochemistry, Yale University, New Haven, CT 06518, phone: 203-432-5595, FAX: 203-432-6946.

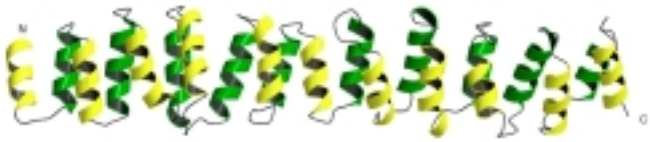
The fusion of neurotransmitter filled vesicle with their target membranes in neuronal cells is mediated by a class of membrane fusion proteins known as SNAREs. Assembly of the synaptic fusion SNARE complex leads to membrane fusion. We have solved the X-ray crystal structure of the core of the synaptic fusion complex composed of cytoplasmic fragments of the vesicle associated protein synaptobrevin II, and the target membrane associated proteins, syntaxin-1A and SNAP-25B. At the center of the SNARE complex is a highly conserved ionic layer. This layer may serve a crucial role in the assembly or disassembly of the synaptic fusion complex. The fusion activity of the synaptic fusion complex is regulated by transient Ca2+ concentrations on the pre-synaptic membrane. The receptor of these Ca2+ signals may be the synaptic vesicle associated protein, synaptotagmin. Synaptotagmin is a 50 kDa protein with a short intravesicular amino-terminus, a transmembrane domain, two tandem domains and a short carboxy terminal region. We have solved the crystal structure of the cytosolic portion of synaptotagmin III including the C2A, C2B-domains and the carboxy-terminal tail.

R.B. Sutton, D. Fasshauer, R. Jahn, and A.T. Brunger. Crystal structure of a SNARE complex involved in synaptic exocytosis at 2.4 Å resolution. *Nature* **395**, 347-353 (1998).

M09.OA.003 THE STRUCTURE OF CLATHRIN. E. ter Haar, T.L. Kirchhausen, Dept. of Cell Biology and Center for Blood Research, Harvard Medical School, Boston MA 02115, USA and S.C. Harrison, Howard Hughes Medical Institute and Children's Hospital Laboratory of Molecular Medicine, Boston MA 02115

Clathrin triskelions form the lattice that organizes recruitment of proteins to coated pits and helps drive vesiculation of the lipid bilayer. Clathrin is recruited to the plasma membrane by adapter molecules bound to cytoplasmic domains of trans-membrane receptors. Clathrin binds the adapter molecules with the N-terminal domain of the clathrin heavy chain. The N-terminal domain of clathrin is a seven blade β–propeller, well adapted to interact with multiple partners, such as AP-1, AP-2 sorting adapter complexes and the nonvisual arrestins. We have determined the 2.9Å structure of the clathrin terminal domain in complex with the clathrin-binding domain of arrestin-3. The arrestin-binding site is a groove between blade 1 and 2 and facilitates binding of arrestin via hydrophobic and β-sheet-like interactions.

M09.OA.004 THE CLATHRIN FILAMENTOUS LEG IS A REPEATING SUPERHELIX WITH HELIX FACES FOR MEDIATING SELF-ASSEMBLY. Peter K. Hwang, Joel A. Ybe, Frances M. Brodsky and Robert J. Fletterick, Department of Biochemistry & Biophysics, G. W. Hooper Foundation, Department of Microbiology & Immunology, University of California San Francisco, San Francisco, CA 94143 USA



Clathrin self-assembly is required for the formation of coated vesicles that mediate protein sorting during endocytosis and intracellular organelle biogenesis. The clathrin triskelion is a trimer of three heavy chain subunits, each folding into a filamentous leg and capable of binding a single light chain subunit. We have determined the crystal structure, to 2.6A resolution, of a leg segment vital in controlling assembly. The structure reveals an elongated right-handed superhelix coil of α-helices, generated from 29-residue structural units of paired antiparallel helices. Structural and sequence alignments indicate these units are organized into a longer 145-residue motif that repeats seven times to produce the entire filamentous portion of the triskelion leg. Sequence analysis predicts that the clathrin motif appears in other proteins, most of which are involved in vacuolar protein sorting. A resulting model of the triskelion leg proposes continuous, flat surfaces of packed helices as the basis for clathrin heavy chain self-assembly, light chain binding, and trimerization.

M09.OA.005 PROTEIN-PROTEIN RECOGNITION IN CLATHRIN-MEDIATED ENDOCYTOSIS. P. R. Evans, D. J. Owen and H.T.McMahon, MRC Laboratory of Molecular Biology, Hills Road, Cambridge, CB2 2QH, UK

Clathrin mediated endocytosis is the main mechanism by which proteins and lipids are internalised from the cell surface. Clathrin coated vesicles are formed when a patch of membrane containing the components to be internalised becomes invaginated due to the binding of a protein coat, made of clathrin and its adaptor (AP2) complex, on its cytoplasmic side. The vesicle is finally 'pinched' off the membrane through the action of dynamin (reviewed in [1]).

The role of AP2 is pivotal. It recognises short sequence motifs on the proteins which marks them for internalisation mainly via the μ2 subunit and provides a mechanical link to the clathrin scaffold of the coat. In addition it recruits a number of proteins with a variety of regulatory roles in coated vesicle genesis via the α subunit. We have determined the crystal structures of several domains of the AP2 heterotetramer, including the ear domain of α-adaptin and part of μ2-adaptin, as well as the SH3 domain of amphiphysin [2], and combined the structural information with *in vitro* and *in vivo* assays to understand the nature of many of these protein / protein interactions.

The 2.7Å resolution crystal structure of the internalisation signal binding domain of μ2-adaptin was solved complexed with peptides corresponding to the internalisation signals of a number of proteins [3]. The protein is an all β-sheet, banana-shaped

structure. The signal peptides adopt an extended conformation forming an extra strand on the edge of one of the sheets. Specificity is conferred by hydrophobic pockets which bind the tyrosine and the leucine in the peptide. In the crystal the protein forms dimers which could increase the strength and specificity of binding to dimeric receptors. The surface of μ2 possesses a very positive electrostatic potential indicating that it may interact with the negatively charged headgroups of the phospholipid membrane.

M09.OA.006 CRYSTAL STRUCTURE OF THE ECTO-DOMAIN OF HUMAN TRANSFERRIN RECEPTOR. C. Martin Lawrence, Stephen Harrison, Laboratory of Molecular Medicine Howard Hughes Medical Institute 320 Longwood Avenue Boston, MA 02115, USA

The transferrin receptor (TfR) undergoes multiple rounds of clathrin-mediated endocytosis and re-emergence at the cell surface, importing iron-loaded transferrin (Tf) and recycling apotransferrin after discharge of iron in the endosome. We have determined the structure of the dimeric ecto-domain of the human TfR at 3.2 Angstroms resolution. The first domain of the three domain monomer closely resembles carboxy- and aminopeptidases. The sequence of nearly the entire TfR ectodomain is similar to that of membrane glutamate carboxy-peptidase II (mGCP), a dipeptidase that cleaves the neurotransmitter NAAG, but TfR does not itself have protease activity. The other two domains appear to regulate ligand binding and mediate dimerization. We propose models for the interactions of TfR with Tf and with HFE, a protein thought to modulate affinity for Tf.

P09.OA.001 THE STRUCTURAL BASIS OF PROTEIN RECOGNITION BY S100 EF-HAND PROTEINS. A. Lewit-Bentley and S. Réty, LURE, BP34, 91898 Orsay, France, V. Gerke, Institute for Medical Biochemistry, ZMBE, University of Münster, von-Esmarch-Straße 56, 48149 Münster, Germany and F. Russo-Marie, INSERM U332, ICGM, 22 rue Méchain, 75015 Paris, France

S100 proteins are a family of small EF-hand calcium-binding proteins probably involved in cytoskeleton dynamics. Among their cellular targets described to date are several annexins, another family of calcium, but also phospholipid, binding proteins. Annexins may be involved in processes such as exo- and endocytosis, especially when complexed to S100 proteins. We have solved the structure of a complex between two members of the S100 protein family, p11 and S100C, and their cognate peptides, the N-termini of annexin II [1], and annexin I.

The basic unit for the S100 protein is a tight, non-covalent dimer. With two EF-hand motifs per monomer, the dimer is a four EF-hand entity like calmodulin. Unlike calmodulin, though, the S100 complexes bind two, rather than one, peptides per S100 dimer. While calmodulin folds to enclose its target peptide, in the S100 complexes the peptides are periferal. Each annexin peptide forms hydrophobic interactions with both S100 monomers, as well as a small number of specific hydrogen bonds. The two complex structures are extremely close, in spite of significant sequence differences.

While S100C binds Ca^{2+} ions in both its EF-hands, p11 has modified EF-hands that are incapable of metal binding. The close similarity of the two structures shows that p11 has adopted a fold that makes it ready to bind target molecules in the absence of any metal. Using our results we can now propose models for the entire annexin/S100 complexes.

The S100 proteins are, in both cases, cross-linked by S-S bridges, within the dimer for S100C and between two dimers for p11. We speculate that these proteins may be under subtle redox control in situations where they participate in the maintenance of cellular structures.

09OB NEW FRONTIERS IN MACROMOLECULAR CRYSTALLISATION (sponsored by NASA)

M09.OB.001 THE USE OF DYNAMIC LIGHT SCATTERING AS A PREDICTIVE TOOL FOR PROTEIN CRYSTALLIZATION: HOW GOOD IS IT?. T. Bergfors, Department of Cell and Molecular Biology, Biomedical Center, Box 596, > SE-751 24 Uppsala Sweden.

Dynamic light scattering (DLS), like size exclusion chromatography and native polyacrylamide gel electrophoresis (PAGE), are methods for determining the size homogeneity of macromolecules. Numerous studies report a correlation between the DLS profile of a protein and whether it can crystallize or not. In the study presented here, 35 proteins were characterized by both DLS and native PAGE to determine which of the two methods was most predictive of the subsequent crystallization behavior. 81% of the proteins crystallized had DLS profiles with a homogeneous size distribution. By contrast, only 61% of the proteins which stained as single bands on native PAGE produced crystals. The diffraction quality of the crystals was also compared to the DLS profiles of the proteins. Proteins which did not crystallize usually had polydisperse DLS profiles and multiple bands on PAGE. Interestingly some polydisperse proteins did produce highly diffracting crystals while some monodisperse proteins completely failed to crystallize. These exceptions and their implications for the usefulness of DLS as a predictive tool will be discussed. Finally, practical recommendations for performing the DLS experiments will be presented.

M09.OB.002 MICROGRAVITY PROTEIN CRYSTAL GROWTH. Lawrence J. DeLucas, Karen Moore, Marianna Long, Terry Bray, Mike Harrington, Johanna Lewis, William McDonald, William Crysel, Lance Weiss and Craig Smith, Center for Macromolecular Crystallography, University of Alabama at Birmingham

Since 1985, the Center for Macromolecular Crystallography (CMC) has performed microgravity protein crystal growth experiments on thirty-seven U.S. space shuttle missions. The candidate proteins flown on these missions were selected based on scientific evaluation by a protein selection committee consisting of researchers from academia, industry and NASA. Microgravity-grown crystals were analyzed by the associated principal investigators and compared to crystals obtained from ground-control experiments, as well as the best data available from any protein batch or crystallization method. In addition to supporting microgravity crystallization, NASA has also supported a wide range of laboratory studies to elucidate the fundamental mechanisms/variables that affect the crystallization process, in an effort to develop enhanced 1g and microgravity crystallization methods. Results from our microgravity program clearly indicate that crystals of enhanced quality and, in some cases, superior size can be obtained from the microgravity environment. The development of sophisticated "dynamically-controlled" laboratory crystallization systems have allowed us to control the approach to nucleation and post-nucleation growth phase, thereby optimizing 1g and microgravity crystallization

conditions. More recently, the CMC, in conjunction with industry partners, has developed a robotically-controlled X-ray Crystallization Facility for the International Space Station.

M09.OB.003 OPTIMIZING CRYSTALLIZATION CONDITIONS USING THE ANALYTICAL ULTRACENTRIFUGE. J. Behlke and O. Ristau,Department of Protein-Interactions, Max Delbrück Center for Molecular Medicine, D-13092 Berlin, Germany.

Although methods for protein crystallization have been studied intensively in the past the crystallization of biological material remains a limiting step in the determination of the three-dimensional structure using X-ray diffraction. Protein crystallization can be considered as a complex molecular assembly process. A basic problem is finding optimal solution conditions that induce protein-protein interactions that are suitable for crystallization. Usually optimal solution conditions are derived from screening methods considering various parameters. To reduce this number we have developed a method of analytical ultracentrifugation that allow to determine the second virial coefficient (B_2) of a protein solution that is sensitive to protein-protein and protein-solvent interactions. The contributions to this parameter are complex in interpretation for aggregates but more simple for monomers. Our method allows to accurately determine B_2 (error < 5 %)[1]. This enables us to differentiate between the excluded volume and Donnan effect. The high contribution of electrostatic repulsion to B_2 induced by the net charge of the protein can be reduced by addition of neutral salts. The remaining part should be comparable to the excluded volume part of B_2 to induce the aggregation or nucleation events which lead to the formation of crystals and can be demonstrated too.

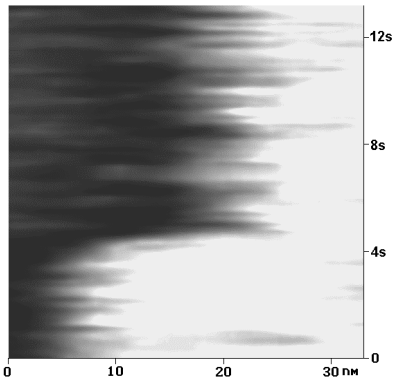
1. J. Behlke & O. Ristau (1999). J. Biophys. Chem. 76, 13-23.

M09.OB.004 PROTEIN CRYSTAL GROWTH USING ORDERED SELF ASSEMBLED MONOLAYERS. Christine M. Arnold, Ramon Villazana, Michael Graupe, T. Randall Lee and Jonathan M. Friedman, Department of Chemistry, University of Houston - CHEM 5641, 4800 Calhoun, Houston, TX 77004, USA

Four types of chemically unique, transparent self-assembled monolayers (SAMs) were prepared on glass coverslips typically used for protein crystallization. The SAM-functionalized surfaces appeared to exhibit a much higher degree of order and chemical uniformity than silanized glass, as judged by contact angle measurements with hexadecane. These characteristics led to a reproducible increase in the range of solution conditions under which large crystals of proteins were observed to form. The results are rationalized in terms of a marked reduction in the rate of non-productive nucleation relative to the rate of crystal growth.

M09.OB.005 DETERMINING THE MOLECULAR GROWTH MECHANISMS OF PROTEIN CRYSTAL FACES BY ATOMIC FORCE MICROSCOPY. Arunan Nadarajah,[1] Huayu Li,[1] and Marc L. Pusey,[2] [1]Department of Chemical and Environmental Engineering, University of Toledo, Toledo, OH 43606 and [2]Biophysics Branch ES76, NASA/Marshall Space Flight Center, Huntsville, AL 35812.

A high resolution atomic force microscopy (AFM) study had shown that the molecular packing on the tetragonal lysozyme (110) face corresponded to only one of two possible packing arrangements, suggesting that growth layers on this face were of bimolecular height. Analysis of the packing also indicated that growth of this face should proceed by the addition of growth units of at least tetramer size corresponding to the 4_3 helices in the crystal. In this study an AFM linescan technique was devised to measure the dimensions of individual growth units on protein crystal faces as they were being incorporated into the lattice. Images of individual growth events on the (110) face of tetragonal lysozyme crystals were observed, shown by jump discontinuities in the growth step in the linescan images as shown in the figure. The growth unit dimension in the scanned direction was obtained from these images. A large number of scans in two directions on the (110) face were performed and the distribution of lysozyme growth unit sizes were obtained. A variety of unit sizes corresponding to 4_3 helices, were shown to participate in the growth process, with the 4_3 tetramer being the minimum observed size. This technique represents a new application for AFM, allowing time resolved studies of molecular process to be carried out.



M09.OB.006 POST-CRYSTALLIZATION SOAKING IMPROVES THE DIFFRACTION QUALITY OF MTCP-1 CRYSTAL. Zheng-Qing Fu [1][2], Garrett C. Du Bois [1], Sherry P. Song [1], Robert W.Harrison [1], and Irene T. Weber [1]. [1] Kimmel Cancer Center, Thomas Jefferson University, Philadelphia, PA19107, USA. [2] Bruker AXS, Inc., Madison, WI 53719, USA.

Significant improvement of X-ray diffraction quality of MTCP-1 protein crystals was observed on post-crystallization soaking. The MTCP-1 crystals, grown from 1.5M ammonium sulfate in Tris buffer pH7.8, diffracted to 3.0 angstrom with streaky spots and diffuse scattering, which suggested defects in the crystals. Some crystals showed possible twinning. After soaking in an artificial solution with 2.0M ammonium sulfate, the crystals had much stronger diffraction up to 1.9 angstrom, and all spots were clearly formed without streaking. Selenomethionine-enriched MTCP-1 crystals demonstrated similar effects after soaking. Data sets from the soaked crystals have been used to solve the structure by MAD phasing. This very simple technique has not yet been reported for crystallization of other proteins. So, it is not clear whether this phenomenon is generally useful, nor what happens during the soaking. In general, the diffraction quality and resolution of crystals are determined by the molecular packing or correlation between the molecules, as well as the molecular building blocks. For protein crystals, the loose packing (due to the flexible surface residues) and the large volume of disordered solvent generally results in weak diffraction with high diffuse scattering. Mutation of residues on the protein surface can produce a different lattice type and altered packing. Also, dehydration of some protein crystals can improve the diffraction (private communication with B.C. Wang, W. Furey, A. McPherson). The crystal lattice usually shrinks on dehydration. However, no significant lattice shrinking was observed on MTCP-1 crystals after soaking, and, most importantly, the streaking and diffuse scattering due to disorder was eliminated or significantly reduced after soaking. The lattice shrinking alone is unlikely to give a satisfying explanation. So, we propose another mechanism. The remarkable difference of the diffraction quality may arise from rearrangement of the surface residues during soaking, similar to the annealing of small molecular crystals. During

crystallization, some surface residues may not pack optimally, or may form inappropriate interactions. In other words, the system may be trapped in a local energy minimum. Soaking in a different solution introduces certain disturb to the system. When the disturb is strong enough to overcome the potential barrier, the surface residues and thus the contacts among them may be rearranged in favor of the energy, which corrects the packing error and leads to the improvement of diffraction.

M09.OB.007 NASA'S BIOLOGICAL CRYSTAL GROWTH PROGRAM ON THE INTERNATIONAL SPACE STATION. C.E. Kundrot NASA/MSFC, Mail Code ES76, MSFC, AL 35812, USA.

NASA's Biological Crystal Growth Program (BCG) on the International Space Station (ISS) will consist of two phases. The first phase is during assembly of the ISS and will accomodate payloads that currently fly in the orbiter middeck. The second phase begins after assembly of the ISS is complete and BCG payloads will occupy part of the Biotechnology Facility aboard the ISS. During both phases of the program, there will be two types of BCG payloads. One will emphasize the production of crystals for structure determination back on Earth. These types of payloads will allow hundreds of crystallization conditions to be tested. The second type of payload will be designed to study the crystallization process with the primary aim of developing new methods to further optimize the use of the microgravity environment. Access to these facilities is through the NASA BCG Guest Investigators program. Details of the crystallization hardware, the Guest Investigator program, and the operational aspects of the program will be described.

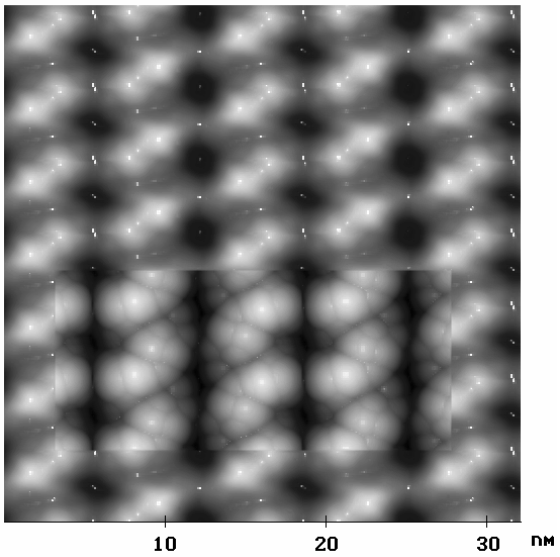
P09.OB.001 RESOLUTION IMPROVEMENT TO 0.9 Å IN CRYSTALS OF HUMAN ALDOSE REDUCTASE. E. Howard, V. Lamour, A. Mitschler, P. Barth, D. Moras and A. Podjarny. UPR 9004 de Biologie Structurale, IGBMC, 67404 Illkirch, France

As the action of human aldose reductase (hAR) is thought to be linked to the pathogenesis of diabetic complications, analysis of the catalytic mechanism and development of specific inhibitors has attracted many efforts. We report here the overexpression in E. coli of the recombinant hAR using a T7 based expression system and its purification using metal affinity column. The peptidic sequence of recombinant hAR has been completly verified and its catalytic constants determined (Km = 6mM and kcat = 0.5 sec-1). In addition, the native and SeMet hAR were crystallized with the cofactor NADP+ at 4°C in presence of the precipitating agent PEG 6000 using the vapor diffusion method. The crystals diffract to high resolution (1.1 Å) and belong to the P21 space group with unit cell parameters a= 49.97 Å b= 67.14 Å c= 48.02 Å b= 92.2° with one molecule per asymmetric unit. These crystals were further improved by changing the crystallisation temperature to 24° and applying micro-seeding techniques. The last tests at the LURE synchrotron source indicated a resolution limit of 0.9 Å. The analysis of these crystals should allow the analysis of the protonation state of the residues involved in catalysis.

P09.OB.002 QUANTITATIVE MODELING OF MOLECULAR FEATURES OBSERVED ON THE (110) FACE OF TETRAGONAL LYSOZYME. Mary Ann Perozzo[1], Huayu Li[2], John Konnert[1], Arunan Nadaradjah[2] and Marc L. Pusey[3]. [1]Laboratory for the Structure of Matter, Naval Research Laboratory, Washington, DC 20375, USA, [2]Department of Chemical and Environmental Engineering, University of Toledo, Toledo, OH 43606, USA, [3]Biophysics Branch ES76, NASA/Marshall Space Flight Center, Huntsville, Alabama 35812, USA.

The molecular features observed on the (110) face of lysozyme with the atomic force microscope (AFM) have been simulated with a model, the parameters of which are atomic coordinates, van der Waals radii and assumed tip shape. The model parameters are adjusted to maximize the correlation coefficient between the experimental and simulated images.

The figure displays the model image inserted into the experimental image. The correlation coefficient between the two images is 0.91. To obtain this degree of correlation, the molecules were displaced over 6 Å from their positions within the bulk of the crystal. Molecular dynamics and energy minimization have been carried out with XPLOR to check the plausibility of the model surface. That the intermolecular interactions at the surface are different from those within the crystal may have implications concerning the growth mechanism(s) of the crystals.



This research was supported by the U. S. National Aeronautics and Space Administration and the Office of Naval Research.

P09.OB.003 CRYSTAL QUALITY ANALYSES BY X-RAY DIFFRACTION OF PROTEINS GROWN BY NEW AND CLASSICAL TECHNIQUES. M. Soriano-García [1], V. M. Bolaños-García [2], J. Mas-Oliva and A. Moreno [3]. [1] Dept. Bioestructura. Instituto de Química, UNAM. Mexico, D.F. 04510. MEXICO. [2] Dept. Bioquímica. Instituto de Fisiología Celular, UNAM.Mexico, D.F. 04510 MEXICO, [3] Dept. Bioquímica. Instituto de Química, UNAM. México, D.F. 04510 MEXICO.

Protein crystallization has been the crucial step in the three-dimensional structural analysis for X-ray crystallography. There are several approaches to overcome this task, nowadays the most popular is crystal screening I and II from Hampton Research Co. These useful kits have well established statistical conditions in order to search for the best crystallization conditions, but do not explain what is really happening or what the important crystal growth parameters are from the qualitative point of view to be considered all over crystal growth phenomena. In addition, there is a lack of knowledge about the kinetic crystallization parameters

that are important in protein nucleation control in order to have high quality crystals for 3D X-ray characterization. Thus, using the implementation of the gel acupuncture technique, which permits the crystallization in capillary tubes, our goal in this work will be focused on monitoring the quality of crystals from model proteins such as thaumatin, lysozyme, concanavalin *A* by X-ray analyses. This crystal quality could be controlled by the porous network of the silica gel, which is used as a membrane in the aforementioned implementation of the gel acupuncture technique based on either the nucleation or transport phenomena investigations. The quality of crystals grown by classical techniques are compared with crystals grown in capillary tubes. Additionally, the annealing techniques for increasing the quality of protein crystals is explained from the basis of the supersaturation control.

Grant from DGAPA-UNAM project IN 218597.

P09.OB.004 FLUORESCENCE STUDIES OF PROTEIN CRYSTAL NUCLEATION. Marc L. Pusey Biophysics ES76, NASA/MSFC, Huntsville, AL 35812

Fluorescence can be used to study protein crystal nucleation through methods such as anisotropy, quenching, and resonance energy transfer (FRET), to follow pH and ionic strength changes, and follow events occurring at the growth interface. We have postulated, based upon a range of experimental evidence that the growth unit of tetragonal hen egg white lysozyme is an octamer. Several fluorescent derivatives of chicken egg white lysozyme have been prepared. The fluorescent probes lucifer yellow (LY), cascade blue, and 5-((2-aminoethyl)aminonapthalene-1-sulfonic acid (EDANS), have been covalently attached to ASP 101. All crystallize in the characteristic tetragonal form, indicating that the bound probes are likely laying within the active site cleft. Crystals of the LY and EDANS derivatives have been found to diffract to at least 1.7 Å. A second group of derivatives is to the N-terminal amine group, and these do not crystallize as this site is part of the contact region between the adjacent 43 helix chains. However derivatives at these sites would not interfere with formation of the 43 helices in solution. Preliminary FRET studies have been carried out using N-terminal bound pyrene acetic acid (Ex 340 nm, Em 376 nm) lysozyme as a donor and LY (Ex ~425 nm, Em 525 nm) labeled lysozyme as an acceptor. FRET data have been obtained at pH 4.6, 0.1M NaAc buffer, at 5 and 7 % NaCl, 4°C. The corresponding Csat values are 0.471 and 0.362 mg/ml (~3.3 and ~2.5 x 10-5 M respectively). The data at both salt concentrations show a consistent trend of decreasing fluorescence intensity of the donor species (PAA) with increasing total protein concentration. This decrease is more pronounced at 7% NaCl, consistent with the expected increased intermolecular interactions at higher salt concentrations reflected in the lower solubility. The calculated average distance between any two protein molecules at 5x10-6 M is ~70nm, well beyond the range where any FRET can be expected. Results from these and ongoing studies will be presented.

P09.OB.005 IDENTIFICATION OF ANIONS AND CATIONS IN PROTEINS USING A SCANNING PROTON MICROPROBE (SPM) Elspeth Garman, Laboratory of Molecular Biophysics, Department of Biochemistry, University of Oxford, Oxford, OX1 3QU, U.K.

The identification of anions and cations in protein structure electron density is often inferred from the temperature factor of the ion and from its coordination distances to surrounding amino acids. In many cases unambiguous identification is not possible without the use of additional techniques.

The application of a scanning proton microprobe to the identification of anions and cations in protein samples is described. Using this technique, all elements heavier than neon (atomic number 10) can be detected at a sensitivity of 1 part in a million of the dry weight. The incident proton beam induces X-ray emission from the atoms in the sample, and the X-ray spectrum is detected in a lithium drifted silicon detector which has good energy resolution. Each element has a unique X-ray emission spectrum and the different elements can thus be identified. If the protein sequence is known, quantitative information on the number of cations and/or anions per protein molecule can be obtained by using the sulphur concentration from methionines and cysteines as an internal calibration.

Results from more than ten different proteins have been obtained using the Oxford SPM (1), which can routinely produce a 1 micron by 1 micron beam size. The technique allowed unambiguous identification of various elements in all the protein samples, and quantitative measurements have been made in five cases. The method of sample preparation and the advantages and limitations of the technique will be presented. The technique has been used both on protein solutions as a diagnostic tool following protein purification and also on protein crystals for identification of putative ions in solved structures. Although the method has not previously been fully described, results of measurements have already been reported in the literature on a range of proteins including HIV1 reverse transcriptase with an oligonucleotide bound (2), an EGF-like domain of Factor IX (3), a viral neuraminidase (4), and protein phosphatase 1 (5).

The technique should prove a useful addition to the analytical tools available to the structural biologist.

Carotenoproteins provide the varied colouration of many invertebrate species. Examples include the multimacromolecular complex crustacyanin of the lobster carapace and also the astaxanthin proteins V620 and V600 of the surface-living oceanic chondrophore Velella velella. The function of these proteins is probably cryptic colouration, and whereby the oligomerisation to the multimacromolecular complex affects the wavelength response of the carotenoid. Crystallisation of various proteins in this related family has now been successfully achieved [1-6]. Isomorphous heavy atom derivatives have been difficult to obtain and xenon binding studies indicate only weak binding upto 25 bar pressure for apo C1 [7]. MAD experiments on a (non-isomorphous) heavy atom derivative and of a seleno- methionine variant of the lobster

apo C1 crustacyanin subunit are planned as well as xenon pressure experiments on apo A1.

P09.OB.007 THE EFFECT OF IMPURITIES ON PROTEIN CRYSTAL GROWTH: CASE STUDIES ON EARTH AND IN MICROGRAVITY. R.A. Judge, AMMSA, NASA/MSFC, Huntsville, AL 35812, USA, M.G. Sportiello, Chemical Engineering Department, ECCH 111, University of Colorado-Boulder, Boulder, CO 80309, USA, and E. H. Snell, Biophysics ES 76, NASA/MSFC, Huntsville, AL 35812, USA.

The presence of protein impurities is reported to be one of the major impediments in obtaining crystals of appropriate size and quality for x-ray structure analysis. In ground based research, studies on the impact of impurities on two crystallization systems, ovalbumin[1] and lysozyme[2], revealed that impurities consisting of proteins structurally different from the target protein are unlikely to have a negative impact upon crystal growth rates or solubility and are not incorporated in to the crystals. Impurities that adversely effect crystallization, appear to be impurities that have a structural similarity to the target protein and that are incorporated into the crystal. In light of this, one theory offered for the reported improvements in crystal size and crystal quality in microgravity, is that in the microgravity environment, impurity incorporation into the growing crystal may be reduced [3]. Results from recent crystallization experiments on STS-95, will be presented to show the effect of microgravity, in comparison to ground based studies, for the incorporation of impurities for two crystallization systems, lysozyme and glucose isomerase. The effect of microgravity on the reduction of incorporated impurities, and the resulting effects on crystal size and crystal quality will be discussed. Crystal quality measurements were performed for these two systems at the Stanford Synchrotron source.

P09.OB.009 DYNAMICALLY CONTROLLED PROTEIN CRYSTAL GROWTH: NEW HARDWARE AND RECENT RESULTS. T.L. Bray, D.L. Powell, R.J. Gray, A. Arabshahi, and L.J. DeLucas, University of AL at Birmingham, Center for Macromolecular Crystallography, 1716 University Blvd., Birmingham, AL 35294, USA, and W.W. Wilson, Dept. of Chemistry, Mississippi State University, Starkville, MS 39762, USA.

Our laboratory has been working for several years to develop systems capable of controlling the concentration and/or supersaturation of protein solutions as a means of gaining control of the kinetics of protein aggregation, nucleation, and crystal growth. Efforts have focused on two methods, vapor diffusion and temperature, to achieve these goals. In addition, humidity, temperature, and static light scattering sensors are used to monitor the protein solutions and to allow real-time modification of the experiments in response to solution events. This approach allows virtually any desired evaporation or temperature profile to be investigated and for optimization of crystallization results.

The vapor diffusion systems utilize a controlled flow of dry gas to vary the evaporation rate of solvent from the growth solution, affecting the kinetics of protein aggregation, nucleation, and crystal growth. We have developed new, modular hardware components that have allowed us to create large capacity systems and to collect data on many different proteins. The results continue to demonstrate that control of the evaporation rate directly affects the crystal populations and sizes in a systematic fashion, with slower evaporation profiles generally producing smaller populations of larger crystals than faster evaporation profiles.

The temperature systems utilize the variable solubility versus temperature dependence exhibited by some proteins as the means to control the supersaturation of the protein solution. Execution of temperature ramps has been used to produce systematic variation in crystallization results. Temperature control is achieved using thermoelectric devices, which allow the temperature of a given protein solution (and hence the superasaturation) to be varied as precisely and rapidly as the user desires.

P09.OB.010 THE ROLE OF Mg++ IONS IN THE CRYSTALLIZATION OF AN OLIGONUCLEOTIDE. Stephen P. Cape, Moha Shah, and Paul Todd, Department of Chemical Engineering, University of Colorado, Boulder, Colorado, 80309.

Nearly all solutions made for the study of DNA, RNA, nucleoside phosphates, and oligonucleotides contain divalent magnesium ions. It is thought that in vivo and in vitro a stable cation-anion complex is formed, and that this complex is the physiological and chemical reacting unit in aqueous solutions. Additionally, Mg++ is one of the solutes that is manipulated in the crystallization of oligonucleotides, and most published mother liquors specify a Mg++ concentration. While investigating the possibility of replacing methypentane diol (MPD) with poly(ethylene glycol) (PEG) we found that a critical equilibrium exists that depends on Mg++ concentration. The solubility, crystallization and aggregation of a specific RNA dodecamer ("UU-dodecamer") were investigated. This oligomer exists as a duplex with Watson-Crick hydrogen bonds except in the case of 2 U's complementing 2 U's. Using MPD and PEG as precipitants, and manipulating ionic strength with monovalent ions, molecular interaction studies were performed as a systematic function of Mg++ concentration. These consisted of crystallization, determination of osmotic second virial coefficient by static light scattering, solubility equilibria, and aggregate growth measured by dynamic light scattering. The manipulation of Mg++ concentration is at least as important as controlling the concentration of the traditional precipitants MPD and PEG, leading to the notion that, at suitable concentrations Mg++ serves as "precipitant", and its control plays a significant role in the growth of high-quality crystals for diffraction study.

P09.OB.011 THE EFFECT OF pH ON THE GROWTH RATES OF TETRAGONAL LYSOZYME CRYSTALS. Elizabeth L. Forsythe,[1] Arunan Nadarajah,[2] and Marc L. Pusey,[3] [1]Universities Space Research Association, 4950 Corporate Drive, Suite 100, Huntsville, AL 35805, [2]Dept. of Chemical and Environmental Engineering, University of Toledo, Toledo, OH 436006, and [3]Biophysics SD48, NASA/MSFC, Huntsville, AL 35812.

Although the growth rates of protein crystals continues to be well studied, most investigations have focused on the effect of protein concentration and temperature, as measured by the supersaturation, on the growth rates. In this study a comprehensive investigation of the effect of pH on tetragonal lysozyme crystal growth rates was undertaken. The measurements were made with an automated growth rate apparatus capable of simultaneously measuring the growth rates of several crystals in a single run. Growth rates of the (110) face of tetragonal lysozyme crystals were measured dro pH values ranging from 4.0 to 5.4 at different salt and protein concentrations and temperatures. Lowering the ph increases the net positive charge of the protein, which might be expected to decrease the growth rates due to enhanced electrostatic repulsion. However, the growth rates were found to increase sharply with decreasing pH. These effects prevailed at all temperatures and protein and salt concentrations. The strong dependence on pH suggests the importance of electrostatic interactions to protein crystal growth, but its inverse relationship also suggests that this effect is a complex one.

09OC PHYSICAL PROPERTIES AND NOVEL MATERIALS UNDER HIGH PRESSURE

M09.OC.001 SUPERCONDUCTIVITY AND MAGNETISM IN THE SPIN LADDER COMPOUND (Sr, Ca)$_{14}$Cu$_{24}$O$_{41}$. Jun Akimitsu, Aoyama-Gakuin University, Setagaya, Tokyo, 157-8572, JAPAN

In recent years, much attention has been focused for the spin ladder compound, which is composed of two legs and CuO_2 chains. The ground state of a spin ladder compound is given by spin singlet in so-called "rungs" which interact with each other along the chains. Most interesting point of this system is an expectation of the superconductivity in the doped spin ladder system. Two years ago, we found the superconductivity in the doped spin ladder compound $Sr_{0.4}Ca_{11.6}Cu_{24}O_{41}$ under high pressure. We report in the conference the present experimental situation of the superconducting and magnetic properties of the $(Sr,Ca)_{14}Cu_{24}O_{41}$ single crystal. In particular, special attention has been focused on the superconducting properties under pressure. The superconducting transition under high pressure is accompanied by the metallic resistivity across the ladders.This strongly suggests that pressure brings about the dimensional crossover from one-to two-dimension and the superconductivity in this system is a consequence of insulator to superconductor transition in the anisotropic two-dimensional system. We also observed the coexistence between antiferromagnetism and spin gap state at ambient pressure which will be also discussed in the conference.

M09.OC.002 HIGH PRESSURE MÖSSBAUER STUDIES ON HEAVY FERMION SYSTEMS. M.M. Abd-Elmeguid II. Physikalisches Institut, University of Cologne, 50937 Cologne, Germany.

The purpose of this talk is to demonstrate how recent experimental results obtained from 170Yb high pressure Mössbauer studies on selected Yb heavy fermion systems provide valuable information on the nature of the ground state of this class of materials.

M09.OC.003 SEARCH FOR SUPERCONDUCTIVITY AT Mbar REGION. K.Amaya and K.Shimizu, Graduate School of Engineering Science, Osaka University,1-3 Machikaneyama, Toyonaka, Osaka, Japan.

Search for superconductivity at Mbar region performed by the use of DAC and dilution refrigerator is shortly reviewed.

Observed materials are simple systems such as I,Br,S and O (1) as well as organic iodanil and ionic CsI (2). Electric and magnetic measurements employed are also discussed.

M09.OC.004 HIGH-PRESSURE NEUTRON-DIFFRACTION STUDY OF NEW MAGNETIC PHASES IN MIXED-VALENCE *f*-ELECTRON COMPOUNDS. J.-M. Mignot, LLB, CEA-CNRS, CEA/Saclay, 91191 Gif sur Yvette, France, I.N. Goncharenko, RRC "Kurchatov Institute", Moscow 123182, Russia, P. Link, LLB, CEA-CNRS, CEA/Saclay, 91191 Gif sur Yvette, France T. Matsumura and T. Suzuki, Department of Physics, Tohoku University, Sendai, 980-77, Japan.

Advanced high-pressure neutron-diffraction techniques based on sapphire- and diamond-anvil cells now provide access to the 0-10 GPa range for measurements on single-crystals at liquid-helium temperature. This offers a unique opportunity to gain an insight into the physical properties of materials in which the magnetism depends sensitively on interatomic distances. In mixed-valence rare-earth compounds, such a situation occurs because two different 4*f*-electron configurations with markedly different ionic radii are nearly degenerate in energy. Furthermore, fluctuations between these two valence states deeply affect the magnetic properties of the material at low temperatures.

We present novel results obtained on the thulium monochalcogenide series Tm*X* (*X*= S, Se, Te). These systems behave quite differently from usual mixed-valence compounds in which magnetic fluctuations are known to destabilize the 4*f* magnetic moments. Here, on the contrary, a variety of magnetically ordered phases exists at low temperature, and transport measurements have revealed pronounced changes when pressure is applied, including several transitions between semiconducting and metallic states.

The magnetic structures of the new high-pressure phases have been determined in TmTe (ferromagnetic above 2 GPa) and in TmS (lock-in antiferromagnetic at P= 5.7 GPa). In the former compound, the observed pressure dependence of the Curie temperature and of the thulium magnetic moment might correspond to the proximity of a quantum critical point.

M09.OC.005 ABNORMAL PROPERTIES OF SINGLE WALL CARBON NANOTUBES UNDER PRESSURE. D.E. Sklovsky, V.A. Nalimova, Department of Chemistry & Physics of High Pressures, Moscow State University, Moscow 119899, Russia, V.L. Kuznetsov, Boreskov Institute of Catalysis, Lavrientieva 5, 630090, Novosibirsk, Russia J.E. Fischer Department of Materials Science and Engineering and Laboratory for Research on the Structure of Matter, University of Pennsylvania, Philadelphia PA 19104 USA.

Single wall carbon nanotubes (SWNT) produced by double laser ablation of metal-doped graphite targets* were studied under the high quasi hydrostatic pressures up to 90 kbar in different types of anvil apparatus.

Piston-cylinder volumetric studies have shown the remarkably high and reversible volume compressibility of SWNT material up to 30 kbar, a factor 3-5 greater than the theoretically calculated values. The model of deformations at high pressures, based on crushing or flattening of SWNT cross-section from circular to elliptical is presented.

At 90 kbar pressure and room temperature the tubular structure of nanotube was shown to undergo phase transition to planar graphene planes - to graphite. The mechanism of such phase transition is proposed.

* The authors wish to thank A. Thess, A.G. Rinzler and R.E. Smalley of Rice University, Houston, USA for provision of purified SWNT material.

M09.OC.006 STRUCTURAL PRINCIPLES OF SIMPLE ELEMENTS AND INTERMETALLIC ALLOYS AT HIGH PRESSURE. J.S. Tse, Z.Q.Li, R. Rousseau, K. Uehara and D.D. Klug, Steacie Institute for Molecular Sciences, National Research Council of Canada, Ottawa, Ontario, Canada K1A 0R6 and J. Xie, Theoretical Division, Los Alamos National Laboratory, Los Alamos, NM 87548, U.S.A.

The effect of pressure on simple element such as diamond, gallium, and cesium and intermetallic alloys such as the K-Ag system have been examined by theoretical electronic structure and phonon calculations. Selected results will be reported on the following investigations including the observation of a negative thermal expansion coefficient in diamond at high pressure and low temperature; the phonon spectra associated with the iso-structural phase transition in Cs II – Cs III; and an interpretation for the unusual electronic structure of Cs IV. We will also discuss the validity of the Zintl's concept and the application of Miedema's rules in the electronic structure of intermetallic alloys at high pressure.

P09.OC.001 HIGH-PRESSURE AND HIGH TEMPERATURE EQUATION OF STATE OF PERICLASE. A. Dewaele and G. Fiquet, École Normale Supérieure de Lyon, 69364 Lyon Cedex 07, France, D. Andrault, IPGP, 75252 Paris Cedex 05, France and D. Hausermann, ESRF, 38042 Grenoble Cedex, France.

We present here an experimental determination of the Equation of State (EoS) of periclase at high pressure and high temperature. Motivations of this study are: (1) MgO is probably the second most abundant material in the Earth's lower mantle; its EoS is thus needed to constrain chemical models of the Earth; (2) lots of theoretical methods have been used to calculate the EoS of MgO and must be tested; (3) thanks to its large pressure and temperature stability domain, MgO can be used as a pressure calibrant in high pressure experiments.

We have carried out volume measurements on MgO, in a CO_2-laser heated diamond-anvil cell, up to 55 GPa and 2400 K, using monochromatic X-Ray diffraction at the ESRF (France). Temperature has been deduced from the thermal emission spectrum of the sample, and pressure by the use of a pressure calibrant (Platinum) mixed with the sample. Thermal pressure was taken into account in this way. Two-dimensional powder diffraction patterns were used to determine the MgO and Pt lattice unit cell parameters by LeBail refinement.

Inversion of the P-V-T data of MgO leads to the values of K_T (incompressibility), α (the thermal expansion coefficient) and their first pressure and temperature derivatives. The values of these parameters are: at ambient temperature, K_0 = 161 GPa, K'_0 = 3.95 (with a third-order Birch-Murnaghan equation of state); under high temperature: $\alpha(P = 0,T) = (3.0+0.0012\ T)\ K^{-1}$; $(\partial K_T / \partial T)_P$ = -0.022(3) GPa/K. The harmonic Debye model seems to correctly describe the temperature dependence of the volume under high pressure; with γ_0 = 1.54, (Grüneisen parameter under ambient conditions), a value of q (parameter that describes volume dependence of γ) of 1 ±0.3 is obtained.

P09.OC.002 PRESSURE EFFECT ON PHASE TRANSITION IN NaV_2O_5. K.Ohwada, H. Nakao, N. Takesue, M. Isobe, Y. Ueda and Y. Fujii, Institute for Solid State Physics, The University of Tokyo, 7-22-1 Roppongi, Minato-ku, Tokyo 106-8666 Japan, and Y. Wakabayashi and Y. Murakami, Photon Factory, Institute of Material Science, High Energy Accelerator Research Organization(KEK), Tukuba, Ibaraki 305-0801, Japan.

Very recently we have successfully observed two types of phase transitions in NaV_2O_5, i.e. spin-gap formation driven by charge order and lattice dimerization at low temperature (T_c=35K at 1atm.) and pressure induced structural phase transition at room temperature. Na atoms in its orthorhombic structure are located between V_2O_5-layers composed of two-dimensionally connected VO_5-pyramids and play a role of an electron donor to create a magnetically active V^{4+}(S=1/2). Pressure dependence of the lattice dimerization behavior of NaV_2O_5 has been studied at low temperatures for the first time. We measured the temperature dependence of the superlattice intensity from a single crystal up to 1.2GPa. The phase transition is significantly suppressed as $dT_c/dP \sim -13(1)$(K/GPa)), and the negative slope is consistent with the anomalous volume expansion below T_c through Ehrenfest's relation. Anomalous lattice properties and structural phase transition of NaV_2O_5 have also been studied under hydrostatic high pressure at room temperature using powder x-ray diffraction techniques. The c-axis along the stacking direction of V_2O_5-layers contracts rapidly and the b-axis along the one-dimensional magnetic chain direction expands, while the a-axis contracts up to about 4GPa and then begins to expand. Structural analysis of NaV_2O_5 and the previous data of V_2O_5 indicate that the Na atoms between the V_2O_5-layers govern these lattice properties. A structural phase transition is found to take place around 13GPa. A detailed structure analyzed by the Rietveld method reveals that the approach of the apical oxygen of VO_5-pyramid of under layer to the V atom in VO_5-pyramid plays an important role in the phase transition.

P09.OC.003 SINGLE WALL CARBON NANOTUBES AT PRESSURES UP TO 9.0 GPa. D.E. Sklovsky, V.A. Nalimova, Department of Chemistry & Physics of High Pressures, Moscow State University, Moscow 119899, Russia, A.D. Bozhko, Department of Low Temperature Physics, Moscow State University Moscow 119899 Russia; G.N. Bondarenko, Topchiev Institute of Petrochemical Synthesis, Russian Academy of Sciences, Leninsky pr., 29, Moscow, Russia, E.D. Obraztsova, Natural Sciences Center, General Physics Institute RAS, 38 Vavilov street, 117942, Moscow, Russia, V.L. Kuznetsov, Boreskov Institute of Catalysis, Lavrientieva 5, 630090, Novosibirsk, Russia, J.E. Fischer Department of Materials Science and Engineering and Laboratory for Research on the Structure of Matter, University of Pennsylvania, Philadelphia PA 19104 USA.

This poster presentation is supposed to complement to the talk on abnormal properties of single wall carbon nanotubes (SWNT) under pressure, describing the variety of methods, applied for this investigation. The precise volumetric technique along with XRD, HRTEM, Raman- and IR-spectroscopies enabled to elaborate the model of SWNT deformation under pressure, describing the unusually high and reversible volume compressibility of this material up to 30 kbar - crushing or flattening of SWNT cross-section from circular to elliptical.

In situ resistivity *vs.* pressure investigations in different types of anvil apparatus up to 9 GPa pressure showed the different mechanisms of local defect formation in nanotube material in different pressure ranges and proved the higher stiffness of alkali metal doped SWNT material.

XRD and HRTEM studies of SWNT samples quenched at different pressures evidenced the phase transition from SWNT ropes to planar graphite even at room temperature.

P09.OC.004 PRESSURE-INDUCED TRANSITION FROM Eu (4f) TO Co (3d) MAGNETISM IN $EuCo_2P_2$. M.M Abd-Elmeguid, M. Chefki, H. Micklitz, C. Huhnt, W. Schlabitz [1], M. Reehuis, W. Jeitschko [2], [1] II. Physikalisches Institut, Universität zu Köln, Zülpicher Strasse 77, D-50937 Köln, Germany, [2] Anorg.-Chemisches Institut, Westf. Wilhelms-Universität Münster, Wilhelm-Klemm-Strasse 8, D-48149 Münster, Germany

Magnetically ordered $EuCo_2P_2$ (Eu(2+); TN=66.5 K) undergoes a pressure-induced isostructural phase transition at p(c) = 3.1 GPa. 151Eu high-pressure Mössbauer experiments (0 <= p <= 5 GPa) reveal a valence transition of Eu from Eu(2+) to nonmagnetic Eu(3+) (7F0) at p > p(c) with the consequence that the disappearance of the Eu(4f) sublattice magnetism is accompanied by a simultaneous appearance of Co(3d) sublattice magnetism (TN= 260K). The latter is explained by the filling of the 3d states.

P09.OC.005 STRUCTURAL AND MAGNETIC PHASE TRANSITIONS UNDER HIGH PRESSURE IN THE AMNF4 (A=CS,RB,K) SERIES. M.C. Moron and F. Palacio [1], M. Ishizuka, S. Henmi, S. Endo [2], [1] Instituto de Ciencia de Materiales de Aragón, CSIC-Universidad de Zaragoza, E-50009 Zaragoza (Spain), [2] CREST (JST) and Research Center for Materials Science at Extreme Conditions, Osaka University, Toyonaka, Osaka 560 (Japan)

The $AMnF_4$ (A=Cs,Rb,K) series of layered-perovskites consist of two- dimensional network of layers of Jahn-Teller distorted MnF_6 octahedra, separated by the alkali ions. A reduction on the size of the alkali ion when going from CsMnF4 through $RbMnF_4$ to $KMnF_4$ (chemical pressure), shows a reduction of the unit cell volume and crystal symmetry.(1) The size of the alkali ion also has a dramatical effect on the magnetic behavior of these compounds. Neutron powder diffraction experiments evidence that $CsMnF_4$ orders as a ferromagnet below 18.9K, while the other members of the series exhibit antiferromagnetic ordering at lower temperatures. Synchrotron x-ray powder diffraction experiments, performed on the members of the series under high pressure up to 18GPa, have shown the equivalence between chemical and hydrostatic pressure along this series. Thus, the crystal structure of $CsMnF_4$ (tetragonal) changes at 1.4GPa and 6.3GPa to, respectively, the crystal symmetry of $RbMnF_4$ (orthorhombic) and $KMnF_4$ (monoclinic).(2) Changes in magnetism, in particular from ferro- to antiferromagnetic ordering, may be expected to occur when increasing pressure on $CsMnF_4$. We have investigated the magnetic behavior of this compound under pressure following the evolution of the magnetization with temperature up to pressures of 4GPa by using a diamond-anvil cell cooled down to 1.5K and a SQUID vibrating magnetometer. Our results indicate that there is also a close correlation between chemical and hydrostatic pressure effects on the magnetic structure of the $AMnF_4$ series. The relationships of these magnetic in character results with the structural properties of this series are discussed.

P09.OC.006 X-RAY CRYSTAL STRUCTURES OF MOLECULAR CONDUCTORS AT LOW TEMPERATURE AND UNDER HIGH PRESSURE . D. Chasseau, D. Le Pevelen, Y. Barrans, G. Bravic, J. Gaultier, P. Guionneau. Laboratoire des Sciences Moléculaires, Institut de Chimie de la Matière Condensée de Bordeaux, UPR CNRS 9048, Avenue du Dr A. Schweitzer, F-33608 Pessac Cedex.

Electrical and magnetic properties of molecular conductors have been intensively studied for the last twenty years as a function of temperature and pressure. For a better understanding of these properties, it is necessary to know the evolution of the structural properties in the same conditions. For this reason, our research group has developed for the last ten years a specific X-Ray diffraction technique which allows to visualize the reciprocal space and to determine the crystal structure of molecular compounds from 400 K to 7 K (ambient pressure) and from 1 bar to 15 kbar (room temperature). Very recently, two new results were obtained on molecular conductors under high pressure and at low temperature (6 kbar at 7 K). Thus, it is now possible, from a structural point of view, to have access to the (P, T) phase diagram of this kind of compounds.

The molecular salt $(TSeT)_2Cl$ presents a very high conductivity at ambient conditions. Its resistivity indicates the occurrence of a first order transition at 5kbar between two metallic states. The X-ray analysis performed at 5 kbar (300K) shows a change in the crystal symmetry which leads to a reorganisation of the Cl^- anions and of the (TSeT) network. This crystal structure, at 5 kbar, remains the same when the temperature is lowered to 7 K.

$(TMTSF)_2ClO_4$, was the first molecular salt to become superconducting at ambient pressure. Previous results, obtained by X-ray diffuse scattering, have shown the existence of superstructure reflections (wave vector 0 1/2 0) at 24 K. The crystal structure has been refined at 7 K (ambient pressure) in the (a, 2b, c) unit cell and shows clearly the ordering of the ClO_4 anion. On the contrary, the X-ray measurements, at 5 kbar (7 K), have not shown the existence of these superstructure reflections; the ClO_4 anion, in the (a, b, c) unit cell remains disordered. In both cases, dimerization of the TMTSF stacking is reduced.

09OD SYNCHROTRONS AND CHARGE DENSITY ANALYSIS

M09.OD.001 CHARGE DENSITY ANALYSIS AT THE SUNY X3 BEAMLINE AT THE NATIONAL SYNCHROTRON LIGHT SOURCE. P. Coppens, G. Wu and A. Volkov, Department of Chemistry, SUNY at Buffalo, Buffalo, NY 14260-3000, USA.

Because of its brightness, high intensity and energy, synchrotron radiation is eminently suitable for charge density analysis. Nevertheless, full realization of its potential has been quite a slow process. The reasons are manyfold and include beam instabilities which may not significantly affect other experiments and may therefore be ignored by those responsible for operation of the facility, sample instabilities and incomplete absorption of the beam by the area detector phosphor when hard radiation is used. This talk will discuss lessons learned in the last three years, successful examples of very low temperature synchrotron charge density studies, with both imaging plates and CCD detectors, and the interpretation of the results.

Support of this work by the National Science Foundation (CHE9615586, CHE9522232) and the U.S. Department of Energy (DE-FG02-86ER45231) is gratefully acknowledged.

M09.OD.002 ON THE QUALITY OF EXPERIMENTAL DENSITIES FROM SYNCHROTRON-CCD DATA T. Koritsanszky, Department of Chemistry, University of the Witwatersrand, Private Bag 3, WITS 2050, Johannesburg, South Africa.

The experimental determination of the electron density (ED) in the crystalline state relays on the precision and the resolution of X-ray diffraction data and on the adequacy of the refinement model applied to interpret them. Both of these aspects of the method are being revolutionized; the technical procedure

involved is due to the application of synchrotron (SYN) radiation combined with CCD intensity detection, the interpretation is due to sophisticated computer packages to reduce the data, to monitore the refinement and to analyse the ED extracted. Recent successes [1] suggest routine applications with increasing demand for extending such studies to large systems of biological relevance but the basic dilemma remains; to what extent a good fit of the data implies accuracy. The question can be approached - although cannot be answered - by comparative studies of different types. Here we report on comparing fine details of EDs obtained by using the same refinement model in the interpretation of different data either of the same crystal or of different crystals of chemically analog systems. These includes comparisons of EDs of: a. serine (conventional and CCD, SYN and MoKα) b. an antithrombotic farmacon (CCD, SYN and MoKα), c. two penicillines (CCD and SYN). The multipole refinements were performed with the program package XD [2] and the comparisons are based on the topological properties [3] of the static EDs. The results show that the SYN-CCD technique can lead to relative accurate and consistent densities suggesting the importance of high data resolution and redundancy reachable.

M09.OD.003 SYNCHROTRON CHARGE DENSITIES IN ACTION. Bo Brummerstedt Iversen, Department of Chemistry, University of Aarhus, DK-8000 Århus C, Denmark.

It is well known that synchrotron radiation potentially can improve the accuracy of experimental charge densities (CD) due to reduction of systematic errors. CD's of a quality comparable to the best conventional densities now can be measured regularly.[1] This allows a shift of focus away from methodological aspects, and in the talk recent applications of CD analysis in enzyme catalysis and intramolecular electron transfer processes will be discussed.

The cleavage of peptide bonds is an important reaction in nature, which involves the catalytic triad of residues (Ser--His--Asp) in the active site of the serine proteases class of enzymes. It has been suggested that a low-barrier hydrogen bond is involved in the reaction mechanism as a partial proton transfer between His^{57} and Asp^{102}. In order to investigate short N-H--O bonds, we have carried out combined very low temperature (28 K) X-ray and neutron diffraction studies of the cocrystal between betaine, imidazole and picric acid. The complex serves as a model for the catalytic triad, and the system is attractive *a priori* since it contains three different short N-H--O contacts (< 2.7Å) in the same crystal.

Polynuclear transition metal complexes occur widely in nature and their study spans fields reaching from biology to photo-physics. In bio-inorganic chemistry oxy-bridged polymetal systems have received enormous attention. In the case of intra-molecular electron transfer processes much work has been devoted to the classical basic carboxylates. We are undertaking a project involving systematic CD studies of a number of such compounds. In the talk results on a mixed valence compound, $Fe_3O(COOC(CH_3)_3)_6(C_5H_5N)_3$ will be presented. Since the system allows great flexibility in the variation of either the metals, the bridging ligands or the terminal ligands, it is hoped that comparative studies will give an increased understanding and control of the electronic structure of the central M_3O core.

M09.OD.004 ROOM TEMPERATURE ELECTRON DENSITY DISTRIBUTION IN SODIUM-NITROSYL-PRUSSIDE. A. Kirfel[1], H.-G. Krane[1] and W. H. Morgenroth[2]; [1]Mineral.-Petrol. Institut, Universität Bonn, [2]Mineral.-Petrogr. Institut, Universität Hamburg, Germany.

Due to the excitability of metastable electronic states at low temperatures resulting in a potential use as optical storage medium, $Na_2[Fe(CN)_5NO]2H_2O$ (space group Pnnm) has attracted much interest, and several structure analyses both by neutron and X-ray diffraction including electron density studies have been performed at low temperatures, e.g. [1]. In order to study i) the electron density distribution of the ground state, and ii) the quality of CCD-data in comparison to data conventionally recorded with a scintillation detector (SC), diffraction measurements were carried out on a 0.42 mm diameter sphere using synchrotron radiation at λ = 0.56Å (beam line D3, HASYLAB, Hamburg). For s_{max} = 0.92$Å^{-1}$, the raw data consisted of 13119 (SC, 7 days exposure) and 66075 (CCD, 3.5 days) reflections yielding 3684 and 3786 unique reflections, respectively $(R(F^2)_{int}$ = 0.015 and 0.037). Final agreement indices for conventional IAM refinements were R(F) = 0.0213 (SC) and 0.0296 (CCD).

Identical multipole structure refinements using VALRAY [2] converged at R(F) = 0.0103 (SC) and 0.0197 (CCD), again indicating a somewhat lower, but still sufficient quality of the latter data. This is also supported by ensuing calculations of static deformation density maps whose features are in good mutual agreement. Agreement is also found with theoretical calculations, except for the NO-group situated on the mirror plane m. In both analyses, the oxygen atom of this group is found to exhibit a chemically anomalous deformation pattern, i.e. extraordinary high $\Delta\rho$-peaks of several el/A^3 approximately 0.20 A above and below the mirror plane. Since various refinements with lowered symmetry, split oxygen positions, and anharmonic vibrations for the oxygen atom failed to produce conclusive results, radiation induced changes of the NO-bonding may be suspected.

M09.OD.005 DIRECT OBSERVATION OF ORBITAL ORDER IN $NdSr_2Mn_2O_7$ BY MEM CHARGE DENSITY STUDY. M.Takata, Dept. of Material Science, Shimane University, Mtasue 690-8504, Japan, and E.Nishibori, K.Kato and M.Sakata, Dept. of Applied Physics, Nagoya University, Nagoya 464-8601, Japan, and Y.Moritomo, Center for Integrated Research in Science and Engineering, Nagoya University, Nagoya 464-8601 and PRESTO, JST, Japan.

Recent extensive experimental and theoretical investigations on the doped manganites of perovskite-like structure, which shows colossal magnetoresistive (CMR) properties, begins to reveal a crucial role of the orbital degree of freedom on the magnetic as well as the electronic properties. Among such substances, $NdSr_2Mn_2O_7$ is well known as the layered manganite, which is of tetragonal (I4/mmm) and shows a definite antiferromagnetic transition at T_N =150K. The origin of the antiferromagneticity has been thought to be due to spontaneous ordering of the Mn $\boldsymbol{dx^2\text{-}y^2}$ orbital as for the itinerant $\boldsymbol{e_g}$-electrons. An accurate X-ray charge density study must allows us to reveal a bonding electron localized between the Mn and O atoms associated with Mn($\boldsymbol{3d}$)-O($\boldsymbol{2p\sigma}$) hybridization. Supposing that the orbital ordering really exist in MnO_2 plane in an

antiferromagnetic state, an anisotropy of Mn-O bonding feature in MnO_6 octahedron must be found in the charge density distribution at $T < T_N$. Here, we report the results of direct observation of orbital ordered state of $NdSr_2Mn_2O_7$ in the form of real space charge densities obtained by Maximum Entropy Method(MEM)/Rietveld method[1] using synchrotron radiation powder data. The results very clearly show, for the first time, an electronic layer structure ascribed to the layered antiferromgnetic structure of $NdSr_2Mn_2O_7$.

M09.OD.006 EXTINCTION-FREE SINGLE-CRYSTAL SR DIFFRACTION EXPERIMENTS USING SMALL CRYSTALS. N.Ishizawa, Materials and Structures Laboratory, Tokyo Institute of Technology, 4256 Nagatsuta, Midori-ku, Yokohama 226, Japan

Three-dimensional synchrotron X-ray diffraction data obtained for a small single crystal approximately 10 μm in size were found to be scarcely affected by extinction and provide unambiguous information of charge density in crystals.

Diffraction data were collected at beam line 14A, Photon Factory, KEK, which is equipped with a horizontal-type four-circle diffractometer [1] utilising focused X-rays. The APD detector [2], comprising of four avalanche photodiodes stacked along the beam path, was employed in part of this study. Neither attenuator nor dead time corrections were necessary as all the diffracted intensities were within the dynamic range 10^{-2} - 10^{8} cps of the detector. Case studies for inorganic crystals, including a 10 μm $(Ca,Y)AlO_4$ crystal and a 8 μm $LiNbO_3$ crystal revealed accurate charge densities of the compounds. The maximum peak intensity reached over 10^6 cps. A subtle, though significant, composition deviation from the stoichiometry was confirmed in both compounds. Two close atomic positions occupied respectively by the host and replacing atoms in solid solution were resolved in $(Ca,Y)AlO_4$. An example is shown where the conventional extinction correction included in the least-squares procedure can invoke artifacts if it is applied over a certain limit, leading to misunderstanding of the true nature of charge densities.

M09.OD.007 X-RAY ANALYSIS OF CHARGE DENSITY UNDER MAGNETIC FIELDS. V.A. Streltsov and D.du Boulay, Crystallography Centre, The University of Western Australia, Australia. and R.P. Ozerov, Mendeleev University of Chemical Technology, Russia.

Remarkable changes to the electron distribution in haematite, α-Fe_2O_3 and magnetostrictive Laves, RFe_2 (R=Tb and Sm) have been observed from synchrotron (Photon Factory BL14-A) X-ray diffraction measurements at room T with applied magnetic fields of order 0.07 T at the sample position.

Haematite is a weak ferromagnet at room T. Although its structural symmetry is rhombohedral, the magnetic symmetry is monoclinic. Under magnetic fields in the single domain state, the lattice is expected to deform matching the magnetic symmetry. However, no statistically significant displacement of the Fe atom from its rhombohedral position were found. But, strong distortion of the charge density, especially in the plane perpendicular to the field direction was observed. Superlattice monoclinic reflections of marginal significance were detected. These reflections were considered in [1] as those originating in X-ray photon-spin interactions. Alternatively, they might be explained by the scattering of X-ray photons by part of the charge density distorted due to spin's magnetic interactions.

In an applied field, $TbFe_2$ and $SmFe_2$ undergo large strains along a cubic body diagonal, resulting in rhombohedral distortions. The current atomic model of anisotropic magnetostriction and its variation from positive to negative in $TbFe_2$ and $SmFe_2$, respectively, is based on the proposed asymmetry of the 4*f* electron densities of rare earths [2]. Analysis of the experimental data revealed strong reorganisation of the difference electron density challenging this model.

P09.OD.001 SYNCHROTRON RADIATION CHARGE DENSITY STUDY OF UREA USING A SIX-CIRCLE DIFFRACTOMETER. H. Birkedal, P. Pattison, D. Schwarzenbach and H.-P. Weber, Institut de Cristallographie, Université de Lausanne, BSP Dorigny, 1015 Lausanne, Switzerland, and K. Knudsen, SNBL, ESRF, BP 220, 38043 Grenoble Cedex, France, and R. Mathiesen, Institutt for fysikk, NTNU, 7043 Trondheim, Norway, and D. Madsen, ESRF, BP 220, 38043 Grenoble Cedex, France.

We present a new charge density study of urea obtained using synchrotron radiation at the Swiss Norwegian Beam Line at the ESRF. The beam line is equipped with a six-circle kappa-diffractometer and a point detector. Data of very high quality were collected at 120K. The data are of unprecedented resolution for urea with $\sin(\theta)/\lambda_{max} = 1.442 Å^{-1}$. A total of 3958 reflections were measured, which average to 1826 unique reflections with R_{int}(all) = 1.29% . Of the unique reflections, 1346 have $F_o^2 > 3\sigma(F_o^2)$. The data are compared with earlier laboratory data [1]. The charge density is modeled by refinements with VALRAY [2], the agreements factors being $R(F^2) = 1.31\%$ and $wR(F^2) = 1.76\%$. We discuss the complete topology of the charge density of urea and atomic properties obtained by integration over the atomic volumes. The results are compared with periodic restricted Hartree-Fock ab initio calculations [3].

09OE MICROPOROUS MATERIALS

M09.OE.001 COMPUTER SIMULATION OF ZEOLITE CRYSTAL STRUCTURES. Robert G. Bell, Davy Faraday Research Laboratory, Royal Institution of Great Britain, 21 Albemarle Street, London W1X 4BS, UK

With the advances in computing power seen over the last decade, the atomistic modelling of zeolite framework structures using potential-based energy minimisation methods has become an almost routine procedure. In our laboratory, these types of simulation, in conjunction with experimental techniques, have been used to notable effect in detailed structural studies of a number of microporous materials[1,2]. Using Monte Carlo methods it is additionally possible to predict the siting of adsorbed molecules within the crystalline host framework[3]. This presentation will review progress in the field to date, including the study of MCM-41 type mesoporous materials[4], and will further discuss the relationship between framework topology and lattice energy, and its implications for the synthesis of new framework materials.

M09.OE.002 HOST-GUEST INTERACTIONS IN ZEOLITES AS STUDIED BY SOLID-STATE NMR AND X-RAY TECHNIQUES. Andrew R. Lewis,[1] Anix C. Diaz,[2] and Colin A. Fyfe, Chemistry Department, University of British Columbia, Vancouver, B.C. V6T 1Z1, Canada. [1] Present address: Laboratoire de Matériaux Minéraux, ENSCMu, Université de Haute-Alsace, 3 rue Alfred Werner, 68093 Mulhose Cedex, France. [2] Present address: Intevep S.A. Departamento de Análisis y Evaluación, Centro de Investigación y Apoyo Technológico Filial de Petróles de Venezuela, Apdo. 76343 Caracas 1070 A Venezuela.

We report solid-state NMR methods developed for locating guest species within the channels and cages of inorganic microporous materials. The ultimate aim of these experiments is the determination of the 3-dimensional structures of the host-guest complexes formed by zeolites and sorbed organic molecules or other guests. Such techniques are important because relatively little is known about the exact location of guest species within these framework structures; single crystal X-ray structure determinations are often precluded by the lack of suitable crystals, and Rietveld refinement of powder data may not always provide reliable guest locations.

Using Magic Angle Spinning combined with Cross Polarization from nuclei in the guest species to ^{29}Si nuclei in the framework of siliceous microporous materials, we have been able to demonstrate the feasibility of measuring accurate host-guest distances. In addition, we have successfully determined the location and orientation of *p*-xylene molecules within the channels of ZSM-5. The NMR-determined distances and structures are in agreement with the corresponding information obtained from single crystal X-ray diffraction refinements. These NMR techniques can be extended to other systems, and the structures obtained serve as a useful check of the validity of structures predicted from molecular modeling calculations.

M09.OE.003 DYNAMICS OF MOLECULES IN POROUS MATERIALS INVESTIGATED BY NEUTRON SPECTROSCOPY. B. Asmussen[1)], I. Krasnov[1)], C. Gutt[1], W. Press[1)], W. Langel[2)], R. Kahn[3)], M. Ferrand[4)],1) Institut fuer Experimentelle und Angewandte Physik, Univ. Kiel, Germany, 2) Univ. Greifswald, Germany, 3) LLB, Saclay, France, 4) ILL, Grenoble, France.

Structure and dynamics of condensates in porous media are strongly influenced by the presence of pore walls. The presentation will focus on the (rotational and translational) dynamics of methane molecules in various mesoporous host materials (silicagels, Controlled Pore Glasses, MCM-41, porous TiO_2) with pore diameters d covering a wide range 20 Å ≤ d ≤ 350 Å. Basing on extensive measurements of sorption isotherms, different degrees of filling could be realized: (1) pores completely filled with methane and (2) walls of the host material covered by a multilayer film.

High-resolution inelastic incoherent neutron scattering with time-of-flight techniques is a powerful tool for the investigation of dynamical processes of hydrogen containing molecules due to the large scattering cross section of the proton. The rotational spectra of methane condensates at low temperatures (T ~ 5 K, i.e. in the regime of quantum rotations) can be used as very sensitive probes for strength and symmetry of local potentials. They allow us to distinguish between a core of unperturbed solid CH_4 in its low-temperature phase II in the center of the pores and an orientationally disordered layer on the pore walls.

Quasielastic neutron measurements have covered the region of the melting-transition of the methane condensates (70 K ≤ T ≤ 95 K). The onset of translational motions of the condensate molecules at the melting point leads to a corresponding decrease in the elastic intensity in the neutron spectra. For the multilayer coverages, this decrease is smeared out over a broad temperature range ΔT = 20 K. The melting was found to be much more abrupt for the filled pores, but here the melting point shifts (depending on the pore diameter) to lower temperatures, compared to the bulk value. The results from the dynamical experiments are supported by strucutral investigations with x-ray diffraction and neutron small-angle scattering.

M09.OE.004 NEGATIVE THERMAL EXPANSION IN ZEOLITES. D. A. Woodcock, P. Lightfoot and P. A. Wright, School of Chemistry, University of St. Andrews, Purdie Building, North Haugh, St. Andrews, Fife, UK, KY16 9ST, M.A. Camblor, L.A. Villaescusa, M.J. Díaz-Cabañas, Insituto de Technologia Química, Avda. Los Naranjos s/n, 46071 Valencia, Spain and D. Engberg, ISIS Facility, CLRC Rutherford Appleton Laboratory, Chilton, Didcot, Oxon. OX11 0QX

Negative thermal expansion has been found to be present in numerous zeolite and microporous framework structures such as the pure silica polymorphs ITQ-1, ITQ-3, SSZ-23[1] and faujasite[2], AlPO-17[3] and ZSM-5[4]. AlPO-17 is of particular interest as it is the most contracting material known.

Our in house X-ray diffraction experiments on ITQ-1, ITQ-3 and SSZ-23 revealed that all three materials showed a contraction as a function of temperature on each axis, but that the contraction did not appear to be due to any obvious structural characteristics. For example, ITQ-1 is a layer structure, the layers lying perpendicular to the c axis. It might be expected that the strongest contraction would be between the layers and that α_c would be more pronounced than either α_a or α_b. This proved not to be the case and it was concluded that a detailed structural study would be necessary in order to understand fully the subtle causes of these dramatic effects.

We present here the results of neutron powder diffraction experiments from the OSIRIS instrument at the ISIS facility, introducing both some new materials and some suggestions on a possible mechanism.

M09.OE.005 FIRST DETERMINATION OF ELECTROSTATIC PROPERTIES OF SYNTHETIC ZEOLITES FROM HIGH RESOLUTION X RAY DIFFRACTION. F. Porcher, M. Souhassou, Y Dusausoy, C. Lecomte N.-E. Ghermani, LCM^{3}B, CNRS UPRESA 7036, Université Henri Poincaré, Nancy 1, BP 239, Vandoeuvre lès Nancy cédex and H. Graafsma, European Synchrotron Radiation Facility, B.P. 220, 38043 Grenoble cédex

The peculiar physico-chemical properties of zeolites are based on the existence of large cavities in their structure that can lodge neutral or charged hosts molecules. The sorption properties are related to the structure of the flexible alumino-silicated framework and to the distribution of the exchangeable charge compensating cations inside the pores. Despite numerous studies, the later influence is still not well understood, mainly because the cation distributions are highly disordered and very uncertain, particularly for aluminum-rich zeolites.

As a first approximation, the interaction between cations and sorbed molecules is limited to the long range electrostatic interactions, the dispersion term being negligible for cation-sorbant distances of few angstroems. It is therefore possible to evaluate the sorption energies from the electrostatic potential of empty dehydrated zeolites. This later can be derived from the electron density distribution of the material.

Since this system is too large (~700 atoms per unit cell) for accurate ab initio calculations[1] and since molecular dynamic calculations requires empirical atomic charges, high resolution X ray diffraction is a necessary tool for the estimation of electron density and electrostatic properties that govern the sorption mechanisms in the zeolite.

In this goal, we have measured high resolution X ray diffraction data sets on dehydrated NaX[3], LiX and CaX zeolites using synchrotron radiation (λ = 0.248Å, ESRF) and a rotating anode (Mo(Kα), LCM3B): Structural, electron density and electrostatic properties derived from these experiments will be discussed.

P09.OE.002 NEW INORGANIC-ORGANIC OPEN FRAMEWORKS. Z. A. D. Lethbridge and P. Lightfoot, School of Chemistry, University of St Andrews, Purdie Building, North Haugh, St Andrews, Fife, KY16 9ST, UK.

Inorganic open frameworks such as zeolites and aluminophosphates are well known. Non-tetrahedral metal structures have also been synthesised, for example the iron phosphate $[H_3N(CH_2)_3NH_3]_2[Fe_4(OH)_3(HPO_4)_2(PO_4)_3]$ [1]. Metal organic frameworks are another expanding family of materials, containing metal atoms bridged by organic ligands. These are usually rigid oxygen or nitrogen donors, as in the material reported by Yaghi et. al. $Co(C_6H_3(COO)_3)(NC_5H_5)_2.2/3NC_5H_5$ [2].

Here, we report results of our work, which aims to synthesise frameworks containing both inorganic and organic anions. It is hoped that these hybrid materials will combine the thermal stability of inorganic frameworks with the wide structural diversity of organic materials. We have made use of phosphate anions, and organics such as dicarboxylic acids, bipyridyl and pyrazine.

P09.OE.003 STABLE CRYSTALLINE MICROPOROUS SOLIDS FROM LINKED METAL BORATE CLUSTER ASSEMBLIES. Ian D. Williams, Herman H-Y. Sung, Alvin Siu and Mingmei Wu, Dept of Chemistry, Hong Kong University of Science and Technology, Clear Water Bay, Hong Kong, China.

The development of hydrothermal and molten boric acid flux syntheses of metalloborates, especially vanadoborate clusters [1] has now been extended to heterometallic borate compounds yielding novel stable microporous compounds.

The mixed-valence cluster $[V_{12}B_{18}O_{60}H_6]^{10-}$ can be formed hydrothermally from V_2O_5, borax and ethylenediamine (en), as its water soluble Na salt, which allows for cation exchange. From this, the formation of neutral expanded 'super clusters' $[V_{12}B_{18}O_{60}H_6\{M(en)_2\}_6]$ is possible for M = Zn, Ni, and Co. Modified hydrothermal synthesis with $Zn(OAc)_2$ also allows preparation of the green tetragonal phase (a = 17.147(3), c =20.329(4)Å) This has an open 2-D polymer network containing $[Zn_4V_{10}B_{28}]$ cluster units. These incorporate Zn atoms within the cluster skeleton which assist formation of 10-membered vanadyl rings. The clusters are connected through additional $Zn(en)_2$ bridges which ligate via cluster V=O groups.

By contrast addition of $Cd(OAc)_2$ to the hydrothermal reaction mixture can result in formation of stable microporous compounds with 3-D interpenetrating channels. A body centred cubic phase $[V_{12}B_{18}O_{60}H_6\{Cd(en)(H_2O)\}_3]$ with 6Å channels has been characterized (space group Ia-3d, a = 31.972(3)Å). In this the Cd atoms form cross-links between clusters by chelate attachment to cluster O-B-O groups. A second cubic phase of space group Pn-3 (no previous examples in CSD) and a = 19.100(3)Å has been prepared in good yield and purity. This is isomeric to the body-centered compound and also has a similar open network of 3-D intersecting channels. It has been studied by high T single crystal diffractometry and shown to retain its crystallinity even after water loss and heating up to 300°C. Further results on the surface area studies, sorption and magnetic properties of these novel linked cluster materials will be presented.

09OF POLYMORPHISM AND ISOMORPHISM (sponsored by Bruker AXS)

M09.OF.001 POLYMORPHISM AND ITS RELATION TO ISOSTRUCTURALITY. Alajos Kálmán and László Fábián, Institute of Chemistry, Chemical Research Center, Hungarian Academy of Sciences, Budapest, P.O.Box 17., H-1525, Hungary

Since the structure determinations of the *reappearing* low melting (358K) dimorph of 1,2,3,5-tetra-*O*-acetyl-β-D-ribofuranose [1], the anhydrous form of sulfaguanidine [2] and the recognition of isostructurality shown by digirezigenin [3] and several digitoxigenin derivatives [4] along with the plethora of related papers in the literature, we have become more and more convinced that similar molecules can have dissimilar crystal structures and that dissimilar molecules can have similar structures. A connection between *polymorphism* and the less common crystal *isostructurality* was exemplified first by a group of paradisubstituted benzylideneanilines [4,5].

Further examples: (*A*) While 5-methoxysulfadiazine exhibits a wide range of polymorphism its clathrates built up with (a) dioxane, (b) tetrahydrofuran and (c) chloroform are isostructural [6]. (*B*) Novel inclusion compounds formed by a Pietfort-type host compound 2,4,6-tris-(3,5-di-*t*-butylphenoxy)-1,3,5-triazine were found recently [7] to exhibit isostructurality, polymorphism and pseudopolymorphism, as well. Details of these investigations compared with others are discussed.

M09.OF.002 POLYMORPHISM AND DISORDER. T.R. Welberry, Research School of Chemistry, A.N.U, Canberra, ACT 0200, Australia

The energy difference between different polymorphs for organic crystals is estimated to be of the same order of magnitude as the energy for torsional conformation parameters in many organic molecules, so that it is often found that molecules with torsional degrees of freedom may adopt different conformations in different polymorphs. Similarly, many examples of disordered crystals occur in which, to a first approximation, a given (rigid) molecule exists in either of two different orientations within a particular molecular site, and the energy difference between these possibilities is also of a comparable magnitude. In order to understand the relationship between disorder, molecular conformation and polymorphism a very detailed analysis of the crystal structure is required.

Analysis of disordered systems by conventional crystal structure determination using Bragg reflections may reveal the average molecular site in sufficient detail that the two different molecular orientations can be distinguished. However, even if this is the case, this is an incomplete picture of what is going on in the crystal, and in order to make predictions about the relative stability of different polymorphs, a detailed local structural picture is paramount. Such information cannot be obtained from the Bragg experiment but it is obtainable from diffuse scattering experiments [1]. In this paper we outline the methods that may be used to obtain this information.

The methodology is illustrated with reference to the systems p-chloro-N-(p-methylbenzylidine)aniline, $C_{14}H_{12}ClN$ (MeCl), and p-methyl-N-(p-chloro-benzylidine)aniline, $C_{14}H_{12}ClN$ (ClMe). These compounds are just two examples from a number of parasubstituted benzylidene anilines that have been of interest to theoretical chemists studying the way in which shape and conformation influences the crystal structure of a compound [2].

M09.OF.003 POLYMORPHS OF BENZFURAZAN-1-OXIDES AND THEIR ISOMORPHISM (SOMETIMES) WITH PHTHALIC ANHYDRIDES. Doyle Britton, W. E. Noland, M. Pinnow [1], C. R. Ojala [2], W. H. Ojala [3], J. Z. Gougoutas [4], [1] Department of Chemistry, University on Minnesota, Minneapolis, MN 55405, [2] Department of Chemistry, Normandale Community College, Bloomington, MN 55431, [3] Department of Chemistry, University of St. Thomas, St. Paul, MN 55105, [4] The Bristol-Myers Squibb Pharmaceutical Research Institute, P.O. Box 4000, Princeton, NJ 08543

5,6-Dichlorobenzfurazan-1-oxide (CBF) forms three polymorphs at ordinary temperatures. All three involve disorder across a two-fold or pseudo-two-fold axis. 4,5-Dichlorophthalic anhydride (CPA) is isosteric with the disordered CBF and forms crystals that are isomorphous to CBF polymorph A. Polymorph C contains two-dimensional layers that are similar to those in A but that stack differently. 4,5-dibromophthalic anhydride is not isomorphous with CPA but again contains two-dimensional layers that are similar to those in CPA but that stack differently. 5-Chlorobenzfurazan-1-oxide is actually a disordered mixture of the 5- and 6-chloro isomers at all accessible temperatures. The analogous 5-bromobenzfurazan-1-oxide is isomorphous with the same disorder at room temperature but forms an ordered polymorph a low temperature. In spite of the molecular isomerization during the transformation, a single crystal of one form transforms to a single crystal of the other.

M09.OF.004 COLOR POLYMORPHISM. J.-O. Henck, Universität Innsbruck, Institut für Pharmakognosie, Josef-Moeller-Haus, Innrain 52, A-6020 Innsbruck, Austria**,** J. Bernstein and A. Ellern, Ben-Gurion University of the Negev, Department of Chemistry, P.O.Box 653, Beer-Sheva 84105, Israel

What are the major scientific questions facing researchers in polymorphism? First, although the appearance of a new polymorphic structure in any particular system is no longer a surprise, the *a priori* prediction of the existence of polymorphism or any particular crystal structure is still essentially beyond our ability. Secondly, even assuming that a specific system might be predicted to be polymorphic, there are no prescriptions for preparing those polymorphic structures that could be expected. Third, even supposing that we know how to prepare predicted polymorphic forms there is almost no way of predicting the properties they would have.

Polymorphism means variety in structure, and since variety in structure implies variety in properties, those whose research deals with polymorphism are practitioners in a wide variety of techniques and disciplines. The ability to characterize and obtain a particular preferred polymorph can determine the success or failure of a product. Such considerations are an increasingly important factor in industrial development and production of new materials, from e.g. pigments to pharmaceuticals. One of the latest published dramatic examples is the case of Norvir (the protease inhibitor ritonavir) [1].

The color and properties of solid pigments and dyes also depend on their crystal structure. Different polymorphs of such materials can have different colors [2]; thus they are excellent systems for investigating structure-property relationships. In 1910 Hantzsch [3] described a series of mono-, di- and trinitroaniline derivatives showing color polymorphism ("Chromoisomerie"). In this contribution we will present the thermodynamic and structural relationships among the phases of a number of compounds exhibiting color polymorphism.

M09.OF.005 POLYMORPHISM IN 2,6-DIHYDROXYBENZOIC ACID : OSTWALD'S RULE, SOLVENT EFFECTS AND MOLECULAR SELF ASSEMBLY. R. J. Davey, H. Alison, N. Blagden, and S. Fuller, Colloids, Crystals and Interfaces Group, Department of Chemical Engineering, UMIST, Manchester M60 1QD, UK.

The impact of the solvent on the polymorphic outcome of crystallisation from solution is well known[1] but poorly understood. At the same time the process of crystallisation from solution is a key experimental feature of many aspects of crystal engineering as practised both academically and industrially in the pharmaceutical and specialty chemicals sectors.

The work reported here focuses on a particular material, 2,6-dihydroxybenzoic acid, which is known to be polymorphic with forms 1 and 2 having been grown for crystallographic studies from toluene and chloroform respectively[2,3]. Structurally the two polymorphs exhibit different hydrogen bonding networks: in form 1 molecules pack as H-bonded dimers while in the non-centric form 2 they form infinite H-bonded chains. One of the objectives of this study has been to understand the role of the solvent in determining the polymorphic outcome of different crystallisation strategies. Firstly thermodynamic data concerning the thermochemistry and solubility of the two polymorphs will be

presented. This is complemented by spectroscopic data and MOPAC calculations aimed at exploring possible modes of molecular self assembly in solution. Finally crystallographic data is used to assess the likely impact of the solvent on the competing processes of nucleation and crystal growth from the two solvents. Overall the study demonstrates the importance of combining crystallographic data with other sources of information in order to understand a process as complex as crystallisation in a polymorphic system.

M09.OF.006 SOME INTERESTING POLYMORPHS I HAVE KNOWN. Walter C. McCrone, McCrone Research Institute, Chicago, IL USA

I will select several unusual polymorph systems from pharaceutical companies who look for thermodynamically unstable crystal forms to achieve higher solubility and from those who produce and use explosives who want the most stable forms to be assured of a safe high density product.

P09.OF.001 DISAPPEARING POLYMORPHS AND THE ROLE OF IMPURITIES AND REACTION BY-PRODUCTS. N. Blagden, R.J. Davey, Colloids, Crystals and Interfaces Group, Department of Chemical Engineering, UMIST, PO Box 88, Manchester M60 1QD, UK.

The phenomenon of polymorphism, whereby a molecule can adopt more than one crystal structure is well known in crystal chemistry In terms of developing a robust process for isolating polymorphic materials a purely structural approach is limited since it neglects the role of kinetics in determining the appearance of polymorphic structures. This was recognised by Ostwald (1899) in his famous Rule of Stages. This situation is highlighted by the issue of so called 'disappearing polymorphs' i.e. the sudden appearance of a new structure or the unexplained disappearance of an existing one. The role of additives and reaction by-products in controlling polymorph appearance in this context will be discussed. A combined modelling and experimental strategy has been applied to the problem of impurity and reaction by-product influence on the appearance of polymorphs from solution. Two examples will be discussed. **Case (I)**, from a pure aqueous solution of sulphathiazole after 24 hrs at 25 ^{o}C the most stable phase, form IV of sulphathiazole was isolated. This work shows for the first time that a reaction by-product, ethamidosulphathiazole, from the final hydrolysis stage at concentrations as low as 1 mol % stabilises the metastable modification, form I. The role of the impurity was accounted for from an analysis of the respective hydrogen bond networks and crystal morphologies of each phase. **Case (II),** trimesic acid at 1 mol % is capable of stabilising the meta stable form of glutamic acid from solution for one week, thermostated at 40 ^{O}C. This contrast with a pure aqueous suspension which transform in under half an hour. The trimesic acid was shown to mimic the conformation of glutamic acid in the stable β form and thus disrupts the transformation from the metastable α from, this was accounted for through growth inhibition of the fastest growing faces of the stable β form.

P09.OF.002 PHASE TRANSITION BY GRINDING OF SALICYLIDENEBENZYLAMINES. REMARK-ABLE CHANGE IN THE CHROMIC BEHAVIOR. Shiori Yoshida, Koki Takasawa, Toshikatsu Fujiwara and Keiichiro Ogawa, Department of Chemistry, Graduate School of Arts and Sciences, The University of Tokyo, Komaba, Meguro-ku, Tokyo, 153-8902 Japan

Salicylideneanilines belong to a class of the most popular compounds indicating thermo- or photochromism. These phenomena, which are ascribed to tautomerism, are known to be mutually exclusive. However, some derivatives of *N*-salicylidenebenzylamine, which has a methylene group inserted between C=N and the phenyl group, are known to be both thermo- and photochromic. *N*-(2-hydroxy-4-methoxybenzylidene)benzyl-amine (**1**) is one of such compounds reported by Hadjoudis *et al* [1]. We report here a remarkable difference in chromic behavior and the phase transition between polymorphic forms of **1**.

The crystalline film which was prepared from the melt (form I) showed thermochromism and photochromism. The crystals that recrystallized from ether solution (form II) did not show either thermo- or photochromism. The X-ray powder patterns of the both forms were, however, identical. The facts indicate that a phase transition from the form I to II takes place on grinding.

09AA WHY LOW RESOLUTION? METHODS AND OUTCOMES

M09.AA.001 LOW RESOLUTION PHASING. ACHIEVEMENTS AND PERSPECTIVES. V.Y.Lunin, Institute of Mathematical Problems of Biology RAS, Pushchino, Moscow region, 142292 Russia, and A.G.Urzhumtsev, LCM^{3}B, Faculté des Sciences, Université Henri Poincaré, Nancy I, 54506, Vandoeuvre-lès-Nancy, France and A.D.Podjarny, UPR de Biologie Structurale, IGBMC, BP 163, 67404 Illkirch CEDEX, CU de Strasbourg, France.

Until the last decade, the low resolution (LR) reflections were traditionally neglected due to experimental and modeling problems. However, phasing the LR data is important for a number of cases, especially when the LR image has valuable information in itself (e.g., the ribosome); crystals do not diffract to high resolution; a LR cut-off causes large image distortions; molecules are a mixture of ordered and disordered regions *etc*. Furthermore, the knowledge of LR phases or a molecular envelope may be useful (and sometimes necessary) to enhance the possibility of direct methods. The traditional experimental approaches to phasing macromolecular data may be applied to LR reflections to some extent only, making it necessary to develop direct LR phasing methods. When phases of middle and/or high resolution reflections are available, those of LR reflections (and partially, magnitudes) may be estimated from these data. In the other case *ab-initio* phasing procedures must be applied.

The main problem in LR *ab-initio* phasing is that all suggested figures of merit FOM) for LR phase sets have the same features, unfavorable for phasing:

- the best value of FOM may be coupled with a wrong phase set;
- the FOM corresponding to the true phases may be relatively low;
- the local phase refinement may result in high FOMs without any phase improvement.

The cluster analysis methods and several suggested procedures of best cluster choice, adapted to this problem, allow to overcome the problem to some extent.

M09.AA.002 *AB INITIO* PHASING OF LOW RESOLUTION DATA. David A. Langs, Hauptman-Woodward Medical Research Institute, Inc., 73 High Street, Buffalo, NY, 14203, U.S.A.

There are a number of necessary conditions to be met in devising a plan to phase low resolution data by *ab initio* direct methods. Firstly, one must find reliable real & reciprocal space figures of merit that are optimal for the correct phases and significantly worse for all other values of the phases. This implies the true values of the phases would be stable toward further optimization of the FOM's. It would also be desirable that these properties would hold if the data set were reduced to a smaller fraction which included just the largest structure factor amplitudes. This might make the sampling of plausible random phase trials more efficient. Secondly, one would have to devise a strategy by which the phases can be reliably refined to optimize the FOM values in an efficient manner. Finally it would necessary to show that low resolution solutions can be obtained from some of the random phase starting sets if we are persistent.

Perhaps it may be possible to achieve all these things without consciously thinking of such things as structural models, solvent flatting, histogram fitting, phase invariants, density modification, entropy and likelihood.

Research support from NIH grant GM-46733 is gratefully acknowledged.

M09.AA.003 SOLVENT MODELLING AT LOW RESOLUION. A.G.Urzhumtsev, LCM3B, UPRESA 7036 CNRS, Université Henri Poincaré – Nancy 1, B.P. 239, 54506 Vandoeuvre-les-Nancy.

The voids between macromolecules in a crystal are filled by smaller molecules, many of those placed differently in different unit cells. This disorder in space as well as in time gives en effect of the "disordered solvent": a specific contribution to the diffraction intensities, important at the resolution of about 5-6Å and lower, which should be modelled together with the macromolecule itself. Even more, this solvent modelling should be done *before* the construction of an atomic model, as early as the envelope is known, to reduce the errors in the electron density maps.

The first idea to model the bulk solvent contribution is to calculate structure factors from the *flat solvent region* and to choose the optimal scale factors for them to minimise the discrepancy between experimental amplitudes and the ones calculated from an available atomic model plus solvent [1]. This approach was further developed and modified by several researchers. An alternative approach is to model the solvent density distribution as a function of the distance $\boldsymbol{D}$ to the molecular envelope [2].

The points, equidistant to the envelope can be, nevertheless, in quite different conditions, in cavities or at convexities, which can be distinguished when the envelope is calculated at different resolutions. Typical 2D histograms of the couples {ρ-value, $\boldsymbol{D}$}, corresponding to the *set of envelopes* calculated at different resolutions, can be *used together* to estimate the density value at a given point. A more direct modelling of the bulk solvent needs to simulate the space disorder among *different cells*. It can be replaced by the generation of *many* models identical in all cells and by averaging structure factors over *all generated models*. This can bring an alternative information to model the solvent contribution.

M09.AA.004 PSEUDOATOM GLOBS AND DIRECT PHASE DETERMINATION - RUBREDOXIN AT 6 Å RESOLUTION. Mary P. McCourt, Douglas L. Dorset, Electron Diffraction Department, Hautpman-Woodward Medical Research Institute, 73 High Street, Buffalo, NY 14203-1196 USA.

The re-scaled pseudoatom scattering factor approximation to the Fourier transform of globular density units has been very useful for the low- resolution direct phase analysis of integral membrane proteins with high alpha-helix content (using electron diffraction amplitudes). For a 3-D application, the crystal structure of rubredoxin was determined from experimental x-ray data by direct methods at 6 Å resolution. The Sayre equation expanded a relatively small basis set and screening criteria, such as density flatness and the Patterson correlation coefficient, selected the best of several possible solutions. In the two-dimensional determination, principal peak positions were located in the maps, giving a mean phase error of 58 deg. for all 17 hk0 reflections after two cycles of Fourier refinement. In the three-dimensional determination, the initial phase set could be compared to the original x-ray model as a mean deviation of 85 deg for all 127 hkl reflections but only 54 deg. for the 23 most intense maxima. Refinement improved the overall fit (mean error: 77 deg. but only 62 deg. for the 23 most intense reflections). Because the phase value of the strongest reflection was greatly improved, the electron density map was closer to that of the actual structure. However, assumption of globular substructure causes the 3-D density map to become discontinuous. The success of this phasing attempt is quite surprising for an example where the solvent space contains a high concentration of ammonium sulfate, where the contrast at low resolution should be reversed. On the other hand, simulations of 'missing cone' problems with this protein model revealed the same accuracy for predicting missing phase information, irrespective of whether the observed or calculated x-ray amplitudes were used for expanding the basis set.

M09.AA.005 VERY LOW RESOLUTION PHASING OF RIBOSOMAL PARTICLES USING MOLECULAR REPLACEMENT WITH MODELS FROM EM. I. Agmon, Weizmann Institute, Rehovot, Israel; A. Tocilj and A. Yonath, Weizmann Institute, Rehovot, Israel and MPG, Hamburg, Germany

The ribosome is the universal cell organelle which plays an essential role in protein biosynthesis; it catalyzes the translation of genetic information encoded in mRNA into proteins. The elucidation of the ribosome structure, which is a prerequisite for understanding the molecular mechanism of protein biosynthesis, is therefore of great interest.

The packing schemes of the whole 70S ribosome and the large subunit (50S) from Thermus Thermophilus were determined at very low resolution using molecular replacement, with 3D cryo EM reconstructions serving as models. The applicability of such a procedure for correctly placing particles lacking internal symmetry in their crystallographic cells, was shown by Urzhumtzev & Podjarny [1].

The MR searches gave a single well contrasted solution for each of the particles, which permitted the determination of their position and orientation in the unit cells, followed by the assembling of very low resolution maps.

Several types of verification tests were performed, all found to support the MR results. These include: 1. packing examination; 2. scaling Fc from the suggested structures to Fobs; 3. using calculated phases to locate heavy atom sites (T50S); 4. comparing a projection of the suggested packing to that observed previously in electron micrographs of thin sections of crystals (T70S).

P09.AA.001 THE CONNECTIVITY-BASED CHOICE IN MACROMOLECULAR LOW RESOLUTION AB-INITIO PHASING. N.L.Lunina and V.Y.Lunin, Institute of Mathematical Problems of Biology RAS, Pushchino, Moscow region, 142292 Russia and A.G.Urzhumtsev, LCM^{3}B, Faculté des Sciences, Université Henri Poincaré, Nancy I, 54506, Vandoeuvre-lès-Nancy, France.

The known figures of merit (FOM) do not allow usually, to make unambiguous choice of the best phase set when applied in a restricted low-resolution (LR) zone. Nevertheless, when coupled with cluster analysis methods they allow to reduce the phase problem to the problem of the choice among a relatively small number of alternative phase sets [1]. The connectivity features may be used as an additional criterion to perform this choice. The idea to use the number of connected components in the region of high electron density values as a FOM was suggested first [2] for middle and high resolution syntheses. It is expected at these resolutions to have the minimal possible number of connected components for well phased syntheses and multiple "drops" for the badly-phased ones. On contrary, LR poorly phased syntheses show rather merged molecular images than multiple drops and the region of high density at a good LR synthesis usually contains as many equal connected images as the number of molecules in the unit cell is. The minimal possible cut-off level in a Fourier synthesis, still resulting in the desired number of connected components, may be used as a selection criterion in LR ab-initio phasing. A special modification of LR syntheses can be applied in some cases to make them more suitable for the application of this criterion [3].

P09.AA.002 AB INITIO PHASING USING MOLECULAR ENVELOPE FROM X-RAY SOLUTION SCATTERING. Q. Hao, De Montfort University, Leicester, LE1 9BH, UK, F. E. Dodd, J. G. Grossmann and S.S. Hasnain, CLRC Daresbury Laboratory, Warrington, WA4 4AD, UK.

A method for macromolecular structure determination is presented which utilizes the low resolution molecular shape obtained from solution X-ray scattering data. The molecular shape of a protein is an important structural property and can be determined directly by the small angle scattering technique. The idea of locating this molecular shape in the crystallographic unit cell has been tested with experimental diffraction data from nitrite reductase (NiR) [1]. The conventional Patterson search [2] proved to be unsuccessful as the intra-envelope vectors are uniformly distributed and do not match those of intra-molecular (atom to atom) vectors. A direct real space search for orientation and translation was then performed. A self rotation function using 2.8Å crystallographic data yielded polar angles of the non-crystallographic three-fold axis. The knowledge of the orientation of this axis has reduced the potential 6-dimensional search to 4 (Eulerian angle γ and three translational parameters). The direct 4-dimensional search within the unit cell has produced a clear solution. The electron density map based on this solution agrees well with the known structure and the phase error calculated from the map was 61 degrees within 20Å resolution. It is anticipated that the low resolution envelope can be used as a starting model for phase extension by the maximum entropy and density modification method.

09BB MOLECULAR BASIS OF DISEASE AND TOXICITY

M09.BB.001 STRUCTURAL STUDIES ON HIV-1 CORE PROTEINS. Christopher P. Hill, Biochemistry Department, University of Utah School of Medicine, 50 N. Medical Drive, Salt Lake City, UT 84132, USA.

Retroviruses, such as HIV-1, assemble into virions comprised primarily of the Gag protein. Cleavage of Gag into its constituent domains of matrix (MA), capsid (CA), and nucleocapsid (NC) proteins, is performed by the viral protease, and serves to signal for a dramatic rearrangement of the viral core that is known as maturation.

The viral MA protein serves as the membrane-binding domain of Gag and remains associated with the membrane following maturation. We have determined the X-ray crystal structure of HIV-1 MA. This reveals a trimeric association that is conserved in three different crystal forms and in the crystal structure of the protein from SIV. Mutagenic data suggest that the crystallographic trimer is biologically relevant and indicates the likely membrane-binding surface.

The HIV-1 CA protein forms an essential interaction with the cellular protein cyclophilin A (CypA). We have determined the crystal structure of a complex between the CA N-terminal domain and CypA. This result suggests that CypA may function as a sequence specific binding protein, although the basis of HIV-1's requirement for CypA remains unclear. We have also determined the crystal structure of the CA C-terminal domain, which is the dimerization domain of full-length CA. This structure reveals the dimerization interface and provides a model for the full-length protein. A combination of the high-resolution crystal structures with cryo electron microscopic analysis of capsid assemblies provides a model for the cone-shaped core of mature infectious virions.

M09.BB.002 CRYSTALLOGRAPHIC STUDIES OF THE ANTHRAX LETHAL TOXIN. Robert Liddington, Biochemistry Department, University of Leicester, U.K. New address from 10/99: The Burnham Institute, 10901 North Torrey Pines Rd., La Jolla, CA 02037 USA.

Anthrax is probably best known as an agent of biological warfare, but the toxin produced by anthrax is also being developed for medical use as a protein delivery system that could deliver useful proteins into cells. Anthrax Toxin comprises two distinct proteins: the so-called Protective Antigen (M.W. 83 kDa), named for its use in vaccines; and the Lethal Factor (M.W. 87 kDa), a metalloprotease whose target is currently under investigation [1]. The two proteins are harmless by themselves, but in combination they kill their host by invading macrophages and overstimulating the immune response, leading to death by toxic shock. We have recently determined the crystal structure of the 735-residue Protective Antigen in its monomeric form as well as the membrane-inserting heptamer (M.W. 440 kDa) that is produced following activation on the host cell surface [2]. We have recently made substantial progress in the structure determination of Lethal Factor, and this will be presented. Heptameric PA binds tightly to Lethal Factor; the complex is endocytosed, and acidification of the endosome triggers membrane insertion and translocation of the Lethal Factor into the cytosol. The structural information is now being used in the design of experiments that will elucidate how these steps are achieved at the atomic level [3].

M09.BB.003 STRUCTURE OF A THIOL-ACTIVATED CYTOLYSIN AND A MODEL OF ITS MEMBRANE FORM. J. Rossjohn, S.C. Feil, W.J. McKinstry, R.K. Tweten & M.W. Parker. The Ian Potter Foundation Protein Crystallography Laboratory, St. Vincent’s Institute of Medical Research, 41 Victoria Parade, Fitzroy, Victoria 3065, Australia. Dept. of Microbiology and Immunology, The University of Oklahoma Health Sciences Center, Oklahoma City, Oklahoma 73190, USA.

The mechanism of protein insertion into membranes has generated biological interest. The thiol-activated cytolysins (TACs) are pore-forming toxins that are secreted by taxanomically diverse species of gram-positive bacteria which in turn are responsible for life-threatening infections. To date, more than 20 members have been characterized, including perfringolysin O (PFO) from *Clostridium perfringens*, pneumolysin from *Streptococcus pneumoniae* and listeriolysin O from *Listeria monocytogenes*. Each toxin consists of a single polypeptide chain with molecular weights ranging from 50kDa to 80kDa. The sequence identity amongst the family is high (40 to 70%) suggesting they will all have very similar three-dimensional structures. There is nothing in the primary structures of the TACs to explain how the toxins can insert into membranes to form pores. The longest stretch of sequence identity between the toxins is a C-terminal conserved tryptophan rich sequence (the Trp-rich motif) 458 ECTGLAWEWWR) 468 (PFO numbering). This Trp-rich motif is implicated in binding to the receptor, cholesterol. The toxins share a common mode of action in killing eukaryotic cells: they interact with the target cells via the receptor, cholesterol, which is followed by oligomerization and membrane insertion. This integration into the membrane results in the formation of large oligomeric pores, with diameters exceeding 150Å, causing cell lysis. The structure of PFO was solved by the MIR method. Here I present the 2.2Å crystal structure of PFO, an unusually elongated rod-shaped molecule of dimensions 115Å x 55Å x 30Å, rich in β-sheet. The data presented reveals how the toxin changes from a completely water-soluble protein to a membrane pore.

M09.BB.004 A KEY ENZYME IN INFLAMMATION WITH A BIFUNCTIONAL ACTIVE SITE: LEUKOTRIENE A_4 HYDROLASE AT 1.95 Å RESOLUTION. Marjolein Thunnissen[1], Pär Nordlund[1] & Jesper Haeggström[2]. [1]Department of Biochemistry, University of Stockholm, Arrhenius laboratories A4, S -106 91Stockholm, Sweden: [2]Department of Medical Biochemistry & Biophysics, Karolinska Institute, S-171 77 Stockholm, Sweden.

The eicosanoids (prostaglandins, thromboxanes and leukotrienes) have been shown to play a role in many processes such as inflammation, hypersensitivity and allergic reactions, in diseases such as asthma and arthritis. The potent chemotactic leukotriene B_4 is formed from arachidonic acid via the sequential action of two enzymes: 5-lipoxygenase catalyzes the formation of the epoxide intermediate LTA_4 which is in turn converted into LTB_4 by the enzyme LTA4 hydrolase. In addition to its epoxide hydrolase activity, LTA_4 hydrolase also possesses peptidase/amidase activity towards synthetic substrates. Site directed mutagenesis studies have shown that His295, His299 and Glu318 are Zn binding ligands and that Glu296 is the catalytic amino-acid for the peptidase activity, for which a general base mechanism has been proposed. Much less is known about the epoxide hydrolase activity, although mutations at positions 296 and 383 showed that these residues are not essential. Combined with the fact that the Zn^{2+} ion is essential for both reactions, it appears that the active sites are not identical but rather overlapping. In view of the potential importance of LTA_4 hydrolase as a target for the treatment of inflammatory diseases, novel selective inhibitors have been developed based on substrate mediated inactivation of the enzyme. With the help of structural information, these compounds might be used as lead compounds and ultimately be developed into novel anti-inflammatory drugs.

We have recently solved the crystal structure of human LTA_4 hydrolase complexed with the transition analogue bestatin at 1.95Å resolution. The structure of the 69 KDa protein was determined by MAD methods and is currently being refined. The protein is folded into three domains: N-terminal, catalytic and a C-terminal domain which together form a flat triangular arrangement. Between the domains a deep cleft is formed in which the Zn^{2+} binding site is located. The N-terminal domain has structural homology with bacteriochlorophyll *a,* while the catalytic domain has surprising structural similarity to thermolysin, although sequence identity is minimal. The structure provides the basis for understanding substrate binding, the molecular mechanisms of catalysis, the manner in which the two catalytic functions are organised and the basis for suicide inactivation. Based on the structure we can propose a putative LTA_4 binding site and reaction mechanisms for both the epoxide reaction as well as for the peptidase activity.

M09.BB.005 THE ADENOVIRUS FIBRE SHAFT FOLD, A TRIPLE BETA-SPIRAL. M.J. van Raaij, N. Cohet, S. Cusack [1], G. Lavigne, A. Mitraki [2], [1] EMBL Grenoble outstation, 9 rue Jules Horowitz, 38000 Grenoble, France, [2] Institut de Biologie Structurale, Grenoble, France

Adenovirus binds to its host cells via its trimeric fibre protein. The serotype 2 fibre protein contains three domains: a small N-terminal viral anchor sequence, a long thin shaft containing a 21-fold repeating sequence and a C-terminal cell attachment domain, of which the structure is known. It is of prime interest for gene therapy. We have now solved the atomic structure of the of four of the 21 repeats at 2.4 Å resolution. The shaft repeats contain a striking hitherto unknown fold composed of beta- strands, which allows us to explain its extra-ordinary stability. This fold may have homology in the bacteriophage T4 tail fibre and certain insect silks.

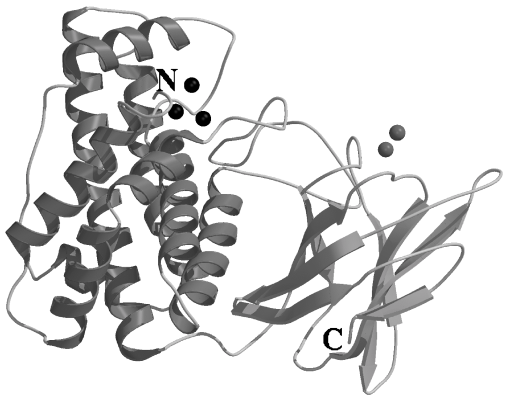
M09.BB.006 CONFORMATIONAL DISEASE : SERPINS AS A MODEL FOR PRION AND OTHER DEMENTIAS. R.W. Carrell, P.E. Stein and D.A. Lomas, Structural Medicine, Dept. of Haematology, University of Cambridge, Cambridge Institute for Medical Research, Hills Road, Cambridge CB2 2XY, UK.

The serpins provide a model for other protein families that have similar inherent ability to change fold. Such transitions however involve risks, as their aberrant occurrence can result in intermolecular linkages with consequent tissue deposition and disease. There is now great interest in such conformational diseases which include the perplexing neurodegenerative disorders; Alzheimer’s dementia and the prion encephalopathies. A series of crystallographic studies of the serpins illustrates the structural diversity of the molecular associations potentially involved : from dimerisation and polymerisation to fully ordered amyloid-fibril formation. The exposed reactive centre loop of serpins readily takes up a ß-pleated structure to allow its insertion as an extra middle strand in the 5-stranded A ß-sheet of the molecule. Pathologically intermolecular linkage can occur from

what is in effect a domain swap, with the reactive loop of one molecule aberrantly inserting into the middle of the A-sheet of the next, to give loop-sheet polymers. But linkage can also occur by external strand addition or displacement. This latter mechanism in the serpin antithrombin demonstrates in precise structural detail the sequential changes occurring at the onset of a conformational disease, with particular relevance to current proposals for the conformational infectivity of the prion encephalopathies. The initial change in antithrombin is a monomeric transition to the inactive 6-stranded latent form, followed by a propagation of conformational change to a normal active molecule with linkage of the two and with glycoform selectivity followed by stabilisation of the complex by heparin-type GAGs. The model is validated with respect to the dementias by recent findings by colleagues (A. Shrimpton, R. Davis, P. Holohan; Syracuse New York) of mutations, in a neurone-specific serpin, present in families with inclusion-body dementias. The mutations provide a striking confirmation of proposals for a conformation-based mechanism for late-onset dementias.

P09.BB.001 THE STRUCTURE OF CLOSTRIDIUM PERFRINGENS ALPHA-TOXIN: A GANGRENEOUS TALE. C. E. Naylor, J. T. Eaton, N. Justin, D. Moss and A. K. Basak, Dept of Crystallography, Birkbeck College, Malet Street, England, WC1E 7HX and A. Howells and R. Titball, CBD, Porton Down, Salisbury, SP4 0QJ, England.

C. perfringens α-toxin is the key virulence determinant in gas-gangrene disease, and has also been implicated in a number of other diseases of man and animals. The toxin is a 370 amino acid zinc metalloenzyme which has phospholipase C, sphingomylinase and haemolytic activities. In the presence of calcium ions, α-toxin can cleave membrane packed phospholipid. Here, we present the structure of the *C. perfringens* α-toxin. It is a 2 domain structure. The N-terminal, catalytic domain (residues 1-246) shows an anticipated structural homology to the non-toxic *B. cereus* phospholipase C. Both proteins contain 3 bound zinc ions: the residues that ligate the metal ions are completely conserved between the two proteins. There are a number of structural differences between the two enzymes, however, and these will be described. The C-terminal domain (residues 255-370) is essential for membrane binding, and is associated with toxicity. This domain has a strong, structural analogy to the eukaryotic C2 domain fold. The C2 domain is normally found acting as a phospholipid and/or calcium-binding domain in intracellular second messenger proteins. This homology has been useful in defining a possible model for membrane binding, which, when compared with other, analogous, but non-toxic, phospholipases, has implicated structural features important for toxicity.



Secondary Structure Cartoon of α-toxin. Zinc ions are shown as black spheres, possible calcium binding sites are highlighted as grey spheres.

P09.BB.002 INSIGHT INTO THE CARDIOLIPIN BINDING BY HUMAN β2-GLYCOPROTEIN I, A KEY STEP IN "ANTI-PHOSPHOLIPID-SYNDROME". B.Bouma [1], J.M.H. van den Elsen [1], R-B. G. Ravelli [2], A. Schouten [1], D.A. Horbach [3], Ph.G. de Groot [3], J. Kroon [1] and P. Gros [1]. [1] Bijvoet Center for Biomolecular Research, Crystal and Structural Chemistry, Utrecht University, Padualaan 8, 3584 CH Utrecht, The Netherlands, [2] EMBL Grenoble outstation, Jean Marie BOIS, BP 156, 38042 Grenoble CEDEX 9, France, [3] Department of Haematology, University Hospital Utrecht, P.O. box 85500, 3508 GA Utrecht, The Netherlands.

The crystal structure of β2-Glycoprotein I (β2GPI), the antigen for anti-β2GPI autoantibodies, provides putative insight into the mechanism of its binding to cardiolipin, an event preceding the autoimmune response in patients with "Anti-Phospholipid-Syndrome" (APS).

The structure of the 45 kDa β2GPI has been determined by the MIR method at 2.7 Å resolution. The orthorhombic crystals contain an extremely high solvent content of 83%, and the asymmetric unit contains one protein molecule. The structure was first built at 3.75 Å using the NMR structure of Vaccinia Virus Complement Control Protein to search for the Sushi domain folding pattern. The final model consists of a.a. residues 1-309, 319-326 and sugar residues attached to four Asn residues. The protein is built up by an elongated chain of four Sushi domains and a fifth modified Sushi domain. The β2GPI-cardiolipin interaction region is located in the fifth domain and consists of a recognition loop with the motif KNKEKK, as deduced by peptide binding studies. The position of this loop and the location of other residues gives structural detail about β2GPI interaction with negatively charged phospholipids. The putative model for β2GPI in the removal of apoptotic cells is supported by this structural insight. The packing arrangement in the crystal gives information about possible β2GPI dimerization interfaces and putative antibody binding sites. The structure-function relationship with respect to APS is currently being evaluated.

P09.BB.004 STRUCTURE OF BACILLUS THURINGIENSIS D-ENDOTOXIN CRY1AC AND LOCATION OF ITS RECEPTOR BINDING SITES. J.Li, D.J.Derbyshire [1], D.J. Ellar [2]. [1] MRC Laboratory of Molacular Biology, Hills Road, Cambridge CB2 2QH, UK, [2] Biochemistry Department, Cambridge University, 80 Tennis Court Road, Cambridge CB2 1GA, UK

Cry1Ac is a pore-forming toxin specifically active against lepidopteran insects. A membrane receptor from the susceptible insects has been identified as aminopeptidase N (APN). N-acetylgalactosamine (GalNAc) was shown to be part of APN, and it competitively inhibits the binding of Cry1Ac to this receptor. We have crystallised trypsin-activated Cry1Ac from B.t. ssp. HD-73 in space group P1, with 4 molecules in a unit cell of dimensions a = 51.78Å, b = 113.23Å, c = 123.41Å, α = 113.10°, β = 91.50° and γ = 91.49°. The structure has been determined at 2.36 Å resolution by molecular replacement from Cry1Aa (PDB code 1CIY) followed by 4-fold averaging. The atomic model, comprising 4 copies of a continuous polypeptide chain between residues 33 and 611 and 591 solvent molecules, has been refined to an R-factor of 21.6% (R-free = 27.3%), with 90% of the residues in the most favoured regions of the Ramachandran plot.

In domain I (helix bundle) responsible for the pore formation, Cry1Ac is highly similar to Cry1Aa with an rms Ca distance of 0.36Å. In domain II (b-prism) they are similar over the sheets (rms Ca distance = 0.61Å), but at the apex loops 2 and 3 have distinct conformations. These localised differences correlate well with sequence exchange and mutagenesis data which implicate residues in these two loops in the initial binding to the receptor. In domain III (b-sandwich), however, striking structural differences between the two toxins are found. In

particular, Cry1Ac shows an insertion relative to Cry1Aa of six residues which form a protruding loop. The inserted sequence is unique to Cry1Ac among the Cry toxins. Exchange of a short sequence which contained the insertion loop, and mutations within this loop, have been found to reduce the specific toxicity of Cry1Ac and abolish GalNAc-dependent receptor binding. Therefore Cry1Ac possesses a second receptor binding site in the region of the domain III insertion, distant from the previously known binding site at the apex of domain II. Furthermore, the outer sheet of domain III in Cry1Ac shows a relative rotation by about 8° and a very different twist when compared with Cry1Aa. Contrasting this difference with the general conservation of domain III structure between the Lepidoptera-specific Cry1Aa and Coleoptera-specific Cry3A suggests that the additional binding site in domain III may be unique to Cry1Ac, which may account for its greater potency among the Cry toxins.

09CC HIGH PRESSURE DATA ACQUISITION AND ANALYSIS

M09.CC.001 NEW METHODS FOR INDEXING IN HIGH-PRESSURE POWDER DIFFRACTION. Scott A. Belmonte and Richard J. Nelmes, Department of Physics and Astronomy, The University of Edinburgh, Mayfield Road, Edinburgh, EH9 3JZ, U.K.

When determining structures from powders, indexing the powder pattern is the crucial first step. If a pattern cannot be indexed no further progress can be made on structure solving. Many materials are being found to have remarkably complex structures at high pressure, with quite large unit cells and many independent atomic coordinates. This complexity combined with the limited quality of the data available in high-pressure experiments make indexing many powder patterns far from trivial. In fact, in these cases, indexing is often the limiting step in the structure determination process.

With this in mind, a new, general, approach for indexing powder patterns based on whole-pattern fitting and genetic-algorithm optimisation of lattice parameters will be presented in detail. The advantages of such a method for indexing powder patterns from materials at high pressure will be discussed together with the possible limitations of the approach. Examples of the successful application of this method will be given.

A second novel technique that exploits information from a textured powder sample to aid indexing will also be described briefly [1]. It will be shown how variations in intensity around powder rings due to preferred orientation can contain information about the lattice parameters.

[1] "TEXTURE AS AN AID TO INDEXING AND STRUCTURE SOLUTION IN POWDER DIFFRACTION", same authors, this Congress.

M09.CC.002 IN SITU X-RAY STUDY IN ELECTRICALLY HEATED DAC – FORM CRYSTAL STRUCTURES TO STRUCTURE OF THE EARTH. L. Dubrovinsky, S. Saxena, S. Rekhi, Department of Earth Sciences, Uppsala University

Since their discovery in 1895, X-rays have proven to be a vital tool of science, making it possible to examine previously hidden worlds ranging from the tiniest of atoms to the most distant galaxies in space. Experimental studies of geophysically important materials at high pressures require in situ x-ray diffraction. It is practically the only method which provides direct information on phase relations and structures. We developed electrical heating assemblage for DAC which allows us to collect diffraction patterns in multimegabar pressure range at temperature to 1200 C using synchrotron or in-house X-ray facilities.

External electrical heating assemblage employs flexible graphite foils of thickness around 1.5 mm. In such a design, both the diamonds and gasket can be heated homogeneously to over a temperature of about 1200ºC. Two rectangular slabs (25*10mm^2) were amputated from a flexible graphite foil of thickness 1mm. Small pieces (10*10mm^2) of the graphite foil of thickness 0.5 mm were glued at the edges of these slabs along their lengths using high temperature graphite glue. These small pieces at the edge of the slabs make the assemblage stable on the cell and "concentrate" the heat on the sample and diamonds. The slabs were indented simultaneously and the Re-gasket was placed in between them. Two molybdenum electrodes (thickness 4mm) were carefully inserted between the two slabs of graphite foils and finally glued using a high temperature ceramic glue. The sample was heated using a DC power supply, with an operating range up to 200A/50V. The maximum current needed for heating a sample at 200 GPa to 1000 C was around 150 A. For measuring the temperature, a Pt/Pt13%Rh precision thin microthermocouple with a junction diameter less than 25 m was used. The junction of thermocouple was carefully inserted between the two parts of the graphite heater foils as shown in figure, such that it can touch the gasket sitting between them.

We used electrically heated DAC to study thermal expansion and phase transition of iron, $MgSiO_3$ perovskite and silica at high pressure and used results for analysis composition and the structure of the Earth.

M09.CC.003 HIGH P-T NEUTRON DIFFRACTION EXPERIMENTS AT LANSCE. Yusheng Zhao, Robert V. Von Dreele, LANSCE, Los Alamos National Laboratory, Los Alamos, NM 87545, U.S.A.

In-situ high P-T neutron diffraction experiments provide unique opportunities to study texture, hydrogen bonding, magnetic moments, structural and thermal parameters of light elements (eg. H, Li, C) and heavy elements (eg. Ta, U, Pu,), which are virtually impossible to determine by x-ray diffraction techniques. For example, we can derive thermoelasticities and Debye-Waller factors as function of pressure and temperature using in-situ high P-T neutron diffraction techniques. These applications can also be extended to a much broader spectrum of scientific problems. For instance, puzzles in Earth science such as the carbon cycle and the role of hydrous minerals for water exchange between lithosphere and biosphere can be directly addressed. Moreover, by introducing in-situ shear, texture of metals and minerals accompanied with phase transitions at high P-T conditions can also be studied by high P-T neutron diffraction experiments.

We have successfully conducted high P-T neutron diffraction experiments at LANSCE and achieved simultaneous high pressures and temperatures of 10 GPa and 1500 K. With an average 5-6 hours of data collection, the diffraction data is of sufficient high quality for the determination of structural parameters and thermal vibrations. We have collected the diffraction patterns of an amorphous material (carbon black), a hydrous mineral (MgOD), and some metals (Mo and Ta). The aim of our research is to accurately map bond lengths, bond angles, and neighboring atomic environments in P-T space. Studies on high-pressure crystal chemistry and thermoelastic equations of state are also ongoing. We are conducting further development of high P-T technology with respect to the press, anvil and furnace design, thermal and electric insulation, selection of gasket materials and re-enforcement rings, protection of electric and thermocouple leads, etc. We expect to ultimately achieve pressures of 30 GPa and temperatures of 2000 K with our new press TAP-98 and new beam-line HIPPO at LANSCE.

M09.CC.004 KINETIC STUDIES AT HIGH PRESSURE AND HIGH TEMPERATURE-DATA ANALYSIS. M. Mezouar and A. P. Hammersley, ESRF, Grenoble, France

A new set-up for collecting high quality data suitable for structural refinements at high pressures and high temperatures has been developed on the beam-line ID30 at the European Synchrotron Radiation Facility (ESRF). The possibility to use high X-ray energies, high brilliance of third generation source, new fast imaging plate detector interfaced to the Paris-Edinburgh large volume press has lead to a significant reduction of acquisition time and improvement of the quality of the data. The rapid acquisition of high quality 2D images allows time resolved experiment in one-minute range and gives access to the kinetics of phase formation and chemical reaction. However, these kind of experiments generate enormous quantities of data, and automatic analysis of this data is highly desirable. In FIT2D the "FILES SERIES" option "INTEGRATE" has been developed to allow the combination of interactive data analysis and subsequent automated analysis. Raw data may optionally be corrected for detector distortions, and integrated to 1-D 2-theta scans with user defined making. After successful integration of the first image the integration is repeated automatically for subsequent images. This allows efficient analysis of enormous quantities of data (Gbytes). Several examples will be presented including:

- The formation processes of the high Tc superconducting compounds $HgBa_2CuO_{4+d}$ and $HgBa_2Ca_2Cu_3O_{8+d}$ [1] from the complex mixing precursors: $BaCuO_2$, Ca_2CuO_3 and HgO at high pressure (2 to 4 GPa) and high temperature (up to 1200°C).
- The in situ study of the C_{60} polymerization at HP and HT.

M09.CC.005 APPLICATION OF MAXIMUM ENTROPY TO HIGH-PRESSURE X-RAY POWDER DATA: CAN IT HELP TO FIND THE PROTONS? R.J. Papoular, LLB, CEA-Saclay, 91191 Gif-sur-Yvette, France.

This paper will focus on the the joint use of powder diffraction data analysis and Maximum Entropy to help track down protons in solids from X-ray data. A Lebail-like analysis will first be introduced to produce error bars on extracted Lebail-intensities. In a second step the use of a non-uniform electron density prior within the framework of Maximum Entropy electron density reconstructions will be advocated to push down the threshold of detectability of weak scatterers. As an example, the data analysis of synchrotron x-ray data pertaining to $Ca(OH)_2$ data under high pressure and the validity of the related results will be discussed. Limitations on the stand-alone application of ME will be stressed, and the use of complementary data processing techniques advocated.

P09.CC.001 SINGLE CRYSTAL DIFFRACTOMETRY AT HIGH PRESSURES. L.W. Finger, Geophysical Laboratory, Carnegie Institution of Washington, 5251 Broad Branch Rd., NW, Washington DC 20015, USA, and R.J. Angel, Bayerisches Geoinstitut, Universität Bayreuth, D95440 Bayreuth, Germany.

Over the past decade we have been developing both hardware and software for the purpose of obtaining more precise measurements of lattice parameter variations with pressure through single-crystal diffraction.

The program SINGLE has been developed to control four-circle diffractometers and to perform both lattice parameter measurements and intensity data collections. Elements of the software essential for obtaining precise lattice parameters include full peak-profiling, the use of Hamilton's method of eight-position centring [1], and vector-least-squares fitting of the UB matrix to the diffractometer setting angles of reflections [2]. The consequences of ignoring these procedures will be illustrated in the poster.

The software is written to be mostly machine- and platform-independent; the computer-diffractometer interface is an entirely separated part of the software and can be rewritten for new installations. SINGLE is currently being used to drive four-circle diffractometers in laboratories in the Geophysical Laboratory, the Bayerisches Geoinstitut, ETH Zürich, and University College London. A comparative study of data collected at these installations is currently under way and will be presented. In particular, the influence of the choice of peak profile function for various diffractometer configurations and the implications for diffractometer design will be discussed.

P09.CC.002 COMBINED CCD/IMAGING PLATE DETECTION SYSTEM FOR MONOCHROMATIC XRD STUDIES AT HIGH PRESSURES AND TEMPERATURES AT THE X-17 BEAMLINE, NSLS. J. Chen, M. T. Vaughan, D. J. Weidner, C. C. Koleda, K. J. Baldwin, W. Huebsch and J. B. Parise, CHiPR§ and Geosciences, SUNY, StonyBrook, NY 11794-2100, USA. § Center for High Pressure Research, an NSF funded Science and Technology Center

The Translating Imaging Plate (TIP) detection system has largely fulfilled its original potential for the acquisition of high quality monochromatic powder diffraction data, allowing the study of time resolved phenomena at high pressure (Chen et al., 1998; Parise *et al.,* 1998). This has allowed not only the elucidation of phase transitions, but also refinement of crystal structure based upon these data (Chen et al., 1998), thereby allowing the transition to be followed on an atomistic level.

Unfortunately, some of the advantages of polychromatic studies, chiefly the excellent collimation, which excludes parasitic scattering from the high pressure vessel, and the quasi-real-time feed back of the diffraction data, are lost in the monochromatic IP experiment. The former problem can be solved using software techniques (Chen *et al*, 1998) but the later can be problematic. For example, a TIP has a limited translation range and requires real-time feedback to provide a trigger to activate the plate at a time appropriate to capture the transition. Ideally this would be done without resorting to guesswork, or to several loadings of the high pressure device. Coupling a CCD detector with the TIP can provide this feedback. Such a device has been installed on the large volume DIA apparatus (SAM-85) at the X-17 beamline at the National Synchrotron Light Source. The device has been tested and used in several classes of experiments. These include rheological studies of olivine, determination of phase transitions in Fe_2SiO_4 and FeS and other applications requiring the resolution, ready quantification and texture analysis afforded by monochromatic powder diffraction with area detectors.

P09.CC.003 FIRST COUPLING OF LOW TEMPERATURE AND HIGH PRESSURE TECHNIQUES FOR MOLECULAR CRYSTAL X-RAY STRUCTURES. Y. Barrans, J. Gaultier, D. LePevelen, D. Chasseau, Laboratoire des Sciences Moléculaires, Institut de Chimie de la Matière Condensée de Bordeaux, 87 avenue du Dr. A. Schweitzer, UPR CNRS 9048 F-33608, Pessac, France.

Since 15 years, two apparatus have been developped by J.G. to study organic single crystal structures either down to 10K or up to 3GPa, and now crystals under pressure can be analyzed by X-Rays down to 7K. Both of them use a vertical He closed cycle APD Displex 202 cryostat. The crystal on a brass rod is linked to the cold finger and surrounded by two Be walled containers. The inner one is filled with He. Between both of them is a heat shield and high vacuum is established.

(i) the special normal beam diffractometer Huber-Gaultier is equipped with the 6.5K cryostat. A specific program is used to collect up to 90% of the diffracted intensities in the whole space with MoKα radiation and a scintillation detector. New containers allow now measurements with the pressure cell (4x4 cm cylinder, diamond anvils, crystal in the hole of a Be gasket filled with a liquid). For the first time in the world, diffracted intensities of molecular compounds have been collected with the coupled techniques low temperature + high pressure and the solved crystal structures show very interesting results (thesis, D.LP, 1999).

(ii) a specially designed camera permits to get Bragg, Weissenberg and Laue patterns from room temperature to 10K with the 10K cryostat. It is used to study the behaviour of crystals, especially the phase transitions, and can be followed by structure determination with the diffractometer measurements It has been modified to receive the pressure cell.

09DD OPTO-ELECTRONIC MATERIALS

M09.DD.001 FERROELECTRIC OXIDES FOR OPTOELECTRONIC APPLICATIONS. Ch. Buchal, Forschungszentrum Juelich GmbH, Institut fuer Schicht-und Ionentechnik ISI-2, D 52425 Juelich, Germany

We discuss the physics and structure- properties- relations of the optical perovskites and related materials and their applications for optoelectronic devices and functions, especially: - optical waveguides - modulators - non-linear devices as frequency converters - amplifiers and lasers - photorefractive components - holographic storage. The following processing issues will be addressed: Ion implantation for doping and damage engineering, waveguide fabrication, epitaxy and thin film growth and patterning.

M09.DD.002 BLUE LIGHT GENERATION BY FREQUENCY DOUBLING AND SUM-FREQUENCY MIXING OF LASER DIODES IN $KnbO_3$. D. Fluck and P. Günter Nonlinear Optics Laboratory, Swiss Federal Institute of Technology ETH-Hönggerberg HPF E7, 8093 Zürich, Switzerland.

Potential applications of compact blue lasers include data storage, colour printing, displays, biofluoresence, photolithography, remote sensing, chemical and biological species detection, high resolution spectroscopy, underwater monitoring and communication. Direct second-harmonic and sum-frequency generation (SHG, SFG) with near infrared semiconductor laser diodes (LDs) offers the possibility of robust, compact and reliable blue lasers.

$KNbO_3$ crystals are very attractive for frequency conversion of near infrared LDs into the blue spectral range due to its high nonlinear optical coefficients, its numerous phase-matching (PM) configurations, and the absence of optical damage and gray tracking effects. Efficient blue light generation at 430 nm and 490 nm by noncritical PM SHG with LDs in $KNbO_3$ has been demonstrated for single-pass, resonant and waveguide configurations. Other wavelengths in the 415 to 475 nm spectral range can be efficiently generated by making use of $KNbO_3$ for SFG with commercially available single-mode AlGaInP, AlGaAs and InGaAs laser diodes.

We will review recent results on compact and efficient blue lasers based on noncritical PM SHG and SFG in $KNbO_3$ and discuss the advantages and disadvantages of different approaches including novel configurations.

M09.DD.003 MATERIALS AND DEVICES FOR Si-BASED OPTOELECTRONICS. S. Coffa, S. Libertino, G. Franzò and A. La Magna, CNR-IMETEM, Catania, Italy

Ion implantation can be successfully used to engineer the optical properties of crystalline Si and to obtain efficient light emission from this semiconductor. A detailed analysis of Er incorporation in Si and the role of codoping with O and F will be presented. Furthermore the mechanisms of excitation (by electron-hole recombination or impact excitation) and Auger-de-excitation of rare-earth ions in Si have been elucidate using photo- and electroluminescence, deep level transient spectroscopy and conductivity measurements. The detailed knowledge of the physical properties of the Er:Si system allowed us to fabricate Si LEDs operating at 1.54 μm with a quantum efficiency of 0.1% at room temperature and allowing direct modulation of the light output at frequencies of 10-100 MHz. These devices have been integrated with Si on insulators rib waveguides fabricated using standard lithography and reactive ion etching and exhibiting losses below 1 dB/cm at $\lambda > 1.2$ μm. These novel device structures have been used to design and fabricate electrically pumped optical amplifiers and lasers whose performances will be presented. Finally, in the talk the state-of-the art performances and perspectives of ion implanted Si light emitters using implantation of rare earths (Er, Tm), isoelectronic impurities (such as C) and Fe (forming small β-$FeSi_2$ precipitates) will be compared and their compatibility with ULSI Si technology assessed.

M09.DD.004 EPITAXIAL GROWTH OF ZnSe- AND GaN-BASED STRUCTURES FOR SHORT WAVELENGTH EMITTERS. Detlef Hommel Universität Bremen, Institut für Festkörperphysik, Kufsteiner Str., D-28334 Bremen

Both ZnSe and GaN are promising materials for short wavelength LEDs and laser diodes (LDs). Whereas GaN-based structures cover the spectral range from ultraviolet to (nearly) red in electroluminescence (LED) LDs emitting between 360 – 450 nm have been realized. Nevertheless, long lifetime stimulated emission has been obtained only around 400 nm (violet). For shorter wavelength a higher Al-content in the cladding layers is needed which increases the probability of cracks in the structure. Longer wavelengths require a higher In-content which is hampered by the miscibility gap between InN and GaN. Therefore, ZnSe-based LDs are the only possibility for the green spectral region where the human eye has its highest sensitivity.

The similarities and basic differences in the growth of GaN- and ZnSe-based structures will be presented and molecular beam epitaxy (MBE) and metal organic chemical vapor phase epitaxy (MOVPE) as growth methods compared. Both materials differ in the defect density they can withstand without disturbing their functionality. Typical etch pit densities (EPDs) for ZnSe LDs must be well below 10^4 cm^{-3} whereas GaN-LDs are still operating when the defect density is at least 3 orders of magnitude higher. The reasons for that will be discussed. In the case of ZnSe the heteroepitaxial approach on (110) GaAs will be compared to the homoepitacial one on conducting ZnSe substrates. Epitaxial

lateral overgrowth (ELOG) and other methods reducing the defect density will be presented in the case of GaN devices. Whereas large GaN crystals as substrate materials are still not available the hydride vapor phase epitaxy (HVPE) as well as thick MOVPE buffer layers offer the possibility of a quasi-homoepitaxial growth.

In an outlook the future of both material systems will be discussed from the crystal growth point of view.

M09.DD.005 FILM DEFECTS AND GROWTH DYNAMICS IN WIDE BANDGAP EPITAXY. F. A. Ponce, Department of Physics and Astronomy, Arizona State University, Tempe, AZ 85287-1504, U.S.A.

The III-V nitride semiconductors have achieved a high degree of notoriety in the last few years due to their unique properties and optoelectronic applications [1]. Light emitting devices based on double heterostructure InGaN/GaN films have been produced with light emission efficiencies exceeding incandescent lighting. Blue diode lasers with continuous operation for more than 10,000 hours have been reported and their commercial availability has recently been announced. The high optoelectronic performance of these materials follow a crystallographic nature that is very different from other semiconductors. Large dislocation densities are observed ($\sim 10^{10}$ cm^{-2}) and are associated with a columnar array of defect-free crystallites. The microstructure strongly depends on the initial stages of growth which rely on low temperature *nucleation* layers needed to overcome the natural tendency of three-dimensional island growth. The resulting defect structure plays a key role in the relaxation of thermal stresses, allowing the local growth of high quality heterostructures under otherwise highly unfavorable conditions. The nature of the substrate/thin film interfaces will be discussed, as well as the role of the buffer layer. Details of the dislocation arrangement and structure and correlation with light emitting properties will be presented for GaN thin films as well as for InGaN quantum well structures.

P09.DD.001 POWDER OR SINGLE CRYSTAL STRUCTURE - EXEMPLIFIED BY β_{co}-(BEDT-TTF)$_2$I$_3$. D. Madsen [1,2], M. Burghammer [1], S. Fiedler [1] and H. Müller [1]. [1] ESRF, BP220, F-38043 Grenoble Cedex, France. [2] Centre for Crystallographic Studies, University of Copenhagen, Universitetsparken 5, DK-2100 Copenhagen, Denmark.

The organic superconductor β-(BEDT-TTF)$_2$I$_3$ is a well-known system [1]. Former studies on electrochemically produced crystals have shown that the crystals contain a mixture of phases and that the T_c is 1.4K. Furthermore, a structural phase transition is observed at 175K [2]. Using a novel preparation method, a powder has been obtained containing a pure phase of β_{co}-(BEDT-TTF)$_2$I$_3$ with a T_c of 7.1-7.9K [3]. A powder study of the phase pure crystals was performed at 293K, but the refinement showed unrevealed structural features related to the superconducting properties of the compound. At ID13 at the ESRF, we have therefore performed a single-crystal study on several crystals with dimensions about 10×10×2μm. Full data collections were carried out to a resolution of about 0.7Å at 293(2)K, 200(2)K, 130(2)K, and 100(2)K with an LN2 cryostream, and a dataset at 35(5)K with an LHe cryostream constructed at the EMBL Grenoble Outstation. A structural phase-transition was observed between 200K and 130K of the phase pure single-crystals as was previously observed in the electrochemically produced crystals [2]. Full structure refinements have been carried out for the datasets at 293(2)K and 200(2)K while the datasets at 130(2)K, 100(2)K and 35(5)K still are under quantitative evaluation (Jan. 99).

P09.DD.002 EVOLUTION TOWARDS CENTROSYMMETRY OF THE NLO MATERIAL RbTiOPO$_4$ IN THE TEMPERATURE RANGE 293 - 973 K. P. Delarue and C. Lecomte, Laboratoire de Cristallographie et Modélisation des Matériaux Minéraux et Biologiques, LCM3B UPRESA 7036, Université Henri Poincaré, Nancy I, Faculté des sciences, BP 239, 54506 Vandoeuvre Lès Nancy Cédex, France. M. Jannin and G. Marnier, Laboratoire de Physique de l'Université de Bourgogne, LPUB UPRESA 5027, Faculté des sciences Mirande, BP 400, 21011 Dijon Cédex, France.

The crystal structure of rubidium titanyl phosphate, RbTiOPO$_4$ (space group Pna2$_1$), has been refined at room temperature, and at 473, 673, 873 and 973 K, by using single-crystal x-ray diffraction techniques. The data show a large anharmonic motion of the rubidium ions increasing with temperature. A model, which splits the Rb sites, describes the large and gradual Rb ions displacement versus temperature until the phase transition temperature (centrosymmetric space group Pnan). It permits to show the influence of these Rb ions displacements on the framework and principally on the shortest and largest bonds of the titanyl group. The study of the deviation to the centrosymmetric structure correlates directly the change towards centrosymmetry of the titanyl groups with the observed variation of the second harmonic generating (SHG) intensity.

09EE DYNAMIC ASPECTS OF MOLECULAR CRYSTALS

M09.EE.001 MULTI-TEMPERATURE ADP'S: INSIGHT INTO THE DYNAMICS OF CRYSTAL STRUCTURES. S.C.Capelli, H.B.Bürgi Laboratorium für Kristallographie der Universität Bern, Schweiz.

The observation that diffraction intensities decrease with temperature[1] proved that crystals are not dead objects but that atoms in crystals move around their equilibrium positions. Anisotropic displacement parameters (ADP), determined by x-ray or neutron diffraction, quantify this observation; they describe the time and space average distribution of atoms around their mean position in crystals.

Many components contribute to these parameters: the mean square atomic displacements from all possible motions (libration, translation, internal vibrations), from disorder (static or dynamic) and from systematic errors (either in the data or in the refinement model).

An analysis of ADP's aimed at uncovering non-trivial details of the dynamics of molecules in crystals must separate the different contributions and provide information on the correlation of atomic motions. Although in a single temperature diffraction experiment this information is lost, it can be retrieved from the temperature dependence of ADP's.

An algorithm capable of achieving these goals has been developed and implemented in a computer programm[2]. Accurate multi-temperature ADP's have been analyzed for a number of molecules. In each case an improved description of the crystal structure and of the molecular dynamics were obtained. The information would not have been accessible from ADP's measured at a single temperature.

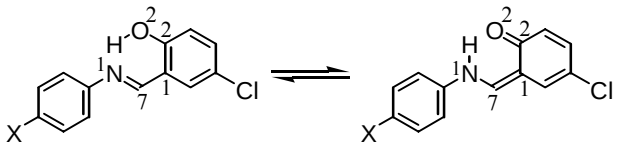
M09.EE.002 STRUCTURAL CHANGE FOR THERMOCHROMY OF SALICYLIDENEANILINES. THE FIRST OBSERVATION BY X-RAY ANALYSIS. Keiichiro Ogawa, Yoshiro Kasahara, Yohko Ohtani and Jun Harada, Department of Chemistry, Graduate School of Arts and Sciences, The University of Tokyo, Komaba, Meguro-ku, Tokyo, 153-8902 Japan.

Reversible change in color of substances with variation of the temperature is known as thermochromism and has attracted much interest from chemists for a long time. *N*-Salicylideneanilines belong to a class of the most popular thermochromic compounds. For example, the crystals of *N*-(5-chloro-2-hydroxybenzylidene)aniline (**1**) are orange-red at room temperature and pale yellow at 77 K, and their color changes reversibly with variation of temperature. Extensive studies have revealed that the thermochromism of *N*-salicylideneanilines originates from the tautomerism between the OH and NH forms. A change in the crystal structure for their thermochromy has, however, never been observed, although an attempt to do so was reported for **1** by Bregman et al. We wish to report the first observation of a crystal structure change for the thermochromy of ***N***-salicylideneanilines, using variable temperature X-ray analysis of *N*-(5-chloro-2-hydroxybenzylidene)-4-hydroxyaniline (**2**) [1].



OH form **NH form**

M09.EE.003 A UNIFIED APPROACH TO NUCLEAR DENSITY: NEUTRON DIFFRACTION, INELASTIC SCATTERING AND SIMULATION. G. J. Kearley, B. Nicolai, and M. R. Johnson, Institut Laue Langevin, BP156, 38042, Grenoble, Cedex 09, France, P. Schiebel, Institut fur Kristallographie, Universitat Tubingen, 72070, Tubingen, Germany.

Time-averaged nuclear density is conveniently fitted within the harmonic approximation, but a physical justification for this, and the true nature of the underlying dynamics are not necessarily considered. Maximum entropy and reverse Monte Carlo methods make no such assumption, but their success depends critically on the quality of the data, and again the dynamics can only be inferred. The dynamics of the nuclei is measured directly by inelastic neutron scattering and it is now relatively simple to analyse these data by molecular dynamics, which normally includes all aspects of classical motion, or molecular mechanics when quantum motion is dominant. This analysis leads back to the time-averaged nuclear density.

We will present examples where consistency between neutron diffraction, spectroscopy and numerical simulation has been achieved so that nuclear density distributions can be understood rather than just "fitted".

M09.EE.004 PHYSICS FROM CHEMISTRY? ORGANIC STRUCTURES AT MORE TEMPERATURES BY A MULTIPLE SINGLE CRYSTAL METHOD. C. C. Wilson, ISIS Facility, CLRC Rutherford Appleton Laboratory, Chilton, Didcot, Oxon OX11 0QX, UK.

A novel multiple crystal data collection method has recently been developed on the single crystal diffractometer SXD at the ISIS pulsed neutron source. The method allows neutron diffraction data to be obtained simultaneously from several randomly oriented crystals of even low-symmetry molecular materials. The method exploits the ability of time-of-flight neutron Laue diffraction to resolve the overlapping diffraction patterns from a multiple crystal sample. This opens up the possibilities of collecting data sets more rapidly (for example in variable temperature structure scanning), under more extreme sample environment conditions and from smaller single crystal samples.

The presentation will describe the method and highlight its application in one area: that of studying organic crystal structures at many temperatures. The use of such variable temperature methods can lead to new insights into the physics underlying chemical structures, and often more structure determinations at more temperatures are required in order to distinguish between subtly different physical models.

Since the method has been applied to neutron diffraction data, the focus has been on examining hydrogen atom parameters, particularly the anisotropic displacement parameters, and there is often much of interest happening even in apparently innocuous ("normal") crystal structures. Examples will be presented of "anomalous" behaviour of hydrogen atoms revealed by multiple temperature data collection, and the modelling enabled by increasing the number of data sets available.

M09.EE.005 STRUCTURE AND DYNAMICS OF *T*-BUTYLCALIX[4]ARENE-TOLUENE INCLUSION COMPOUND. G. D. Enright, E. B. Brouwer, C. I. Ratcliffe and J. A. Ripmeester, Steacie Institute for Molecular Sciences, NRC, Ottawa, Canada, K1A 0R6.

By using a combination of solid state NMR (^{1}H and ^{13}C CP/MAS) and X-ray diffraction we have shown that *t*-butylcalix[4]arene-toluene is a fluxional guest-host system at room temperature. As the temperature is lowered the NMR measurements indicate that the guest motion changes from 90° to 180° jumps about the 4-fold axis, thus freezing in the guest-induced elliptical distortions of the host lattice. At even lower temperatures the 180° reorientations cease and the local symmetry is further reduced. Our initial diffraction studies (Cu Kα) indicated that even at the lowest temperatures space-averaging results in a high lattice symmetry (tetragonal, space group P4/n) unchanged from that observed at room temperature. At low temperatures weak, transient diffraction peaks were noted at half-integral values of h,k, indicating possible correlations in the alignment of guests in adjacent calixarene sites. We have recently collected low-temperature diffraction data with Mo K_α radiation. Surprisingly the half-integral peaks were persistent and not as weak. The structure could be solved in P4 revealing layers of ordered, elliptically-distorted calixarene cavities (at 2-fold sites) alternating with layers of fully disordered elliptical cavities (at 4-fold sites).

M09.EE.006 STOCHASTIC THERMAL MOTION ANALYSIS AND THE RADON-NIKODYM PROPERTY. Carroll K. Johnson, Chemical and Analytical Sciences Division, Oak Ridge National Laboratory*, Oak Ridge, TN 37831-6197, USA.

Atom positions a_1, a_2, scaled anisotropic temperature factor matrices B_1, B_2, and Radon-Nikodym density (RND) $\omega_{2,1}$, (derivative of Gaussian density μ_2 with respect to μ_1 assuming absolute continuity), provide a stochastic estimate of correlated thermal motion. Let $C = B_2^{-1/2}$ (a symmetric matrix), $b = C(a_2\text{-}a_1)$, $c(x) = C(x\text{-}a_1)$, and $D_{2,1} = C(B_1\text{-}B_2)C$. The symmetric Hilbert-Schmidt matrix $D_{2,1}$ yields eigenvalues λ_k and eigenvectors e_k, k=1,2,3. The Gaussian RND equation [1] is

$$\omega_{2,1} = \frac{d\mu_2}{d\mu_1}(x) =$$

$$\exp\left(-\frac{1}{2}\left(\sum_{n=1}^{3} \left(e_k^t c(x)\right)^2 \frac{\lambda_k}{(1+\lambda_k)} - \ln(1+\lambda_k) \right) + c^t(x)b - \frac{b^t b}{2} \right)$$

Since RND is always ≤ 1 there is a separatrix (partition) surface at $\omega_{2,1}(x) = 1$ (which is also $\omega_{1,2}(x) = 1$), on which $\mu_1(x) = \mu_2(x)$. Additional atom pairs and chain differentiation $\frac{d\mu_2}{d\mu_3} = \frac{d\mu_2}{d\mu_1}\frac{d\mu_1}{d\mu_3}$ provides a dented body partition [2] surrounding each Gaussian centroid. Contoured dented body drawings can be made by ORTEP type calculations at increasing probability density levels, with plotting of ellipsoid pair intersections (closed 4th-order curves).

Critical net [3] peak, pass, pale, and pit points occur at atom centroid, kissing point for two ellipsoids, intersection point of three (or more) ellipsoids, and dented body corners, respectively. Dented body face areas (integrated ω density) and face curvature provide motion correlation and convex set chemical grouping information, respectively. Experimental testing of this RND approach is underway.

M09.EE.007 THE FIRST *IN SITU* DIRECT OBSERVATION OF LIGHT-INDUCED RADICAL PAIR FROM HABI DERIVATIVE BY X-RAY CRYSTALLOGRAPHY. M. Kawano and Y. Ohashi, CREST, Japan Science and Technology Corporation, and Department of Chemistry, Tokyo Institute of Technology, Tokyo 152-8551 Japan, and T. Sano and J. Abe, Department of Photo-Optical Engineering, Tokyo Institute of Polytechnics, Kanagawa 243-0297 Japan.

A radical species plays an important role as a reactive intermediate in chemical reactions and biological system. While a number of radicals in solid state have been extensively investigated by spectroscopic methods, crystallographic approach is relatively less common for unstable radicals, and has been applied to stable radicals, *viz.* radical ion pairs, stabilized radicals, and so on, which can be crystallized. To our knowledge, the crystallographic investigation on energetically unstable reactive radical pairs (RPs) has never been reported. We report the unprecedented example of the *in situ* direct observation of RP of a photo/thermochromic compound, hexaarylbiimidazolyl derivative (*o*-Cl-HABI), cryotrapped in a single crystal by X-ray diffraction. There are two crystallographically independent *o*-Cl-HABI molecules, A and B, in a unit cell before irradiation. The C-N bond connecting two triaryimidazolyl rings of not A but only B molecule is cleaved by irradiation to produce two planar radicals (RP). The irradiated crystal thermally converts into the initial dimer structure, which can be crystallographically confirmed. The CW-ESR experiments of the single crystal were carried out in the temperature range from 77 K to room temperature. Irradiation on the single crystal at 77 K produced a triplet-state signal of RP accompanied with Δm_S = 2 transition. The geometries of the initial dimer and RP are in good agreement with the theoretical results calculated by DFT Beck3LYP/6-31G*.

P09.EE.001 ANOMALOUS CH3 ROTATIONAL DYNAMICS AND CRYSTAL STRUCTURE OF MANGANESE ACETATE. Beatrice Nicolai [1], Gordon J. Kearley [1], Alain Cousson [2], Werner Paulus [2] [3], Francois Fillaux [4], [1] Institut Laue Langevin, BP156, 38042 Grenoble, FRANCE, [2] Laboratoire Leon Brillouin, CE Saclay, 91161Gif sur Yvette Cedex, France, [3] Universite de Rennes 1, Laboratoire de Chimie du solide et Inorganique Moleculaire, LCSIM/UMR6511, Campus de Beaulieu, Avenue du general Leclerc, 35042 Rennes Cedex, France, [4] LADIR-CNRS, 2 rue Henry Dunant, 94320 Thiais, France

Manganese acetate contains three crystallographically distinct CH_3 groups all of which undergo quantum-rotational tunnelling at low temperatures, but curiously, show no measurable librational (or torsional) transitions. To investigate this problem we have determined the low-temperature structure of manganese acetate by single crystal neutron diffraction and have measured the librational ground-state splitting by single crystal neutron scattering. This allows us to assign tunnelling transitions to each of the three distinct CH_3 rotors and thus to calculate the rotational potential for each of them from the known crystal structure. However, the measured tunnel splittings are very different from those calculated via the rotational potential from the crystal structure. Nevertheless, a classical molecular dynamics simulation reveals highly anisotropic proton density, particularly for one of the CH_3 groups, which compares well with the thermal parameters from the diffraction study, and reveals that classical, thermally activated rotation, in this crystal does not occur about a simple fixed axis. This explains the apparent disagreement between the tunnelling spectrum and the crystal structure and may explain the absence of librational transitions.

09FF GROWTH OF MESOSCOPIC CRYSTALS

M09.FF.001 BETWEEN CRYSTAL GROWTH AND PHASE TRANSFORMATION KINETICS IN NANO-CRYSTALLINE TITANIA. J.F. Banfield and H. Zhang [1], R. Lee Penn [2], [1] Dept. Geology and Geophysics, University of Wisconsin-Madison, WI 53706, USA, [2] Dept of Earth and Planetary Sciences, Johns Hopkins University, Baltimore, MD 21218, USA

Crystal growth and phase transformation kinetics of nanocrystals are strongly interconnected. The activation energy for crystal growth is low, ~ 70 kJ/mol, and growth in porous aggregates occurs rapidly. Until particles grow to greater than ~ 14 nm, the phase transformation is prohibited because anatase is more thermodynamically stable than rutile. Anatase-to-rutile transformation kinetics depend on temperature and aggregate structure. With higher packing densities and lower temperature, the transformation of nano-anatase to rutile occurs predominantly via interface nucleation.

Interface nucleation was studied using low-temperature hydrothermal experiments. Growth occurs largely by oriented attachment: contacting crystals rotate to achieve interfacial coherence, followed by elimination of the joining surface. Interfacial coherence can be achieved with the second particle in two possible orientations, leading either to single or twinned crystals. The phase transformation is initiated in twin surfaces, which share structural elements with rutile, and proceeds via a mechanism that combines bond bending and atomic displacements. Particle rotation is inhibited in dry powders, but smaller structural units common to rutile are apparently achieved (Ea ~ = 170 kJ/mol). When packing is less dense and/or the temperatures are higher, transformation occurs primarily via surface nucleation (Ea ~ = 465 kJ/mol) over longer reaction times. Particle growth and phase transformation in dry powders can be markedly retarded by partially separating the 6 nm or 8 nm

diameter anatase particles with 6 nm diameter nano-alumina. Both initial crystal size and packing densities affect the extent of retardation. We infer that higher retardation of crystal growth and phase transformation will occur in more densely packed aggregates, where interface nucleation is important.

M09.FF.002 QUANTUM EFFECTS IN ULTRATHIN METAL OVERLAYER EPITAXY. Zhenyu Zhang, Solid State Division, Oak Ridge National Laboratory, Oak Ridge, TN 37831-6032, USA and Department of Physics, University of Tennessee, Knoxville, TN 37996, USA

This talk presents the main results from recent studies of metal overlayer growth on semiconductor substrates [1]. It will be shown that a variety of novel phenomena can exist in such systems, resulting from several competing interactions. The confined motion of the conduction electrons within the metal overlayer can mediate a surprisingly long-range repulsive force between the metal-semiconductor interface and the growth front, acting to stabilize the overlayer. Electron transfer from the overlayer to the substrate leads to an attractive force between the two interfaces, acting to destabilize the overlayer. Interface-induced Friedel oscillations in electron density can further impose an oscillatory modulation onto the two previous interactions. These three competing factors, all of electronic nature, can make a flat metal overlayer critically, marginally, or magically stable, or totally unstable against roughening. We further show that, for many systems, these electronic effects can easily win over the effect of stress. First-principles studies of a few representative systems support the main features of the present "electronic growth" concept [2]. We also present experimental support of the concept [3].

M09.FF.003 IRRADIATION INDUCED GRAIN GROWTH, PHASE TRANSFORMATION AND DEFECT EVOLUTION IN NANOCRYSTALLINE MATERIALS. M.Rose, H.Hahn and A.G.Balogh, Department of Materials Science, Darmstadt University of Technology, Darmstadt, Germany

Microstructural defect evolution and grain growth in nanocrystalline Pd and ZrO_2 samples during energetic particle irradiation was studied. Nanocrystalline samples with different initial grain sizes, ranging from 10 to 300 nm prepared by the inert gas condensation (IGC) technique, were irradiated using 1 MeV electrons and 0.2 – 4 MeV Kr^+ ions with fluences from $1*10^{15}$ to $2*10^{16}$ ions/cm^2. Irradiation experiments were performed partially in-situ at the 1 MV high voltage transmission electron microscope of the Max-Planck-Institute, Stuttgart and at the heavy ion accelerator – transmission electron microscope set-up of the Argonne National Laboratory, Argonne.

The irradiation induced grain growth and the defect density were studied by X-ray diffraction and by transmission electron microscopy (TEM). A strong correlation between grain size and defect density was found, showing drastic reduction of defect clusters in small grains below 50 nm. This correlation was linear for the smaller grains, reaching a saturation value of about $3*10^{-3}$ defect cluster / nm^2 in ZrO_2 and about $1.5*10^{-2}$ defect cluster / nm^2 in Pd for grains larger than 100-120 nm. The irradiation induced defects annihilated completely at the nanocrystalline grain boundaries for grains, smaller than a critical grain size of about 25 nm. Using the temperature dependence of the defect free regions, diffusion coefficients in both nanomaterials have been determined and temperature ranges for thermal diffusion and radiation enhanced diffusion (RED) were separated.

In the irradiated nanocrystalline ZrO_2 samples a phase transformation was found. The tetragonal phase, which is normally stable above 1200 °C first, was observed by X-ray diffraction measurements at room temperature above an irradiation fluence of $2*10^{16}$ ions/cm^2.

The reduced defect density of the nanocrystalline samples, interpreted as enhanced radiation resistance, could give emphasis to applications for irradiation environments and space research.

M09.FF.004 CRYSTALLITE AGGREGATION CONTROLLED BY SUCCESSIVE NUCLEATION. Mu Wang*, Da-Wei Li, Xiao-Bo Yin, Wen-Jun Liu and Nai-Ben Ming, Division of Optical and Scanning Probe Microscopy, National Laboratory of Solid State Micro-structures, Nanjing University, Nanjing, China

In nonequilibrium situations the growth morphology is very often ramified and fractal-like, especially in the early stage of 2D growth [1]. In many cases the aggregate consists of crystallites of limited size [2]. Sometimes the crystallographic orientations of these crystallites are strongly correlated [3]. The mechanism of these aggregation behaviors seems still not completely understood. Our recent experi-ments demonstrated that the crystallographic anisotropy and surface kinetics play important parts in the aggregation process, which may be responsible for the periodic roughening transitions occurring to the crystallites surface [4], and also for the anisotropic successive nucleation which leads to a remarkable correlation on the crystallographic orientations of crystallites in fractal aggregation [3]. We suggest that these observations provide in-depth insights to the aggregation mechanism when the crystallite size is below a certain value.

M09.FF.006 DEVELOPING A STRUCTURALLY BASED MODEL FOR NUCLEATION: FROM MOLECULAR AGGREGATION TO PRODUCT CONTROL. M.J. Quayle [1], R.J. Davey [1], G.J. Tiddy [1], J. Garside [1], H.G. Alison [1], G. Jones [2] and D.T. Clarke [2]. [1] Colloids, Crystals and Interfaces Group, Department of Chemical Engineering, UMIST, P.O. Box 88, Manchester. M60 1QD. UK. [2] Synchrotron Radiation Department, CCLRC Daresbury Laboratory, Warrington. WA4 4AD. UK.

The process of primary nucleation is currently being investigated, *in situ*, using synchrotron radiation. The clasical description of primary nucleation is derived from Ostwald's Law of stages [1] and Volmer's kinetic formalism [2]. Though the thermodynamics of liquid – solid phase transformations have been comprehensively described [3], the kinetic aspects have, however, been limited by the size and timescales at which available experimental techniques can probe a transforming system.

A stopped flow reactor is employed to carry out batch crystallisations which result from rapid reaction or 'drown out', through the mixing of two liquid components. Simultaneous small

and wide angle X-ray diffraction experiments are performed on these nucleating systems in real time with detectors that have a time resolution of 10 milliseconds. Thus it is possible to track the development of long and short range order together with the size scale of any emerging or transforming phase.

Systems that have been studied include copper phthalocyanine, 4-methoxy-*E*-cinammic acid, histidine·HCl·H_2O and 2,6-dibromo-4-nitroaniline by mixing of concentrated solutions with water; the cocrystallisation of 1,4-diiodobenzene / 1,4-dinitrobenzene and tetracyanoethene / tetracyanquinodimethane systems and the precipitation of copper carbonate from copper nitrate and sodium carbonate solutions.

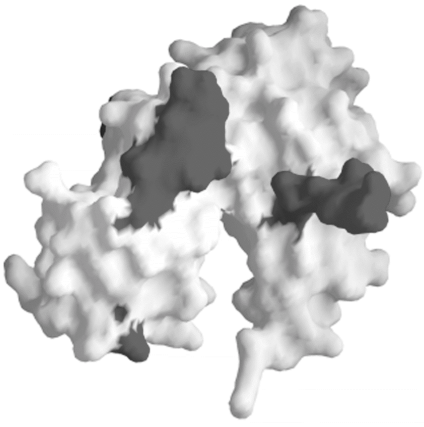
11OA THE IMMUNE SYSTEM AND DESIGNED ENZYMES

M11.OA.001 THE STRUCTURE OF THE HUMAN HIGH-AFFINITY IgE RECEPTOR FROM 5 CRYSTAL FORMS. Scott C. Garman, Jean-Pierre Kinet#, and Theodore S. Jardetzky. Department of Biochemistry, Molecular Biology, and Cell Biology, Northwestern University, 2153 Sheridan Road, Evanston, IL 60208, USA, and #Laboratory of Molecular Allergy and Immunology, Harvard Medical School, Boston, MA 02215, USA.

Antibody Fc receptors couple the diversity of soluble antibodies to the variety of responses available to differentiated immune cells. Allergic responses result from signaling through the IgE Fc receptor on the surface of mast cells. We have solved the structure of the antibody-binding portion (α) of the receptor FcεRI found on the surface of mast cells. Allergens binding to IgE antibodies cause signaling through FcεRIα and result in release of the powerful immune mediators from the cells.



We have solved the structure of FcεRIα in five space groups using different cell lines and constructs. We used MIRAS methods for the best-diffracting crystal form (2.4Å) and MR methods for the others (3.8-3.1Å). The seven N-linked carbohydrates (shown as dark patches) show changes among the different crystal forms. The FcεRIα molecule contains two Ig domains bent over to reveal a patch of four exposed tryptophans at the top of the molecule, away from the membrane-spanning region.

M11.OA.002 CYTOKINE RECEPTOR COMPLEXES VERSES CELL ADHESION INTERACTIONS - UPPING THE AFFINITY. Y. Jones, University of Oxford, UK.

Abstract not available.

M11.OA.003 THE STRUCTURAL EVOLUTION OF A CATALYTIC ANTIBODY. E.C. Mundorff[1], M.H. Hanson[1], P.G. Schultz [1], R.C. Stevens[1] [1]Materials Science Division, Lawrence Berkeley National Laboratory and Department of Chemistry, University of California, Berkeley, Berkeley, CA 94720.

Through the use of catalytic antibodies we are able to explore the relationship between binding energy and catalysis in protein structure. In this study we examined the affinity maturation of the antibody AZ-28 which catalyses the oxy-Cope rearrangement, a pericyclic reaction which is common in organic synthesis but for which there is no known enzyme. Although the six mutations produced during affinity maturation of AZ-28 increases the binding affinity to the hapten, one somatic mutation, Ser(L34)Asn, causes a dramatic decrease in the catalytic rate. The germline antibody possesses a catalytic rate that is close to that of chorismate mutase, an enzyme which also catalyzes a pericyclic reaction, and through affinity maturation this rate decreases to a more modest rate for the mature antibody with a k_{cat}/k_{uncat} of 169,000 and 5300 respectively for the germline and mature antibodies. A structural analysis of this system was pursued to gain an understanding of the interplay between binding energy and catalysis. The x-ray crystal structures of the germline analogue of AZ-28 with and without hapten have each been solved to 2.0Å resolution and are compared with the previously solved structure of AZ-28 with hapten[1]. In the structure of the mature AZ-28 with hapten, it appears that while bound more tightly the hapten is restricted into a catalytically unfavorable conformation through multiple binding interactions. The three structures show only small variations in the active site. However, subtle differences at L34 substantially alter catalysis. In the mature AZ-28 there is a hydrogen bond between L34 and H100a effectively tying together the CDRL1 and CDRH3 loops. In the germline plus hapten structure this hydrogen bond is lengthened to a water-bridged hydrogen bond. This appears to give the CDRH3 loop increased flexibility in the germline structure and also may release some restrictive interactions between the CDRH3 and the hapten. The high catalytic rate of the germline therefore may be facilitated by a higher degree of breathing within the active site. Thus, this system provides unique insight into the evolution of binding energy and its effect on biological catalysis.

M11.OA.004 STRUCTURE OF A HETEROPHILIC ADHESION COMPLEX BETWEEN HUMAN CD2 AND CD58 (LFA-3). Jia-huai Wang [1], Alex Smolyar [1], Kemin Tan [1], Jin-huan Liu [1], Mikyung Kim [1], Zhen-yu J. Sun[2], Gerhard Wagner[2],Ellis Reinherz[1], [1] Immunobiology Division, Dana-Farber Cancer Institute, Harvard Medical School, Boston, MA. 02115, USA, [2] Department of Biological Chemistry and Molecular Parmacology, Harvard Medical School, Boston, MA. 02115, USA.

Interaction between CD2 and its counter-receptor, CD58 (LFA-3), on opposing cells optimizes immune recognition, facilitating contacts between helper T lymphocytes and antigen presenting cells as well as between cytolytic effectors and target cells. Here we report the crystal structure of the heterophilic adhesion complex between the amino terminal domains of human

CD2 and CD58. A strikingly asymmetric, orthogonal, face-to-face interaction involving the major b-sheets of respective immunoglobulin (Ig)-like domains with poor shape complementarity is revealed. In the virtual absence of hydrophobic forces, interdigitating charged amino acid side chains form hydrogen bond and salt link network at the interface. These charged interactions not only ensure high specificity, but also provide binding energy for this low affinity adhesion. These features explain CD2-CD58 dynamic binding, which is best suited to permit the T cell to broadly sample the surface of an opposing cell in search of the correct antigenic pepetide/MHC complex and co-stimulatory ligands. We have also inferred from sequence comparison that there is a subfamily within the Ig superfamily (IgSF) that utilizes the same interaction mode for cell adhesion, but the physico-chemical character of the subset of residues involved in interface determines the relative binding affinity to meet the different biological requirement.

M11.OA.005 STRUCTURE OF THE INHIBITORY NATURAL KILLER CELL RECEPTORS. Peter D. Sun, Jeffrey C. Boyington, Greg Snyder, Aisha N. Riaz, Apisit Patamawenu, John E. Coligan, Andrew G. Brooks. Structural Biology, NIAID, National Institutes of Health, 12441 Parklawn Drive, Rockville, MD 20852, USA.

The cytolytic activity of natural killer (NK) cells are modulated by several families of extracellular receptors which recognize surface antigens such as class I major histocompatability complex (MHC) molecules on the surface target cells. These receptors are generally members of either the Ig superfamily or the superfamily of C-type lectin. KIR2DL2 is a natural killer cell inhibitory receptor with two Ig domains and has been shown to interact with allotype HLA-Cw3 where as CD94/NKG2s are members of C-type lectin receptors that have been shown to interact with the nonclassical MHC class I molecule HLA-E. Here we report the 2.9 Å resolution crystal structure of the KIR2DL2 ectodomain and the 2.6 Å resolution crystal structure of the C-type lectin domain of CD94. The hinge angle of KIR2DL2 is approximately 80º, 14º larger than that observed in KIR2DL1 and 5º different from that of a second crystal form of 2DL2, suggesting that the interdomain hinge angle is not fixed. The putative ligand binding site is formed by residues from several variable loops with charge distribution apparently complementary to that of HLA-C. The packing of the receptors in the orthorhombic crystal form offers an intriguing model for receptor aggregation on the cell surface. The structure of CD94 reveals a novel variation to the C-lectin fold with one major α-helix being absent and the lack of the canonical calcium binding site. CD94 forms a unique dimer where the missing α-helix, replaced by a loop, becomes part of the dimer interface. The hydrophobic nature of the interface residues appears to be preserved among the sequences of CD94 and NKG2. We suggest a putative HLA_E binding region based on the structure and sequence variations.

P11.OA.001 PEPTIDE BINDING AND T CELL RECOGNITION OF CLASS I MHC MOLECULES. Edward J. Collins, Rui Zhao, Jennifer Kuhns and Timothy Kirksey, Department of Microbiology and Immunology, University of North Carolina, Chapel Hill, NC USA 27510

Designing peptides with enhanced binding to class I MHC to modulate immune responses requires a full understanding of the interactions of peptide and class I MHC. In order to understand these interactions, we have studied a variety of class I MHC/peptide systems. The structures of two class I MHC/peptide complexes derived from human and mouse that are both recognized by the same T cell receptor show that the T cell receptor does not recognize similar surfaces in charge or shape between the two molecules. Structures of an ignored and antagonistic ligands to this same T cell show interesting structural permutations which have more to do with peptide binding and plasticity of the MHC than with T cell recognition. Examination of structures of potential candidates for HIV therapy show the reasons for increased affinity and potential reasons for altered recognition by the immune system. The structure of a poor binding ligand to HLA-A2 shows that the peptide makes no apparent stabilizing contacts within the center of the peptide. The effects on immunogenicity with relation to flexibility of well binding ligands are different. APL based on the structure of the poor binder show increased binding affinity and different immunological properties.

P11.OA.003 CRYSTALLOGRAPHIC ANALYSIS OF THE SYN ELIMINATION ABZYME 1D4. N.A. Larsen, A. Heine, B.F. Cravatt, R.A. Lerner, and I.A. Wilson. Department of Molecular Biology, BCC 206, The Scripps Research Institute, 10550 N. Torrey Pines Rd., La Jolla, CA 92037, USA.

The catalytic antibody 1D4 selectively catalyzes a highly disfavored syn-elimination reaction. 1D4 significantly accelerates the sterically-hindered transformation over its background reaction. We seek to understand the structural basis for this reactivity. Four high-resolution x-ray diffraction data sets were collected: unliganded 1D4, 1D4 co-crystallized with two stereoisomeric substrate analogs, and 1D4 co-crystallized with a rigid bicyclic transition state analog. Crystals of the unliganded 1D4 and crystals of the substrate analog and transition state analog complexes diffracted to 1.80 Å, 1.90 Å, 2.05 Å, and 1.75 Å, respectively. The structures were determined by molecular replacement using AMoRe, and our current models were refined using CNS and SHELXL. Electron density maps unambiguously show the transition state analog nestled between the hypervariable loops, which form the active site. The molecular surface representation shows that this active site forms a deep binding pocket. The transition state analog fits snugly into this binding pocket, forming close contacts mainly with the second and third hypervariable loops of the heavy chain (H2 and H3). Further comparison of the structures reveals significant conformational differences in the H2 loop. Structural differences in the active site, in particular H2, may have important mechanistic implications. We report here the x-ray crystal structures of 1D4, as well as a proposed mechanism for catalysis of the syn-elimination reaction.

11OB METALLOPROTEINS, ELECTRON TRANSPORT AND EXAFS

M11.OB.001 CRYSTAL STRUCTURES OF REACTION INTERMEDIATES OF CYTOCHROME P450$_{CAM}$. Ilme Schlichting, Max Planck Institute, Dortmund, Germany; Joel Berendzen, Kelvin Chu, Biophysics Group Los Alamos National Laboratory; Robert M. Sweet, Biology Department, Brookhaven National Laboratory; Dagmar Ringe, Gregory A. Petsko, Rosenstiel Center, Brandeis University; Steven Sligar, Department of Biochemistry & Beckman Inst. for Advanced Science and Technology, University of Illinois

Cytochrome P450 enzymes form a family of ubiquitous heme proteins named after an absorption band at 450 nm when complexed to carbon monoxide (CO). P450 enzymes are mixed-function mono-oxygenases. They play a critical role in the synthesis and degradation of many physiologically important compounds and xenobiotics. This makes cytochrome P450s an attractive target for pharmaceutical or environmental industries. The biochemical relevance of the P450-mono-oxygenases in general is their unique ability to catalyze the hydroxylation of non-activated aliphatic or aromatic hydrocarbons. The biochemically and structurally best characterized P450 is P450$_{cam}$

from *Pseudomonas putida*, which catalyzes the stereospecific 5-exo-hydroxylation of camphor. Although many structures of different $P450_{cam}$ complexes have been determined by Poulos and coworkers, the structure of the biochemically important oxygen complex of $P450_{cam}$ has not been determined yet as it is unstable (halflife ca. 3 min at 4C) due to autooxidation. This requires to collect the diffraction data of the short-lived complex either fast (e.g. by the Laue method) or to prolong its life time. Only the latter approach worked in our hands: we use cryocrystallography to determine the crystal structures of unstable intermediates occuring along the reaction pathway of $P450_{cam}$: We chemically reduce ferric P450.camphor crystals to generate the ferrous complex. The ternary P450.camphor.O2 complex is generated by diffusion of oxygen. X-ray radiolysis can be used to trigger the mono-oxygenase reaction in frozen crystals. The intermediate(s) generated can be transformed to the product 5-hydroxy-camphor by rapid thawing and refreezing of the crystals. The methods used, and the structures obtained will be discussed.

M11.OB.002 SPECIFICITY AND MECHANISM OF THE HYDROXYLATING DIOXYGENASE – NAPHTHALENE DIOXYGENASE. S. Ramaswamy, A. Karlsson, E. Carredano, D. Choudhury, H. Eklund [1], R.E. Parales, J. Parales, D.T. Gibson [2], [1]Department of Molecular Biology, Swedish University of Agricultural Sciences, Box 590, Biomedical Center, Uppsala 75124, Sweden, [2]Department of Microbiology, University of Iowa, Iowa City, Iowa 52242, USA.

The initial reaction in the degradation of many aromatic compounds is catalysed by multicomponenet ring hydroxylating dioxygenase systems which add both atoms of dioxygen to the aromatic ring. The first structure of this class of enzymes - that of naphthalene dioxygenase has been determined [1]. Naphthalene dioxygenase catalyses the dihyroxylation of naphthalene to cis-naphthalene dihyrodiol.

The structure revealed that the enzyme is a hexamer of the (alpha)3 beta(3) type. The Rieske center of one subunit is close to the mono-iron active site of its neighbour - the histidine ligand of one is connected the histidine ligand of the other through a single aspartic acid (asp 205) residue.

In order to understand the mechanism of action of this enzyme we have determined structures of the enzyme complexed with substrates/inhibitors with the Fe in both the oxidised and reduced states. We also have determined the structure of the enzyme with an intermediate in the dioxygenation of indole in the active site. Present efforts are focussed on trying to produced a dioxygen/NO bound form of the enzyme in crystals. We hope to put together all these and combine them with mutational studies to work out the possible mechanism of action of naphthalene dioxygenase.

1. B. Kauppi, K. Lee, E. Carredano, R.E. Parales, D.T. Gibson, H. Eklund, and S. Ramaswamy. (1998) STRUCTURE 6 (5), 571-587.

M11.OB.003 POLARIZED EXAFS MEASUREMENTS ON ORIENTED SINGLE CRYSTALS OF CARBONMONOXY-MYOGLOBIN. H.C. Freeman, P.J. Ellis and D. Shi, School of Chemistry, University of Sydney, N.S.W. 2006, Australia, and J.E. Penner-Hahn, Department of Chemistry, University of Michigan, Ann Arbor, MI 48109-1055, USA, and J.A. Ibers and C. Slebodnick, Department of Chemistry, Northwestern University, Evanston, IL 60201, USA.

The geometry of the heme-Fe-C-O site in carbonmonoxymyoglobin (MbCO) is of chemical and biological interest, but has been notoriously difficult to determine [1]. Despite extensive studies by X-ray diffraction, neutron diffraction and vibrational spectroscopy, accurate values for the Fe-C-O angle as well as the tilt of the Fe-C bond with respect to the porphyrin plane have remained elusive. X-ray absorption measurements on MbCO in frozen solution have so far not been helpful, since the EXAFS is dominated by the contributions of the porphyrin atoms.

The problem of resolving the EXAFS contributions of the axial C and O atoms from those of the porphyrin atoms can, in principle, be overcome by taking advantage of the symmetry properties of sperm-whale MbCO crystals. We have recorded polarized Fe *K*-edge X-ray absorption spectra of single crystals of sperm-whale MbCO in six orientations, and have fitted a 3-dimensional model of the heme-Fe-C-O site simultaneously to the six sets of EXAFS data. In the refined model, the Fe-C bond is tilted by 6±1° from the normal to the porphyrin plane, the Fe-C-O angle is 170±3°, and the orientation of the C-O bond is approximately normal to the porphyrin plane. The N(porphyrin)-Fe-C-O torsion angle is not determined uniquely. The robustness of the model has been tested and will be discussed. The value of the Fe-C-O angle is supported by a novel analysis of pre-edge features in the XANES of frozen MbCO solutions and a series of model compounds.

[1] T.G. Spiro & P.M. Kozlowski (1997) J. Biol. Inorg. Chem, 2, 516-520; C. Slebodnick & J.A. Ibers, ibid., 521-525; T. Vangberg, D.G. Bocian & A Ghosh, ibid., 526-530; M. Lim, T.A. Jackson & P.A. Anfinrud, ibid., 531-536; J.T. Sage, ibid., 537-543; J.S. Olson & G.N. Phillips Jr., ibid., 544-552.

M11.OB.004 X-RAY ABSORPTION SPECTROSCOPY OF MOLYBDENUM AND TUNGSTEN ENZYMES. Graham N. George, Stanford Synchrotron Radiation Laboratory, P.O. Box 4349, MS 69, Stanford, California 94309, U.S.A.

Molybdenum and tungsten are the only second and third period transition metals with well defined biological functions. In most cases these metals function in metalloenzymes in the catalysis of two electron oxidation-reduction reactions involving the transfer of an oxygen from the metal to the substrate, or the reverse reaction. Both metals possesses highly flexible chemistries which allows them to adopt a variety of configurations in the enzyme systems. Recent X-ray absorption spectroscopic results on several molybdenum and tungsten enzymes will be presented, and the structural information reviewed and compared with the information available from protein crystallography. In many cases these are at odds and possible reasons for this will be discussed.

M11.OB.005 XAFS AND CRYSTALLOGRAPHIC STUDIES OF COPPER PROTEINS. S Samar Hasnain, Synchrotron Radiation Department, CCLRC Daresbury Laboratory, Warrington WA4, Cheshire, UK Email: S.Hasnain@dl.ac.uk

Crystallographic, XAFS and site directed mutagenesis studies of three copper proteins, namely Rusticyanin, Cu-Zn bovine superoxide dismutase and Cu1-Cu2 nitrite reductase would be presented to emphasise the interplay between the two X-ray techniques. Results from a combined study of high to atomic crystallographic structures [Rusticyanin (1.27Å), superoxide dismutase (1.6Å) and nitrite reductase (2.1Å)] and ultra-high resolution XAFS [~0.2Å at the metal centres] will be presented to demonstrate the importance of this approach in providing the structural basis for the biochemisty of these proteins. The example of Cu-Zn bovine superoxide dismutase illustrates the importance of on-line monitoring of the redox states of metalloproteins crystals by XANES.

P11.OB.001 THE INVESTIGATION OF THE STRUCTURE AND FUCTION OF DENITRIFYING ENZYMES. A. Jafferji, [1] V. Fulop, [2] S. Ferguson, [3], [1] Laboratory of Molecular Biophysics, University of Oxford, [2] Department of Biological Sciences, University of Warwick, [3] Department of Biochemistry, University of Oxford.

The bacterial denitrifying pathway conists of four distinct steps, the conversion of nitrate to nitrite, catalysed by nitrate reductase, nitrite to nitric oxide, catalysed by nitrite reductase, nitric oxide to nitrous oxide, catalysed by nitric oxide reductase and nitrous oxide to nitrogen gas, catalysed by nitrous oxide reductase.

The structure of nitrite reductase has been determined (Fulop et al., 1995), however further studies need to be carried out to determine the relationship between the structure and function of this enzyme and the interaction of this enyzme with the physiological electron donors, cytochrome c550 and pseudoazurin. The structures of the other enzymes are unknown.

Work has been carried out to determine the structure of nitrous oxide reductase and understand the mechanism of action of nitrite reductase and will be presented.

P11.OB.002 THE X-RAY STRUCTURE OF ``PRISMANE'' PROTEIN CONTAINING TWO NOVEL 4FE CLUSTERS. S.J.Cooper[1,2], S.Bailey[1], D.Garner[2], W.R.Hagen[3], P.F.Lindley[4], [1] Daresbury Lab, CCLRC, Warrington WA4 4AD, Cheshire, England, [2] Univ Manchester, Dept Chem, Manchester M13 9PL, England, [3] Agr Univ Wageningen, Dept Biochem, Wageningen, Netherlands, [4] ESRF, BP 220, F-38043 Grenoble, France.

In 1989 an unknown protein was discovered that co-purified with the soluble hydrogenase of a sulphate reducing anaerobic bacterium *Desulfovibrio vulgaris*. On the basic of EPR spectroscopic analysis it was proposed that the iron sulphur prosthetic group of this protein was unprecedented in its structure and redox chemistry: [6Fe-6S] prismane core with four stable oxidation states within a relatively narrow redox-potential window of *ca* 0.5V [1]. The crystal structure of this so called `prismane protein' has now been determined to 1.6Å [2] and does *not* contain a 6Fe cluster. The protein consists of two 4Fe clusters situated 12Å apart close to the interface formed by three domains. Cluster 1, a conventional [4Fe-4S] cubane, is bound near the N-terminus by an unusual sequential arrangement of four cysteine residues. This differs significantly from typical linkage in high-potential iron proteins, aconitase and bacterial ferredoxins. This cluster is bound near the N-terminus of the molecule close to the exterior of the protein and may participate in electron transfer. Cluster 2 appears to be unique among the iron sulphur containing protein whose structures have so far been elucidated. The cluster comprises both O and S bridges between the 4 iron atoms. Two iron atoms (Fe5, Fe6) have what could be described a tetrahedral local environment whilst the other two (Fe7,Fe8) are trigonal bipyramidal. Between Fe7 and Fe5 is unidentified electron density which appears to be partially occupied by a mono or dinuclear species and may represent a substrate binding site.

[1] Hagen W.R. *et al* (1989) J Chem Soc Faraday Trans I 85:4083-4090

P11.OB.003 THE STRUCTURE OF AURACYANIN, A 'BLUE' COPPER PROTEIN FROM *CHLOROFLEXUS AURANTIACUS*. C.S.Bond, H.C.Freeman, J.M.Guss, M.Maher, M.C.J.Wilce, K.Willingham, Department of Biochemistry, University of Sydney, NSW 2006, Australia, R.E.Blankenship and F.Selvaraj, Department of Chemistry and Biochemistry, Arizona State University, Tempe, Arizona.

Auracyanin is a 'blue' single-Cu protein (cupredoxin) produced by the green, filamentous, thermophilic, phototropic bacterium *Chloroflexus aurantiacus*. *Chloroflexus* occupies an important position in current hypotheses concerning the evolution/origin of photosynthesis. Two auracyanin genes are present in *C. aurantiacus* (auracyanins A and B). The structure presented here is that of auracyanin B

Hexagonal crystals of dimensions 0.3 mm x 0.3 mm x 0.6 mm ($P6_422$, a=115.7, c=54.6) grow at pH 7.5 (50 mM Hepes buffer, 2 M Li_2SO_4). The Crystals can be cryo-cooled for data collection by quick washing in a solution of 20% MPD in artificial mother liquor. Data extending to 2.4Å at four wavelengths around the Cu *K* edge (~1.38Å) were used to solve the structure, and a further 1.55Å data set was collected for refinement (BioCARS beamline BM-14D, Advanced Photon Source).

The structure has one auracyanin molecule per asymmetric unit (139 amino acid residues and one Cu atom) along with 248 water molecules, 2 sulfate ions and a chloride ion. The final residuals (REFMAC) are $R = 0.205$ and $R_{free} = 0.234$.

This structure sheds light on the position auracyanin occupies in the family of cupredoxins. Structurally, auracyanin lies between plastocyanin and azurin. While the overall fold is very similar to azurin, the structure of the loops surrounding the Cu site and the geometry of the Cu site itself contain aspects common to both.

P11.OB.004 HIGH RESOLUTION STRUCTURES OF MANGANESE SUPEROXIDE DISMUTASE. Ross A. Edwards and Geoffrey B. Jameson, Institute of Fundamental Sciences, Massey University, Palmerston North, New Zealand, Mei Whittaker and James W. Whittaker, Department of Biochemistry and Molecular Biology, Oregon Graduate Institute of Science and Technology, Portland, OR 97291-1000, USA, and Edward N. Baker, School of Biological Sciences, University of Auckland, Auckland, New Zealand.

The structures of site-directed mutants of manganese superoxide dismutase from Escherichia coli are complementing functional studies that address the mechanism of action of this key enzyme. In addition to the native enyme1 and iron-substituted derivative,2 structures of active-site mutants Y34F, Q146L and Q146H, and of gateway mutants H30A and Y174F are being determined to 2.1 Å resolution or better. In the case of the Y174F mutant, synchrotron data (DESY, Hamburg) have been obtained for the functionally active reduced (Mn(II)) and oxidised (Mn(III)) forms of the enzyme to 0.9 Å resolution, and for the azide data to 1.25 Å were collected. Key data processing statistics are summarised in the table for the high resolution pass of the data collection:

	Mn(II)	Mn(III)	Mn(II)-azide
Resolution range, Å	1.8 - 0.90	2.4 - 0.9	2.5 - 1.25
Completeness (final shell), %	91 (81)	96 (67)	95 (94)
Rmerge (final shell)	0.057 (0.41)	0.045 (0.37)	0.053 (0.33)
I/((I)(final shell)	22 (2.4)	22 (2.4)	19 (3.6)

For the Mn(II) and Mn(III) structures we hope to gain insight into proton movements in the active site. The azide derative models putative interactions of the superoxide substrate with the active site.

P11.OB.005 COMPLETION OF THE PLANT PEROXIDASE REACTION CYCLE. A. Henriksen and M. Gajhede, Protein Structure Group, Dept. of Chem., Univ. of Copenhagen, Universitetsparken 5, DK-2100 København Ø, Denmark and A.T. Smith, School of Biol. Sci., Univ. of Sussex, Brighton BN1 9QG, U.K.

The distal arginine is highly conserved in plant peroxidases and it has been considered to play a minor role in O-O bond cleavage and ligand binding including H_2O_2 binding. Its major, but not very well defined role has been considered to be assisting substrate oxidation. We have solved the X-ray structure of the binary HRPC*-ferulic acid complex and the ternary HRPC*-CN-ferulic acid complex to 2.0 and 1.45 Å respectively. Ferulic acid is a natural occurring phenolic compound found in the plant cell wall and it is an *in vivo* substrate for plant peroxidases. The X-ray structures demonstrates the flexibility of the aromatic donor binding site in plant peroxidases and highlight the role of the distal arginine in substrate oxidation and ligand binding. Cyanide or ferulic acid binding does not affect the position of the distal arginine in the distal heme cavity. Distal arginine contributes significantly to stabilization of the HRPC*-CN complex by supplying a short hydrogen bond of 3.0 Å, demonstrating that distal arginine will also be able to contribute with a similar interaction to O-O bond cleavage. In addition, the arginine has a short hydrogen bond of 3.0 Å to the phenolic oxygen, which has another short hydrogen bond of 2.6 Å to a structurally conserved water molecule in the distal cavity. This structurally conserved water molecule is further linked with a hydrogen bond of 2.9 Å to backbone oxygen of P139, a conserved residue within the superfamily of plant peroxidases, and to the distal histidine with a hydrogen bond of 3.5 Å.

A general mechanism of peroxidase substrate oxidation (Compound I → Compound II and Compound II → resting state) is proposed.

11OC HIGH PRESSURE STUDIES OF BIOLOGICAL AND OTHER SOFT MATTER

M11.OC.001 PRESSURE DEPENDENCE OF THE PHASE BEHAVIOUR OF POLYMER BLENDS AND DIBLOCK COPOLYMERS. Kell Mortensen, Henrich Frielinghaus, Risø National Laboratory, Dietmar Schwahn, Forschungszentrum Jülich, Germany.

Studies of the phase behaviour of polymer systems have proven that the sensitivity to fluctuations is much more distinct than originally anticipated based on theoretical arguments. In blends of both homo- and diblock co-polymers, studies have revealed that fluctuations give rise to significant re-normalised critical behaviour. In block copolymers fluctuations have even more pronounced effects, as it changes the second order critical point at $f = 0.5$ to first order, and additional complex phases are stabilised. It has been argued that the free volume causes an entropic contribution to the Flory-Huggins interaction parameter, χ, and is thereby responsible for the re-normalised behaviour. These properties can experimentally be studied through measurements of the structure factor $S(q)$, obtained as a function of temperature and pressure. Most results on homo-polymer blends are in agreement with the argument that free volume will cause additional entropic contributions to the free energy. Studies on block copolymer systems shows, however, more diverging results, with no generalised rule for the effect on T_c versus pressure. In systems including the polymer PDMS, both homo-polymer blends and diblock copolymers show unique character in the phase diagram. For the diblock copolymer of PEP and PDMS, for example, this manifests itself as first a melting of the ordered mesophase, and subsequently a re-entrant ordered structure. An unexpected singularity in the conformational compressibility, as identified from the peak-position, q*, is moreover observed.

M11.OC.002 POLYMER STRUCTURES AT ELEVATED PRESSURE. H. E. King, Jr., Exxon Research and Engineering Co., Annandale, NJ 08801, USA

Polymers, e.g. synthetic macromolecules having an amorphous or partially crystalline nature, exhibit structures at several length scales. Elevated-pressure studies have aided our understanding of the origin of these structures, and I will discuss several examples to give both a historical perspective and to highlight areas of current interest. For crystalline polymers, the role of high pressure is best exemplified by the extensive studies of linear polyethylene which have shown that for P>330 MPa, chain folding in the crystals is suppressed and "extended-chain crystals" dominate. As is well known, this change closely parallels the appearance of a hexagonal phase in the P-T phase diagram. The importance of this phase to the crystallization behavior as well as its relation to the rotator phases of the alkane molecules are two areas of continuing discussion. For amorphous polymers, the relevant structure is a modified random walk, with details of the monomer-monomer correlation function reflecting interactions between monomers and their surroundings. Therefore, studies of the chain dimensions via neutron or light scattering give information on the thermodynamics of solubility. In polymer blends, use of small angle neutron scattering along with the random phase approximation of de Gennes allows one to directly obtain the polymer-polymer interaction energy. This energy has been measured for polyolefin mixtures as functions of both T and P. Much of the data can be collapsed to a single function of density, presumably due to the dominance of van der Waals interactions. Polymer dimensions for isolated chains in solvents have also been measured as a function of P. There it is found that the chain dimensions of non-ionic water-soluble polymers are influenced by high pressures. One can understand this through appeal to pressure and temperature dependence of hydrogen-bond strength and hydrophobicity. A thermodynamic model for this has been developed and is found to well describe the data.

M11.OC.003 PATTERNS IN THE PHASE AND STRUCTURAL BEHAVIOUR OF LYOTROPIC LIQUID CRYSTALLINE SYSTEMS AT HIGH PRESSURE. R. H. Templer, The Department of Chemistry, Imperial College, London SW7 2AY

Lyotropic liquid crystalline phases form when amphiphilic molecules are mixed with water. The amphiphiles assemble into interfaces where the polar headgroup moities screen the apolar hydrocarbon chains from aqueous contact. These flexible, fluid interfaces form a diverse range of liquid crystalline structures, from periodic stackings of lamellar bilayers, through the warped bilayers of the bicontinuous phases and the hexagonal packings of cylindrical monolayers to the complex cubic packings of spherical micelles.

Conventionally researchers have explored the phase and structural behaviour of these systems with small angle X-ray diffraction, in response to variations in the water composition and temperature. In the last decade a number of groups have extended these studies to include the effects of applied hydrostatic pressure. The experimental complexities of such measurements are of course greater than the more conventional studies, but the great advantage of pressure studies is that it provides a further, independent thermodynamic parameter with which to probe our current understanding of the behaviour of these materials. In this talk, recent work on the phase and structural behaviour of lyotropic liquid crystalline phases as a function of pressure and temperature will be discussed in terms of the general patterns

which can be observed. At the qualitative level we believe that the observations can be rationalised in terms of the effect that pressure has in reducing the desire for interfacial curvature and increasing the energetic cost of hydrocarbon chain extension.

M11.OC.004 PROTEINS UNDER PRESSURE: A MOLECULAR MECHANISM OF PRESSURE-INDUCED UNFOLDING. G. Hummer, Theoretical Biology and Biophysics Group T-10, Los Alamos National Laboratory, Los Alamos, New Mexico 87545, U.S.A.

Proteins unfold under pressures of a few kilobar. However, a molecular mechanism of pressure-induced denaturation remained elusive. Aggravating this lack of a molecular understanding of pressure effects on proteins is that pressure denaturation appears to contradict the standard model of protein stability. Proteins are believed to be stabilized by a hydrophobic core of non-polar amino acids. Upon unfolding, these interior residues become solvent exposed. According to the standard model, proteins should become more stable at pressures above a few kilobar, where the solubility of non-polar molecules in water decreases. This apparent contradiction can be resolved by inverting the standard model of protein unfolding [1]. We focus on the transfer of water into the protein interior rather than the transfer of interior amino acids into water. Indeed, pressure reduces the stability of hydrophobic aggregates in water by insertion of water molecules. We propose a 'swelling mechanism' of pressure-induced unfolding of proteins. Implications on the structural characteristics of the unfolded ensemble, folding and unfolding kinetics, and combined temperature and pressure effects will be discussed.

G. Hummer, S. Garde, A. E. García, M. E. Paulaitis & L. R. Pratt (1998) Proc. Natl. Acad. Sci. U.S.A., **95**, 1552.

M11.OC.005 HIGH PRESSURE X-RAY CRYSTALLOGRAPHIC STRUCTURE OF MYOGLOBIN. P. Urayama, S.M. Gruner [1], G.N. Phillips, Jr. [2], [1] Department of Physics, Cornell University, Ithaca, New York 14853-2501, USA, [2] Department of Biochemistry and Cell Biology, Rice University, Houston, Texas 77005-1892, USA.

Pressure is a significant parameter in biological systems, as pressures in the kilobar range affect reaction kinetics, rigidify membranes, disrupt quaternary associations, and unfold proteins. Of the various high pressure biological techniques, macromolecular crystallography is the least utilized. The only high pressure structure is of hen egg-white lysozyme at 1 kbar, in which Kundrot and Richards find an anisotropic compressibility, no domain hinge movement, and an average decrease in the temperature factor [1]. Now, we present a second high pressure protein structure -- sperm whale myoglobin at 1.5 kbar. We will also describe current high pressure techniques, and a possible alternative for facilitating the collection of high pressure data.

1. C.E. Kundrot and F.M. Richards (1987). J. Mol. Biol., 193, 157.

M11.OC.006 PRESSURE EFFECTS ON PROTEIN STABILITY AND FOLDING KINETICS. C. A. Royer, Centre de Biochimie Structurale, INSERM U414, Faculte de Pharmacie, 15 ave. Charles Flahault 34060 Montpellier France

The factors controlling the process of protein folding remain in large part to be characterized. We have employed pressure perturbation techniques in the study of protein folding and unfolding transitions, as a complement to more traditional approaches employing temperature or chemical perturbations. Mutational studies on the pressure unfolding of staphylococcal nuclease indicate that solvent excluded voids and cavities contribute significantly to the value of the volume changes observed.

The effect of pressure on unfolding and folding rate constants yields the values of the volumes of activation for these processes. The changes in system volume for these transitions provides information about the nature of the transition state and the role of solvation in the rate-limiting step of protein folding and unfolding. Temperature studies have revealed the basis for the shape of the P-T phase diagram of proteins. Comparison of a number of different protein systems has allowed correlation of volume effects with structural and topological constraints imposed by the sequence.

P11.OC.001 THE EFFECT OF HIGH PRESSURE ON THE PHASE SEPARATION AND GELATION OF AGAROSE IN WATER. D.W.N. Edington, J. Crain and W.C.K. Poon, Department of Physics and Astronomy, The University of Edinburgh, Mayfield Road, Edinburgh EH9 3JZ, Scotland, UK

Systems which possess both a gel transition and undergo spinodal decomposition are of great interest. If developing spatial inhomogeneities due to phase separation are arrested by gelation, a complex morphology results which can be controlled by altering the system composition, or as we show here, by altering the pressure at which gelation occurs.

Recent work at Edinburgh showed that a hydrostatic pressure of 1 kbar has a dramatic effect on the spinodal decomposition of gelatin in a 30/70% mixture of methanol and water, but has little effect on the gelation temperature. We extend the study to look at aqueous agarose - another example of a system in which both gelation and spinodal decomposition occur. Preliminary results of spectroscopic (Raman and Brillouin) measurements at higher pressure will also be presented.

P11.OC.002 EFFECT OF PRESSURE ON THE STABILITY AND PHASE BEHAVIOUR OF LYOTROPIC LIPID MESOPHASES AND MODEL MEMBRANE SYSTEMS. R Winter, A. Gabke, and J. Woenckhaus, University of Dortmund, Physical Chemistry I, Otto-Hahn-Straße 6, D-44227 Dortmund, Germany

Lipids, which provide valuable model systems for membranes, display a variety of polymorphic phases, depending on their molecular structure and environmental conditions. By use of x-ray and neutron diffraction, infrared spectroscopy and calorimetry, the temperature and pressure dependent structure and phase behaviour of lipid systems, differing in chain configuration and headgroup structure have been studied. Besides lamellar phases also non-lamellar phases have been investigated. Hydrostatic pressure has been used as a physical parameter for studying the stability and energetics of lyotropic mesophases, but also because high pressure is an important feature of certain natural membrane environments (e.g., marine biotopes) and because the high pressure phase behaviour of biomolecules is of biotechnological interest. Neutron scattering in combination with the H/D contrast variation technique has been used to the study of lateral organization of phase-separated binary lipid mixtures. By using the pressure-jump relaxation technique in combination with time-resolved synchrotron x-ray diffraction, the kinetics of different lipid phase transformations was also investigated. The time constants for completion of the transitions depend on the direction of the transition, the symmetry and topology of the structures involved, and also on the pressure-jump amplitude.

P11.OC.003 DOES HIGH PRESSURE STABILISE LYOTROPIC INVERSE BICONTINUOUS CUBIC PHASES? R. H. Templer , O. Ces and J. M. Seddon, The Department of Chemistry, Imperial College, London SW7 2AY

In studies of homologous series of amphiphile / water mixtures which form inverse lyotropic liquid crystalline phases it has been observed that a reduction in chain length stabilises the inverse bicontinuous cubic phases with respect to the inverse hexagonal phase. We believe that this arises because the shorter chain lengths give rise to a reduced desire for interfacial curvature and are unable to accomodate the variation in chain extension required to pack into the inverse hexagonal phase. We therefore hypothesised that increasing hydrostatic pressure would have a similar effect, since it should also reduce the desire for interfacial curvature and stiffen chains to extension. We will present the results of small angle X-ray studies at high pressure on a homologous series of ether linked phosphatidylethanolamines in water. The evidence indicates that at high pressures there is indeed a triple point from which a region of stability for the inverse bicontinuous cubic phases unfolds.

11OD CRYSTAL ENGINEERING

M11.OD.001 ENGINEERING OF MOLECULES, ASSEMBLIES, CRYSTALS. Jerry L. Atwood, Department of Chemistry, University of Missouri-Columbia, Columbia, MO 65211, USA

One of the important early roles of crystallography was the deduction of molecular structure. Only very recently have the principles of crystallography been seen as an avenue toward the design of the solid state. In this presentation, the use of synthons to prepare complex, useful assemblies and solids will be described. The general principles by which polygons (synthons) are arranged to form assemblies in solution or crystals in the solid state will be presented. It is anticipated that the golden age of crystal engineering is upon us, and that crystallography will play a leading role in these exciting developments.

M11.OD.002 CRYSTAL ENGINEERING USING CONCERTED PHENYL EMBRACE MOTIFS. Ian Dance, School of Chemistry, University of New South Wales, Sydney 2052, Australia.

Inorganic and organometallic molecules commonly have peripheral aryl and heteroaromatic substituents: for instance, the ligands PPh_3, bipyridyl, and terpyridyl and relatives are widespread, and Ph_4P^+ is known by synthetic chemists as an excellent cation for the crystallisation of anions of all types. This occurs because multiple phenyl embraces are dominant crystal supramolecular motifs. These motifs use concerted edge-to-face and offset-face-to-face local interactions between aryl substituents. The common sixfold phenyl embrace (6PE) between two Ph_4P^+ ions is frequently elaborated into one–, two– and three-dimensional networks. The hexagonal array of 6PE is a significant three-dimensional crystal supramolecular motif, which has allowed the crystal engineering of unusual anions.

This lecture will describe the variety and scope of multiple phenyl embrace motifs in crystal structures, as well as calculations of their supramolecular energies, and their applications in crystal engineering.

M11.OD.003 CONTROL AND MEMORY OF CHIRALITY IN HELICAL COORDINATION POLYMERS FROM ACHIRAL COMPONENTS. Y. Aoyama, Institute for Fundamental Research of Organic Chemistry, Kyushu University, Hakozaki, Higashi-ku, Fukuoka 812-8581, Japan, and CREST, Japan Science and Technology Corporation (JST)

An achiral anthracene-pyrimidine derivative **1** (5-(9-anthracenyl)pyrimidine) forms adduct **1**•$Cd(NO_3)_2$•H_2O•EtOH (**2**) in a chiral space group $P2_1$. The metal ion is hexa-coordinated with two pyrimidine ligands (equatorial cis), water and ethanol (equatorial cis), and two nitrate ions (axial trans). The chirality arises from a pyrimidine-Cd^{2+} helical array and is preserved not only in each crystal via homochiral interstrand water-nitrate hydrogen bonding but also in all the crystals in the same chirality as a result of single-colony homochiral crystal growth. Compound **1** also forms achiral (*Pbca*) trihydrate adduct **1**•$Cd(NO_3)_2$•$3H_2O$ (**3**) having nonhelical pyrimidine-Cd^{2+} zigzag chains. Achiral zigzag polymer **2** and chiral helical polymer **3** are interconvertible with each other in the solid states upon exchange of volatile ligands (ethanol and water). The helix winding associated with the conversion of adduct **3** to **2** can be made homochiral by seeding.

M11.OD.004 REACTIVE MOLECULAR CRYSTALS: DESIGN, DISCOVERY AND UNDERSTANDING. Bruce M. Foxman, Department of Chemistry, Brandeis University, Waltham, MA 02454-9110 USA

How can we use our knowledge of molecular solid-state chemistry, crystal packing, and chemical reactivity to *engineer* new reactive materials? In recent years, we have designed several solid-state reactions by using structural analogies derived from the Cambridge Structural Database (examples from organic and inorganic chemistry will be discussed). Following the initial design work, we developed two new series of metal salts and complexes with unique reactivity properties. Solid metal alkynoates and alkenoates undergo oligomerization and polymerization reactions when exposed to ^{60}Co γ-rays. For example, irradiation of solid sodium *trans*-2-butenoate leads to a linear trimer, *one of eight* possible diastereomers, in high yield. Studies of crystalline metal complexes containing such unsaturated ligands provide new insight into solid-state reactivity. In addition to the use of hydrogen bonding and bilayer interactions as agents for the production of reactive phases, changes in metal ion within an isomorphous set of structures may have profound effects on reactivity. We will present recent results which serve to (a) demonstrate the influence of the metal on crystal and molecular structure (including bilayer formation) as well as solid-state reactivity; (b) provide evidence for the unprecedented formation of isotactic polymer via ^{60}Co irradiation of metal salts; (c) deepen our understanding of principles related to the topochemical postulate (is a given solid-state reaction WYSIWYG {what you see is what you get}?).

M11.OD.005 WEAK BUT PERSISTENT: C-H...Y BONDS IN ANION-CATION RECOGNITION IN NUCLEOSIDE SALTS. M.Jaskolski, Deptartment of Crystallography, A.Mickiewicz University and Center for Biocrystallographic Research, Institute of Bioorganic Chemistry, Polish Academy of Sciences, Poznan, Poland.

Molecular recognition requires precise tuning of the interacting recognition points. Yet, it is surprisingly often that favored supramolecular patterns are retained or reproduced, even in altered chemical contexts, through the phenomenon of molecular mimicry. An excellent example is provided by interactions in which classic hydrogen bonds are replaced by C-H...Y bonds. In the crystal structures of N3-protonated cytidinium and 2'-deoxycytidinium salts with composite XY_n anions, such as

$H_2PO_4^-$, NO_3^-, SO_4^{2-}, SiF_6^{2-}, ClO_4^- and BF_4^-, that are capable of accepting hydrogen bonds through their Y atoms, the dominating motif of cytosinium...anion interactions consists of a pair of hydrogen bonds donated from the $N3^+$-H protonation site and from the exoamino N4-H41 group *cis* to N3, and accepted by two Y centers of one anion. This multipoint recognition pattern is stable and robust and thus can be classified as a supramolecular synthon. In the broader class of N3-protonated, N1-substituted cytosinium salts with composite anions it occurs with high frequency. The biologically inactive C5 side of the cytosine system mimics the $N3^+$-H type synthon and shows a propensity to form an analogous motif involving the N4-H42 exo-amino group. In this secondary motif a C5-H5...Y hydrogen bond replaces the strong $N3^+$-H...Y interaction. Since the C-H...Y bond is weaker, the secondary motif shows higher deformability and is less frequent in a survey of the Cambridge Structural Database.

M11.OD.006 VERY SHORT C-H···X AND X-H…C INTERACTIONS IN SOME ORGANIC PHOSPHONIUM AND IMIDAZOLIUM SALTS. M.G. Davidson, J.A. Cowan, A.E. Goeta, J.A.K. Howard, P. Küpper, S. Lamb, M.A. Leech, Department of Chemistry, Science Site, South Road, Durham DH1 3LE, UK; S.A. Mason, Institut Laue-Langevin, BP 156, 38042 Grenoble Cedex 9, France; and J. Clyburne, Department of Chemistry, Acadia University, Wolfville, NS, Canada B0P 1X0.

The existence and structural importance of C-H···X hydrogen bonds between relatively acidic C-H groups and electronegative atoms or electron rich π-systems is well recognized. [1] In order to study such interactions in the absence of stronger intermolecular forces, we have synthesized (by deprotonation of organic acids with phosphorus ylides) and structurally characterized (by low-temperature X-ray and neutron diffraction) a number of phosphonium aryloxides, amides and phosphides. In the solid state, these salts all contain extensive C-H…X interactions (where X = O, N, or P). [2] We have identified common structural motifs within these salts and have thereby been able to rationalize more complex supramolecular structures, for example those of inorganic 'onium' salts and organic salts containing multifunctional anions. By analogy with the synthesis of phosphonium salts from phosphorus ylides, we have recently extended our work by using N-heterocyclic carbenes to deprotonate organic acids to give 'organic' imidazolium salts. Where the organic acid is a phenol, imidazolium aryloxides result which contain very short C-H…O interactions. Of more significance, however, is our recent isolation and X-ray characterization (at 30 K) of a carbene: amine adduct which, because deprotonation of the amine does not occur, contains an N-H…C hydrogen bond. This is, to our knowledge, the first definitive example of an X-H…C hydrogen bond (where X = N or O) to be characterized in the solid state.

[2] M.G. Davidson, *J. Chem. Soc. Chem. Commun.,* **1995**, 919; M. G. Davidson and S. Lamb, *Polyhedron*, **1997**, *16*, 4393; M. G. Davidson, K. B. Dillon, J. A. K. Howard, S. Lamb and M. D. Roden, *J. Organomet. Chem*, **1998**, *550*, 481.

P11.OD.001 BEYOND THE FIRST DIMENSION: ORGANIC/ INORGANIC HYBRID MATERIALS ASSEMBLED *VIA* HYDROGEN BONDS. Alicia M. Beatty and Christer B. Aakeröy, Department of Chemistry, Kansas State University, Manhattan, Kansas, 66506 (U.S.A.)

Higher-dimensional supramolecular assemblies are desirable because of their stability (strength) and versatility (materials!). In pursuit of such systems, crystal engineers typically assemble organic networks *via* directional intermolecular forces (esp. hydrogen bonds) *or* metal-containing networks using coordinate-covalent interactions. Our recent contributions merge these approaches: we use *hydrogen bonds* to assemble *metal-containing* networks. Thus we have the advantages of both worlds: flexible hydrogen-bonded networks (to accommodate an assortment of guests), and a variety of coordination geometries (e.g. square planar, octahedral) that are not available in organic systems. While we began with the test-case of silver, which (due to its tendency to adopt linear coordination geometries) readily forms low-dimensional networks, we will demonstrate the utility of this approach for the assembly of 1-D, 2-D and 3-D networks, using a variety of metal ions. The aim is to assemble metal complexes to form materials for a variety of applications, such as host/guest materials for separations and catalysis, molecular wires, and magnetic materials.

P11.OD.002 OPEN FRAMEWORK ENGINEERING IN NIOBIUM OXOCHLORIDE CLUSTER CHEMISTRY. Ekaterina V. Anokhina, Michael W. Essig, Cynthia S. Day, and Abdessadek Lachgar, Department of Chemistry, Wake Forest University, Winston-Salem, NC 27109 USA

The “mixed ligand approach” has been shown to be a successful strategy to modify structural and physical properties of materials in a controlled way. We used a combination of oxide and chloride ligands in octahedral clusters $[Nb_6L_{18}]^{n-}$ to synthesise a new family of open framework cluster compounds with 1D, 2D, and 3D networks. Single crystal x-ray diffraction analysis showed that their structural features are unprecedented in the crystal chemistry of compounds based on octahedral clusters. Comparative analyses of these structures show strong correlations between the arrangement of the oxide and chloride ligands in the cluster unit and the cluster framework topology. We will demonstrate that the complex and novel cluster connectivity corresponds to the packing of chloride and oxide ligands that minimises their electrostatic repulsions. The presence of cavities and redox-active clusters in these compounds could lead to their application in heterogeneous catalysis and intercalation chemistry.

P11.OD.003 TOWARDS A PICTORIAL GLOSSARY OF INTER-MOLECULAR INTERACTIONS. M.A. Spackman, J.J. McKinnon & A.S. Mitchell, Division of Chemistry, University of New England, Armidale NSW 2351, AUSTRALIA.

We have recently described a remarkable new way of exploring molecular crystals using a novel partitioning of crystal space [1-3]. These molecular Hirshfeld surfaces, so named because they derive from Hirshfeld’s stockholder partitioning [4], divide the crystal into regions where the contribution from the electron distribution of a sum of spherical atoms for the molecule (the promolecule) exceeds the contribution from the corresponding sum over the crystal (the procrystal). They reflect intermolecular interactions in a novel visual manner, offering a hitherto unseen picture of molecular shape in a crystalline environment. Surface features characteristic of different types of intermolecular interactions can be identified, and Hirshfeld surfaces are remarkably different for different polymorphic forms of the same material.

Specific surface features can be revealed by colour coding distance from the surface to the nearest atom in a neighbouring molecule. Close contacts are coloured red (hot spots!), others range through yellow and green to blue for the most distant contacts (cold spots!). This simple device provides a remarkable and immediate visual fingerprint of the types of interactions present, and even reflects their relative strengths from molecule to molecule. For example, the surface for triphenylene reveals two distinct regions: numerous red dimples at one end, characteristic of C–H…π interactions, and a flat green/blue region at the other end, characteristic of π - π stacking.

Compilation of a pictorial glossary is underway, using identifiable patterns of interaction between small molecules to rationalize the often complex mix of interactions displayed by large molecules. Applications of this new tool to a wide variety of interaction types common in molecular crystals will be presented.

P11.OD.004 USING HIRSHFELD SURFACES TO VISUALIZE INTERMOLECULAR INTERACTIONS IN POLYMORPHIC SYSTEMS. J.J. McKinnon, A.S. Mitchell & M.A. Spackman, Division of Chemistry, University of New England, Armidale NSW 2351, AUSTRALIA, and S.L. Price, Centre for Theoretical and Computational Chemistry, University College London, 20 Gordon St, London WC1H 0AJ, UK.

The existence of more than one stable crystal packing arrangement for a particular molecule hints at a very general, and rather subtle, balance between the various types of intermolecular interaction in the formation of molecular crystals. In recent work we have been investigating a remarkable new way of exploring molecular crystals using a novel partitioning of crystal space [1-3]. These molecular Hirshfeld surfaces reflect intermolecular interactions in a striking visual manner, offering a hitherto unseen picture of molecular shape in a crystalline environment.

Colour coding distance from the surface to the nearest atom in a neighbouring molecule reveals specific surface features: close contacts are coloured red (hot spots!), others range through yellow and green to blue for the most distant contacts (cold spots!). Hirshfeld surfaces can be surprisingly similar (e.g. *p*-dichlorobenzene) or dramatically different (e.g. oxalic acid) for different polymorphs, and the colour coding of distances in this fashion can reveal the underlying interactions responsible, and the ways in which their exploitation differs between polymorphs. Because it can summarize information on all close intermolecular interactions simultaneously, we have been using this simple application of Hirshfeld surfaces as a visual tool in the exploration of a number of polymorphic systems.

To date, we have applied this analysis to molecular systems such as acridine, benzene, *p*-dichlorobenzene, fumaric acid, indigo, oxalic acid and terephthalic acid. Detailed examples of colour-coded Hirshfeld surfaces for these systems will be presented, along with more quantitative information derived from the surfaces and tentative conclusions arising from this study.

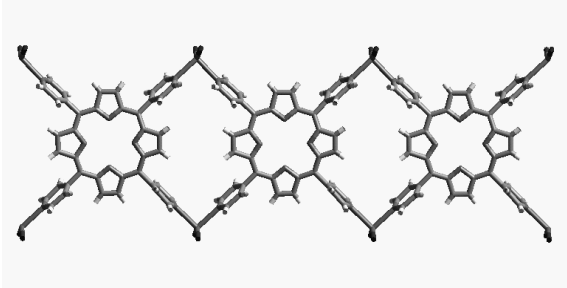
P11.OD.005 APPLICATION OF CRYSTAL-ENGINEERED TETRAPYRIDYLPORPHYRIN COMPLEXES TO HYDROGEN-BONDED SUPRAMOLECULAR ASSEMBLY ON A GOLD SURFACE. Robin D. Rogers, Grant A. Broker, C. V. Krishnamohan Sharma, Brian T. Pyevich, Jason A. Swenson, and Gregory J. Szulczewski, Department of Chemistry, The University of Alabama, Tuscaloosa, AL 35487, USA.

Tetrapyridylporphyrin (TPyP) has been used to construct porous 1D and 2D networks using coordinating metal halides (MX_2; M = Hg, Cd, Pb). For example, the 1:2 complexes of TPyP and HgX_2, (X=I, Br), form porous 1D coordination polymers. The shape and mode of aggregation of 1D polymers leads to the formation of 2D layers with a second type of cavity. Both the cavities in these complexes are capped by solvent molecules and form a bilayer architecture.



The design strategies realized with the synthesis of crystalline solids, have now been applied to organization of porphyrinic chromophores on a surface through hydrogen-bonds, providing a powerful means for the design of novel complexes with useful functional properties. Acid-terminated self assembled monolayers where constructed by immersion of thin gold surfaces in methanolic mercaptyl acid solutions and then immersion in chloroformic solutions. The acid terminated surfaces readily hydrogen-bond with tetrapyridylporphyrin. This presentation will discuss the characterization of these self-assembled, hydrogen-bonded layers of porphyrins through the use of XPS, ellipsometry, and reflection IR. Model crystal structures of hydrogen bonded TPyP complexes will also be presented.

P11.OD.006 CRYSTALS BY DESIGN: IN-SITU ATOMIC FORCE MICROSCOPY INVESTIGATION OF SURFACE GROWTH MORPHOLOGY AND KINETICS. T.A. Land (a), M.T. McBride (b), M. Luo (b), G.T.R. Palmore (b), J.J. DeYoreo (a) a) Lawrence Livermore National Laboratory, Livermore, California, 94550 b) University of California Davis, Department of Chemistry, Davis, CA, 95616

We have used In-situ atomic force microscopy (AFM) to elucidate how changes in molecular structure are manifested in the evolution of surface morphology and step dynamics during growth. The premise of this work is to be able to control the arrangement of molecules in crystalline solids by exploiting the strength, directionality and selectivity of hydrogen bonds. In these experiments, in-situ AFM has been used to investigate the growth of a series of increasingly complex derivatives of 2,5-diketopiperazine (DKP) crystals in order to understand what factors control how molecules assemble into a solid. DKPs are a family of molecules known to form both strong and weak hydrogen bonds with adjacent molecules. Results of in-situ AFM experiments show that growth of GLYDKP occurs on monomolecular steps generated by complex screw dislocations. The step velocity is highly anisotropic with rapid growth occurring in the direction of the strong hydrogen bonds (i.e. N-H--O) and slow growth occurring in the direction of the weak hydrogen bonds (i.e. C-H--O). This anisotropy results in very elongated elliptical shaped hillocks with two very different types of step edges being formed. Very straight steps are observed in the weak hydrogen bonding direction and very ragged steps are observed in the strong hydrogen bonding direction. Due to the symmetry of the crystal, a phenomenon of step interlacing is observed as step velocities alternate between fast and slow with each successive layer. The alternate production of fast and slow type steps results in single steps bunching to form double steps as observed by AFM. Fundamental material parameters have been determined: by measuring the step velocities as a function of supersaturation the kinetic coefficient has been determined, and from measurements of the critical length for step advancement the step edge free energies have been determined. These results will be discussed in the context of how changes in the molecular structure influence the morphology and the kinetics of crystal growth.

This work was performed under the auspices of the U.S. Department of Energy by Lawrence Livermore National Laboratory under contract No. W-7405-ENG-48.

P11.OD.007 INTERACTIONS INVOLVING C≡C–H GROUPS IN CRYSTALLINE SOLIDS. B.M. Kariuki, J.M.A. Robinson, K.D.M. Harris, D. Philp, School of Chemistry, University of Birmingham, Edgbaston, Birmingham B15 2TT, U.K.

As part of our interest in understanding "weak" hydrogen-bonding type interactions in solids, we have recently investigated interactions involving C–H hydrogen bond donor groups, with particular focus on ethynyl (C≡C–H) groups. Results from these studies will be described, including the following.
(1) Investigations of the competitive formation of different types of C≡C–H···π interactions in materials for which different π systems are available for accepting the C≡C–H···π interaction.
(2) Investigations of C≡C–H···O interactions, including the discovery and characterization of an exceptionally strong C–H···O interaction.
(3) Investigations on the interchangeability of halogen and C≡C–H substituents in the crystal structures of di-substituted and tri-substituted benzenes.

P11.OD.008 NEUTRON AND X-RAY STUDIES OF N-H--O/ N--H-O HYDROGEN BOND TAUTOMERISM IN BIPYRIDINIUM PYROMELLITATES. Ian D. Williams, Samuel M-F. Lo, Alvin Siu and Toby Mak, Dept of Chemistry, Hong Kong University of Science and Technology, Clear Water Bay, Hong Kong, China, Judith A.K. Howard and John Cowan, Chemistry Department, University of Durham, Durham, DH1 3LE, UK and Sax A. Mason, Institut Laue Langevin, BP156, 38042, Grenoble, Cedex9, France.

As part of a program to engineer new molecular ferroelectrics involving N-H--O/ N--H-O tautomerism, a series of organic molecular salts have been prepared using hydrothermal crystallization through reaction of 4,4'-bipyridine (4,4'-bipy) and pyromellitic acid (benzene-1,2,4,5-tetracarboxylic acid or 1245-H_4). Three different phases of 2:1, 1:1 and 1:2 stoichiometry have been isolated as crystals >2mm dimension. The 1:1 phase was examined using neutron diffraction at 215K and the distribution of the acidic hydrogens determined. The structure was shown to be [4,4'-bipy-H_2][1245-H_2]H_2O in space group P-1 with Z =1, with two of the acidic H on bipyridinium ions and two involved in ordered intramolecular H-bonds within the dihydrogen pyromellitate dianion.

By x-ray diffraction, the 1:2 phase [4,4'-bipy-H_2] [1245-H_3]$_2$ gave an answer in C2/c in which all non-hydrogen atoms could be located, but the final R-value was only 12% and thermal parameters of several oxygens were unreasonable. The pseudo-symmetry was resolved using neutron data at 20K on D19 (ILL) lambda = 1.3108(1)Å. From this, refinement in C2/c blows up, but in Cc gives R1 0.0238 (wR2 = 0 .0663) The carboxylates in two separate pyromellitates are shown to possess different twist angles. The study also allows definitive assignment of hydrogens to doubly protonated bipyridinium ions and N-H--O tautomerism.

Finally the 2:1 phase has been shown by x-ray diffraction to be 2[bipy-H][1245-H_2] and to contain ordered N-H--O and O-H--N contacts. The two tautomeric states are clearly close enough in energy that coulombic effects dictate the formation of the mono-protonated bipyridine rather than bipyridinium ion in this case.

P11.OD.009 APPROXIMATE SYMMETRY IN CRYSTAL ENGINEERING: PACKING ENERGIES OF RACEMATES AND QUASIRACEMATES. R.E. Davis and N.-L. Chang, Department of Chemistry and Biochemistry, The University of Texas at Austin, Austin, TX 78712-1167, USA and K.A. Wheeler, Department of Chemistry, Delaware State University, Dover, DE 19901, USA

We are interested in designing pairs of molecules that can form quasiracemic crystals. A quasiracemate can be described as a molecular crystal related to a true racemate by a not-too-extensive change in the structure of one of two enantiomeric components, e.g., (*R*)-X and (*S*)-X', where X and X' are sterically similar molecules. This similarity can be achieved by substitution of groups that are sterically similar, though they may be electronically quite different. The resulting quasiracemate crystal, though approximately centrosymmetric in its steric features, is strictly noncentrosymmetric in other aspects, including electronic and optical properties -- a possible advantage for some crystal engineering applications.

We compare hydrogen-bond patterns, packing arrangements and calculated crystal packing energies of proposed or known quasiracemates with those of related racemates (*R,S)*-X and (*R,S)*-X' of known structure. The goal of these studies is a better understanding of factors that favor formation of this special type of cocrystal and the identification of experimentally plausible quasiracemic systems for synthesis and further study.

Supported in part by the Robert A. Welch Foundation, Grant F-233 and in part by the United States Air Force Office of Scientific Research, Grant F49620-97-1-0263.

P11.OD.010 APPROXIMATE SYMMETRY AS A TOOL TO GENERATE MOLECULAR MOTIFS. K.A. Wheeler, M. Hendi, and S. Fomulu, Department of Chemistry, Delaware State University, Dover, DE 19901, USA and R.E. Davis, Department of Chemistry and Biochemistry, The University of Texas at Austin, Austin, TX 78712-1167, USA.

This research is aimed at controlling noncentrosymmetric arrangements of molecules in crystalline solids by exploiting the structural preference for centrosymmetric molecular patterns. Studies of crystal structure data have revealed the tendency for organic molecules to form centrosymmetric patterns. This preference is 10:1 for crystals of achiral, nonpolar organic molecules, and about 4:1 for all structures.

Our efforts center on exploiting this statistical preference for centrosymmetry as a reliable tool towards crystal engineering by:

- Designing and synthesizing quasiracemic crystals. A quasiracemate is described as a molecular crystal composed of (*R*)-X and (*S*)-X', where X and X' are sterically similar molecules.
- Determining and comparing a complete family of related crystal structures [i.e., (*R,S*)-X, (*R,S*)-X', (*R*)-X, (*S*)-X') and quasiracemate (*R*)-X/(*S*)-X'].
- The objective of these studies is to better understand the role of centrosymmetric patterns as a dominant reliable packing motif for crystal engineering studies.

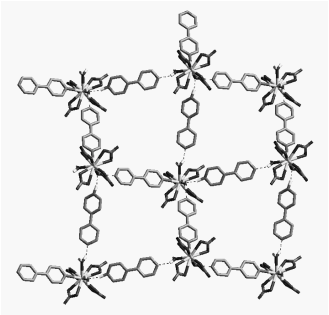
Supported by the Robert A. Welch Foundation (Grant F-233), the Air Force Office of Scientific Research (Grant F49620-97-1-0263), and the National Science Foundation (Grant DMR-9414042).

P11.OD.011 GRAIN BOUNDARIES AND THEIR REGULAR STACKS FOR HIGH TEMPERATURE SUPERCONDUCTING MICROELECTRONICS. E.A. Stepantsov, Institute of Crystallography RAS, Leninski prospect 59, RU-117333 Moscow, Russia, and M.A.Tarasov, Institute of Radio Engineering and Electronics RAS, Mokhovaya 11, RU-103907 Moscow, Russia, and V.Strbik, Institute of Electrical Engineering SAS, SK-84239 Bratislava, Slovakia, and Z.G.Ivanov and T.Claeson, Physics Department, Chalmers University of Technology, S-41296 Gothenburg, Sweden.

Method of multi crystal composite fabrication by means of solid state crystal intergrowth has been developed and optimized for creation of artificial grain boundary (bicrystal) and regular stack of several parallel such boundaries (multi crystal). Such boundaries demonstrate high structural perfection and geometric flatness, and their crystallographic characteristics are monitored with accuracy of a few angular minutes. Composites of Y-ZrO_2 crystals have been used as substrates for epitaxial growth of high critical temperature superconducting (HTS) films. The artificial grain boundary epitaxially grows from the substrate into the HTS film. Such boundary in HTS film form a high quality Josephson junction. Using such a complex with five parallel grain boundaries of symmetrical type and misorientation angle of 24^o separated by a distance of 20 μm in YBaCuO films, we have fabricated series and parallel arrays of Josephson junctions. Such arrays have been used in integrated circuits of two topological types. The first type was a square array of 5x5 junctions forming three Josephson transmission lines with superconducting control lines. The second type comprises one dimensional array of 5 junctions, integrated with a planar log-periodic antenna. Fabricated structures demonstrated parameters consistent with those of individual Josephson junctions, oscillating dependencies of the critical current on magnetic field produced by control lines, and multiple Shapiro steps under submillimeter-wave radiation.

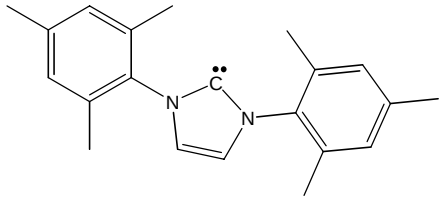
P11.OD.012 LANTHANIDE IONS AS PART OF THE CRYSTAL ENGINEER'S TOOL BOX. Lillian M. Rogers, Grant A. Broker, C. V. Krishnamohan Sharma, and Robin D. Rogers, Department of Chemistry, The University of Alabama, Tuscaloosa, AL 35487, USA.

Much of the current activity in crystal engineering of coordination polymers has focused on utilizing octahedral metal ions (for the available right angles) and linear or angular pyridine-like spacer ligands (e.g., 4,4'-bipyridine, pyrazine, pyrimidine). We are currently exploring larger, more oxophilic metal ions such as the lanthanides which allow an expansion of the coordination sphere from 6 to as high as 12. Using lanthanides, one can easily induce dissymmetry at metal centers simply by coordination with suitable ligand(s) which may thus result in controllable 1D, 2D, or 3D chiral networks with the aid of complementary hydrogen bonding functional groups.



Lanthanum nitrates readily react with bifunctional ligands such as 1,2-bis(4-pyridyl)ethane (bpe), or 4,4'-bipyridyl (bipy) to form chiral open hydrogen bonded complexes under suitable experimental conditions. The crystal structure of [bpeH][$La(NO_3)_4(OH_2)$(bpe)] reveals complementary divergent hydrogen bonding sites located on the back bone of an anionic 1D coordination polymer resulting in a 2D pleated-sheet structure with unusual cavities. Each of these cavities is threaded by two 1D hydrogen bonded linear chains of monoprotonated $bpeH^+$ ligands forming an unprecedented polypseudorotaxane, or "molecular Chinese blinds" structure. The existence of this superb interlocking system offers yet another example of nature's clever ability to solve the void space problem in solids with impeccable self-organization.

P11.OD.013 THE INTERACTION OF N-HETROCYCLIC CARBENES WITH ORGANIC ACIDS. J.A.Cowan, M.G.Davidson, J.A.K.Howard, P.Kuepper, M.A.Leech, Chemistry Department, University of Durham, South Road, Durham, DH1 3LE.



1,3-dimesitylimidazol-2-ylidene.

Carbenes are generally unstable. However, in the C_3N_2 ring, derived from imidazolium, it becomes more stable. The crystal structures of a variety of compounds in combination with the above molecule were investigated. We have found that uniquely, in certain conditions, the carbon atom's lone pair of electrons may act as an acceptor for a X-H..C hydrogen bond. In other situations the carbon becomes protonated, and the hydrogen bond is effectively reversed. This has resulted in an extremely short hydrogen bond. The structures formed by the ligand and metal centres have also produced some very interesting complexes.

Data were collected using a BRUKER SMART area detector, at temperatures down to 100K. The most interesting structures will be repeated at 30K, and further related structures will be investigated.

P11.OD.014 HYDROGEN BONDS BETWEEN OXIME AND CARBOXYL GROUPS — USEFUL TOOL FOR CRYSTAL ENGINEERING. Jan K. Maurin[a,b] and Beata Paluchowska[b], [a]Drug Institute, Chełmska 30/34, 00-725 Warsaw, [b]Institute of Atomic Energy, 05-400 Świerk-Otwock, Poland.

Ten of eleven structures of organic compounds containing both oxime and carboxyl group suggest that oxime group can recognize carboxyl group selectively forming seven-member hydrogen bonded ring. This hydrogen bonded arrangement resembles very much situation observed in both oximes and carboxylic acids hydrogen bonded dimers where six- and eight-member rings are formed, respectively. The preference for oxime-carboxyl interaction was proved also by cocrystalization of oximes with carboxylic acids. Relatively high stability of systems with "multiple hydrogen bonds" is well-known and utilized by crystal engineering.

The *ab initio* quantum chemical modeling was performed for the hypothetical systems containing acid-acid and oxime-oxime dimers and then compared with the results obtained for the system consisted of acid-oxime complexes. This results shows, that oxime-carboxylic acid co-crystals should be favored for 1:1 mixtures of oximes and acids although the energy gain comparing to the usual dimeric systems isn't very high.

Similar calculations have been performed for the systems where oxime and carboxyl groups are placed in one molecule. The

results obtained support and explain the experimental observations for this class of compounds.

Selective recognition of the oxime group by the carboxyl group (and vice versa) makes it possible to utilize this phenomena in crystal engineering for obtaining hydrogen bonded polar chains of molecules and hence polar structures. Although the oxime group could form "multiple hydrogen bonds" with other donor-acceptor groups, such bondings are not so selective as reported here.

11OE QUANTITATIVE ELECTRON DIFFRACTION AND MICROSCOPY

M11.OE.001 BULK STRUCTURES USING DYNAMICAL DIRECT METHODS. L. D. Marks and W. Sinkler, Department of Materials Science and Engineering, Northwestern University, Evanston, IL 60208, USA.

A standard method of determining structures is (kinematical) x-ray diffraction and Direct Methods. This works well if a reasonable size single crystal is available, but it can be difficult and expensive in both time and money to grow such a crystal. An alternative method of obtaining diffraction data is to use transmission electron diffraction. It is simple to obtain information from areas as small as 10nm in a few seconds, making it a very attractive approach.

Unfortunately transmission electron diffraction is rarely, if ever kinematical. Instead it is strongly dynamical which appears to make Direct Methods unworkable. However, if one uses a generalization of Direct Methods using a Feasible Set approach [1], this is not the case. Handled correctly one is obtaining a pseudo-inversion of the diffraction data which gives initial estimates of the atomic positions for subsequent refinement (using either dynamical diffraction models or powder diffraction data).

We have recently been able to employ this approach to solve two previously unknown oxide structures [2]. As a consequence of the dynamical effects [3], it turns out that light atoms (e.g. oxygen) are easier to find at realistic thicknesses. These results will be described as well as extensions to more general cases and the possibility of general pseudo-inversion of dynamical diffraction data from defects.

M11.OE.002 THE PRECESSION TECHNIQUE IN ELECTRON CRYSTALLOGRAPHY. APPLICATIONS TO STRUCTURE DETERMINATION. J. Gjønnes, V. Hansen, E. Sørbrøden, P. Runde and K. Gjønnes, Centre for Materials Science, University of Oslo, Gaustadalleen 21, N-0371 Oslo, Norway.

Electron diffraction patterns from crystals are usually taken with a stationary beam (and crystal), in contrast to X-ray work where the crystal is rotated to produce integrated intensities. With the electron beam entered along a zone axis, dynamical scattering effects are exacerbated.

The recently invented precession technique [1] is a different approach to quantitative electron diffraction: Off-axis beam configurations are used, integrated intensities are obtained, dynamical effects are reduced, more reflections and three-dimensional data can be collected [2]. A 'guided beam' system [3] implemented on a Jeol 2000FX microscope in Oslo will be described. Principles for intensity calculations relating to precession, and applications to structure determination of alloy phases will be presented.

M11.OE.003 USE OF QUANTITATIVE CBED IN MATERIALS SCIENCE. R. Holmestad, C.R. Birkeland, K. Marthinsen, and R. Høier, Dept. of Physics, Norwegian University of Technology and Science (NTNU) N-7034 Trondheim, Norway and J.M. Zuo, Dept. of Physics and Astronomy, Arizona state University, Tempe, AZ, 85287-1504, USA.

The small probe used in Convergent Beam Electron Diffraction (CBED) can give information from minuscule regions beyond the reach of other diffraction methods [1]. By matching experimental CBED patterns with simulations it is possible to determine structure parameters with high accuracy.

The quantitative method is based on pixel-by-pixel comparisons of experimental and theoretical (using Bloch wave theory) intensities. Over the last few years, energy filtering, new digital recording systems, recent development in theory and tremendous advances in computer power have made significant progress in quantitative analysis of CBED.

We will present examples of quantitative CBED used in materials science. Lattice parameters are determined in SiC 4H [2] utilising HOLZ lines in CBED centre disks. Low order structure factors are refined in TiAl intermetallics [3] and CaF_2 from systematic row CBED patterns, to obtain information on bonding charge-density distributions. Three-phase invariants are found in the non-centrosymmetric crystal InP.

M11.OE.004 STRUCTURE REFINEMENT FROM ELECTRON DIFFRACTION DATA TAKING FULL ADVANTAGE OF THE PROPERTIES OF THE SCATTERING. J.Jansen, H.W.Zandbergen, National Centre for HREM, Laboratory of Materials Science, Delft University of Technology, Rotterdamseweg 137, 2628 AL Delft, The Netherlands.

Due to the strong interaction between electrons and crystals, in most cases the kinematical diffraction theory is not a reasonable approximation. Therefore we developed a least-squares procedure to refine crystal structures which incorporates a full dynamical calculation (MSLS). The resulting R-factors obtained with MSLS are comparable in magnitude with the ones one get in single crystal X-ray diffraction. When trying to fit HREM images to dynamically calculated pictures, a similar good match is never achieved. One of the reasons may be scattering contributions. To verify this, we took diffraction patterns with and without energy filtering and diffraction patterns formed by electrons in the plasmon peak of the energy spectrum. Our studies indicate that a substantial amount of electrons is inelastically scattered. On the other hand it appeared that the energy filtering does not have a significant effect on the refined structure and the R-factor. The reason for this is 2-fold 1) since we use integrated intensities, the incoherency between zero-loss and plasmon electrons is of no importance. 2) inelastic scattered electrons with large scattering angles contribute only to the background of diffraction patterns; proper handling of the background eliminates this. Part of our research concerns the applicability of MSLS for structures from relatively thick crystals (>400Å). At those thicknesses the program gets, as expected, very sensitive to the crystal tilt used in the calculations. Another effect observed is that lighter atoms next to heavy atoms tend to move from their correct position. Since we

did those experiments with inorganic materials charge distributions may be a cause for this error. Another explanation may be the present limitations of the multislice method used in the calculations.

M11.OE.005 QUANTITATIVE HREM: VIEWPOINTS ON RESOLUTION, PRECISION AND EXPERIMENTAL DESIGN. A.J. den Dekker, J. Sijbers, and D. Van Dyck Department of Physics, University of Antwerp (RUCA), Groenenborgerlaan 171, B-2020 Antwerp, Belgium.

In principle, quantitative electron microscopy allows the extraction of structural detail beyond the point resolution and even beyond the information limit of the microscope. Essentially, this is achieved as follows. It is assumed that one has a model for the object and the imaging process, including electron object interaction, imaging and recording. This model contains parameters, such as the atom positions (or the positions of projected columns) which are unknown beforehand and have to be determined by the experiment. This is done by fitting the model to the experimental images (or diffraction patterns) with respect to the model parameters, using a proper criterion of goodness of fit (preferably maximum likelihood). In the absence of noise, this would result in a perfect fit, so that exact values for the model parameters would be obtained. The atom positions could then be determined with unlimited precision, independent of the particular setting of the microscope. Notice, that this would also mean that two atoms could always be resolved, no matter how closely spaced, so that there would be no limit to resolution. In reality, however, the precision with which the model parameters can be determined, will always be dose limited. This is due to the inevitable presence of counting noise. Resolution is then reduced to the precision with which atom positions can be determined. From parameter estimation theory [1], one can calculate the lowest possible error bar (standard deviation) on the position of an atom (column) as a function of the controllable experimental parameters for a given electron dose. The experimental parameters corresponding to the lowest error bar (i.e., the highest precision) then suggest the optimal experimental design. For more details we refer to [2].

P11.OE.001 ELECTRON DIFFRACTION FROM MICRO- AND NANOPARTICLES. E. I.Suvorova, Ph. A. Buffat. Centre Interdépartmental de Microscopie Électronique, EPFL, Lausanne CH-1015, Switzerland

On the basis of X-ray and electron diffraction patterns from large regions materials can be called "amorphous" if they give diffuse ring patterns. For diffraction from small crystals the extension of the scattering power around the reciprocal lattice points becomes appreciable in direction perpendicular to the incident beam. The diffraction spots are no longer sharp but are spread out into patches [1]. Assembly of imperfect small crystals with various orientations relatively to the electron beam will provide broadening diffuse rings.

During the study of the crystal growth mechanism of hydroxyapatite which has a large hexagonal unit cell consisting 42 atoms where the Ca atoms are the most heavy it was found that different growth conditions (temperature, supersaturation, concentrations) resulted in formation of crystals with different sizes from a few nm to 1-2 microns. For clarifying the nucleation mechanism it was very important to know the state of hydroxyapatite at the first stage of precipitation from the aqueous solutions. The dry specimens were powders consisting of crystal agglomerates. Selected-area electron diffraction patterns obtained from assemblies of nanocrystals were broad diffuse rings while the polycrystalline and single diffraction patterns were observed from microcrystals. The average size of the individual nanoparticles was 20 nm, microcrystals could reach 1-2 microns. Using electron micro-probes of 3.5-10 nm size gave a possibility to determine the crystalline structure of nanoparticles when the incident beam illuminates only a small area of the specimen and only this area contributs to the diffraction pattern. The size of the microdiffraction depends on the demagnification of the probe-forming lenses, on the electron source size, and on the focus setting, aperture size, and spherical abberation constant of the probe-forming lens. Field emission tip W/ZrO applied in this work had 1micron in size with the crossover diameter of 15 nm (accelerating voltage 300 kV, diameters of the C1aperture 2mm and C2 - 30 microns), convergence angles 2-3 mrad, the spherical aberration constant was 0.65 mm. Hydroxyapatite nanoparticles had a fine grain structure that gave sharp spotty rings. By HRTEM and image calculations with the EMS software [2] the grain sizes and a set of their orientations were determined for individual nano- and microparticles.

P11.OE.002 AN ANALYTIC EXPRESSION IN CLOSED FORM FOR THE ELECTRON EXIT WAVE. P. Geuens, J. H. Chen, A. J. den Dekker, D. Van Dyck, EMAT, University of Antwerp (RUCA), Groenenborgerlaan 171, B-2020 Antwerp, Belgium.

Recently important progress has been made in quantitative structure refinement starting from high resolution electron images and diffraction patterns. The most tedious part in the refinement is the repetitive calculation of the exit wave. A simple expression for the exit wave would allow speeding up both quantitative refinement and image calculations drastically compared to standard multislice or Blochwave calculations.

In this work a simple analytic expression is obtained for the exit wave, of high energy diffracted electrons, for a zone axis plane wave illumination, by parameterisation of the numerical dataset of the normalised and scaled 1S-state presented by Van Dyck and Chen [1].

The electrons are trapped in the electrostatic potential of the atom columns parallel to the electron beam. Hence it is possible to describe the wave function of the diffracted electrons, in terms of the eigenstates of the two-dimensional projected electrostatic potential of the atom columns. It has been shown that this potential has only one important bound eigenstate, which by analogy is called the 1S-state [2].

The Levenberg-Marquardt procedure [3] was used for parameterisation. One normalised gaussian is found to be a sufficient fit. Hardly any improvement is obtained by using two gaussians or one gaussian and an exponential function. The intensities of various diffracted beams in Cu[100] as a function of thickness, calculated both with the presented method and with the standard multislice method, were found in good agreement. The difference between the results is only marginal and smaller than the experimental accuracy.

P11.OE.003 COMPARISON OF ACCURATE X-RAY AND ELECTRON DIFFRACTION DETERMINED STRUCTURE FACTORS FOR α-Al_2O_3. P.N.H. Nakashima and V.A. Streltsov, Department of Physics and A.W.S. Johnson, Centre for Microscopy, UWA, Nedlands 6907, Australia.

To accurately measure the low order structure factors of α-Al_2O_3, two-dimensional convergent beam electron diffraction data from parallel sided platelets (~0.5 μm) have been matched using the Bloch-wave refinement program of Zuo and Spence [1]. In order to further test the precision of the method, as demonstrated in [2], room temperature data sets were collected at 200 and 300 kV, using various crystal thicknesses and orientations. A Philips EM 430 TEM, a Gatan Image Filter™ and a CCD with YAG scintillator were used.

Synchrotron X-ray diffraction data from two small crystals (~10-30 μm) were collected with 0.71 [2] and 0.75 Å wavelengths respectively, using the Photon Factory BL14A diffractometer with a high-speed avalanche photodiode (APD) detector.

The low order Fourier coefficients of the crystal potential determined by electron diffraction were converted to dimensionless X-ray structure factors. The ratios between these structure factors are used to determine the extent of extinction in the synchrotron data.

P11.OE.004 HREM STUDY AND STRUCTURE MODELING OF THE η' PHASE IN AGE-HARDENING Al-Zn-Mg ALLOYS. X.Z. Li, V. Hansen and J. Gjønnes, Centre for Materials Science, University of Oslo, Gaustadalléen 21, N-0317 Oslo, Norway and L.R. Wallenberg, National Center for HREM, Inorganic Chemistry 2, Chemical Center, Lund University, Box 124, S-22100 Lund Sweden.

It is known that the age-hardening effect of commercial Al-Zn-Mg alloys is due to the formation of fine precipitates. One of the most important hardening precipitates is the metastable η' phase [1]. The lattice of the η' phase has a hexagonal lattice with a=0.496 and c=1.402 nm. Knowledge of the η' structure is considered as an essential key to improved understanding of the precipitation process. Several studies relating to the structure of this phase were reported in the literature, however, a definite crystal structure has not been established yet.

In the present work [2], the structure of the η' phase has been studied at atomic level by means of high-resolution electron microscopy (HREM). The individual precipitates were examined in high-resolution images. The HREM images provide valuable structure characteristics of the η' phase. Defects in the structures of individual precipitates have also been observed.

Since the existing models cannot account for the observed images, a new model of the η' phase has been proposed on the basis of the observed images and the structure of the η-$MgZn_2$ phase. Image simulation of the new model shows a good agreement between calculated images and experimental ones Structural features in the present model have been illustrated in comparison with the model proposed by Auld and Cousland [3]. The formation of defects in the structure of the η' phase has also been discussed.

P11.OE.005 HIGH-RESOLUTION ANALYTICAL ELECTRON MICROSCOPY OF FULLERENES AND NANOTUBES IN BORON NITRIDE. D. Golberg, Y. Bando, W. Han, K. Kurashima, and T. Sato, National Institute for Research in Inorganic Materials, Tsukuba, Ibaraki 305-0044, JAPAN, and O. Stéphan, Université Paris-Sud, Orsay 91405, FRANCE, and C. Goringe, University of Sydney, NSW 2006, AUSTRALIA.

Here we report on the precise structural investigation of boron nitride (BN) fullerenes and nanotubes as compared to their carbon (C) counterparts by means of high-resolution transmission electron microscopy (HRTEM), electron energy loss spectroscopy, and nanodiffraction.

Single- and multi-shelled BN fullerenes were synthesized *in situ* from graphitic BN in a JEM-3000F field emission electron microscope by applying intense electron irradiation. Multi-walled BN nanotubes were prepared by laser heating of cubic and hexagonal BN under superhigh nitrogen pressure (up to 15 GPa), or through general substitution chemical reaction from carbon nanotubes.

In contrast to C fullerenes, whose HRTEM images look quasi-spherical (icosahedral symmetry), BN fullerenes displayed rectangle/square-like HRTEM images when viewed in specific projections. The experimentally observed images perfectly matched computer simulated ones for the octahedral structural model. Appearance of four-member ring defects (squares) in the graphene-like BN sheet at the expense of five-member ring defects (pentagons) typical for C was accounted for by the octahedral symmetry of the BN fullerenes. It is thought that a square defect leading to a B-N-B-N atomic chain is favoured in BN due to the higher stability of B-N chemical bonds compared to B-B and N-N bonds.

In contrast to C nanotubes, which show a wide range of helicities, multi-walled BN nanotubes typically displayed remarkable ordering of the tubular shells in a non-helical "zig-zag" form with B-N bond parallel to the tube axis. This is considered to be due to the existense of selection criteria for lip-lip interactions between tube shells in BN nanotubes compared to C ones. BN nanotube tip-ends were found to be blunt in accordance with the stability of even-member ring defects (squares and/or octagons) in contrast to the conical tip-ends caused by pentagonal ring defects in C nanotubes.

P11.OE.006 QUANTITATIVE HIGH RESOLUTION ELECTRON DIFFRACTION FOR DETERMINATION OF THE ELECTROSTATIC POTENTIAL. Avilov A., Kuligin A., and Lepeshov G., Institute of Crystallography RAS, Moscow, Russia 117333, Pietsch U., Potsdam University, Germany, Spence J., Arizona State University, Tempe, AZ, Tsirelson V., Mendeleev University, Moscow, Russia

The structure analysis by with the high resolution electron diffraction (HRED) is based on the use of high energy electron diffraction to reconstruct the electrostatic potential (ESP) and its analysis to extract the structure information. Since ESP is connected with all fundamental physical properties of crystal, its precise determination presents an important problem. To solve this problem this work is devoted to the development of the precise HRED, to quantitative determination of the distribution of ESP in the binary ionic crystals and to the working out of methods of direct calculation of properties of crystals from the electron diffraction data.

The development of quantitative HRED demands solving a number of problems: the precise measurement of intensity of diffraction patterns (DP); calculation of the primary extinction effects (as soon as secondary extinction is absent); and accounting for the inelastic scattered electrons.

The modified scanning of DP system with the statistical accuracy of measurement about 1% was developed. The methods

of the accounting for the effects of primary extinction for partly oriented polycrystalline films, which are normally used in HRED were worked out. The precise HRED investigations of binary ionic crystals MgO, LiF and NaF have been made. The distributions of ESP in this substances were reconstructed with high accuracy both with the aid of Fourier synthesis and by with the analytical models. Some physical properties were calculated (as diamagnetic susceptibility and static electron polarizability). The known in precise X-rays structure analysis κ-model was used for the analysis of the nature of chemical bonding for the first time in HRED. Received results correlate well with precise X-rays data and the results of the calculations by Hartree-Fock method.

Work is supported by CRDF grant No. RP1-208, RFBR grant No. 98-03-32654 and DFG grant No. Pi 217/13-1.

P11.OE.007 ELECTRON DIFFRACTION INTENSITIES FROM PARTICLES AND ZONES IN A MATRIX. GP-ZONES IN AN AlMgZn ALLOY. V. Hansen, L.K. Berg, X.Z. Li and J. Gjønnes, Centre for Materials Science, University of Oslo, N-0317, Norway, M. Knutson-Wedel, Chalmers University of Technology, S-412 96 Gøteborg, Sweden, G. Waterloo, Hydro Raufoss Automotive Research Centre, 2830 Raufoss, Norway

Precipitation hardening alloys are characterised by a dispersion of metastable particles or zones in the nm size-range. Electron crystallographic techniques are the most efficient techniques for obtaining structure information from such systems, which call for quantitative measurement of different intensities from coherent particles, embedded in a metal matrix.

The structures of coherent zones and precipitates in an Al-(Mg, Zn) alloy that occur along the transformation path during a two-step ageing treatment at 100°C and 150°C have been investigated by HREM and electron diffraction. Electron diffraction intensities were measured from photographic films and image plates, taken in a JEOL 200CX and a LEO 412 energy-filtering microscope. Dynamical diffraction effects involving matrix reflections must be included in the interpretation - or reduced by selection of open aluminium projections. Three-dimensional intensity distributions have been constructed and interpreted in terms of two types of zones (GP(I) and GP(II)) and the metastable hardening phase η'. A new structure model for ordering within the GP(I)-zones is presented. The structures are discussed in relation to the transformation sequence from GP-zones via the metastable phase n' to the stable phase η-$MgZn_2$.

P11.OE.009 REFINEMENT OF CRYSTAL STRUCTURAL PARAMETERS BY CONVERGENT-BEAM ELECTRON DIFFRACTION. K.Tsuda, M.Tanaka Research Institute for Scientific Measurements, Tohoku University, Sendai 980-8577, Japan

A new method to refine crystal structural parameters using convergent-beam electron diffraction (CBED), which is applicable to nm-size crystal structure analysis, is presented. This method is based on the fitting between theoretical calculations and experimental intensities of energy-filtered two-dimensional CBED patterns containing higher-order Laue zone (HOLZ) reflections. The two-dimensional CBED data provide much more structural information than zero- and one-dimensional data. The use of HOLZ reflections is essential for method because small displacements of atoms can be sensitively detected using HOLZ reflections with large reciprocal vectors. For this purpose, a new Omega-filter transmission microscope (JEM-2010FEF) which can take energy-filtered CBED patterns up to a high angle with a small distortion, and a new analysis program to refine structural parameters which is based on many-beam Bloch wave calculations and non-linear least squares fitting have been developed. Structural parameters of the intermediate phase of hexagonal $BaTiO_3$ have been refined by the new method. Hexagonal $BaTiO_3$ undergoes a second order phase transformation at 222K from the high-temperature phase of the space group $P6_3/mmc$ to the intermediate phase of the space group $C222_1$.

P11.OE.010 QUASICRYSTAL APPROXIMANTS IN THE Ga-Mn SYSTEM STUDIED BY ELECTRON CRYSTALLOGRAPHY. S. Hovmöller, M. Boström, K. Sun, X.D. Zou, Structural Chemistry, Stockholm University, S-106 91 Stockholm, Sweden.

Several new quasicrystal approximants are found in the Ga-Mn system [1]. Structure models for three of them were derived by the tiling method [2]. This method requires as a starting model a known crystal structure with close structural relationships with the approximant. HREM images of the approximant are compared with those of the known structure. Common tiles are found and the structural model of the unknown approximant is generated using the atomic arrangement in the tiles of the known structure.

It was not possible to derive a structure model for a tetragonal approximant (T-phase, a = 1.25 nm and c = 2.50 nm), since no known structures, related to this T-phase, were found. Instead we try solve the crystal structure from high resolution electron microscopy (HREM) images and refine the atomic coordinates against electron diffraction intensities [3], in short by electron crystallography.

HREM images and selected area electron diffraction patterns of the T-phase are taken along several different zone axes. Only very thin regions of the crystals, where dynamic scattering is minimal, are used. Amplitudes and phases of the structure factors are extracted from the Fourier transforms of each HREM image. Amplitudes are also obtained from electron diffraction patterns. Crystallographic symmetry constraints are imposed on the amplitudes and phases. Projected potential maps are obtained from each zone axis by inverse Fourier transformation of the amplitudes and phases.

We are now trying to construct an atomic structure model in 3D of the T-phase by combining all the projections into one 3D potential map.

11OF PEROVSKITE MATERIALS

M11.OF.001 THE UNUSUAL DIELECTRIC PROPERTIES OF PEROVSKITES: FROM NONVOLATILE MEMORIES TO MEDICAL IMAGING. N. Setter, Ceramics Laboratory, EPFL - Swiss Federal Institute of Technology, 1015 Lausanne, Switzerland

Recent advances in dielectric materials with perovskite and perovskite-based layer structures show great potential for meeting the demands for higher sensitivities, operation at higher frequencies and higher temperatures, smaller power consumption and further miniaturisation of next generation electronic and sensorial components:

Bismuth containing ferroelectric perovskite-based layer structure materials with suppressed ferroelectric fatigue have been developed [1]. This is a key feature towards the commercialisation of ferroelectric non-volatile memories.

Suppression of piezoelectric hysteresis has been demonstrated in other bismuth-based layer structure ferroelectrics [2], making them useful for high temperature piezoelectric sensors.

The control of the temperature coefficient of the resonance frequency of high permittivity dielectrics, critical for high

performance of microwave resonators for wireless communication, was shown [3] to be possible using structural arguments.

Positional disorder in lead-based complex perovskites is known since some time to be responsible for the so-called relaxor behaviour, giving rise to useful properties such as very high permittivity and electrostriction. Certain relaxor-ferroelectrics single crystals have been shown recently to possess giant piezoelectricity [4], potentially very useful for improved resolution of ultrasonic medical imaging.

These and other unusual dielectric, piezoelectric, pyroelectric and ferroelectric properties of perovskite ceramics will be reviewed with emphasise on the role of crystalline structure in achieving excellent functionality.

M11.OF.002 ORDERING, MIXED-VALENCE AND METALLIC CHARACTER ALONG THE REDOX RANGE IN $LnBaM_2O_{5+w}$ (M = Fe and Co). Pavel Karen, Department of Chemistry, University of Oslo, Box 1033 Blindern, N-0315 Oslo, Norway.

A full replacement of the perovskite coordination-octahedra with ordered square pyramids leads to doubling of the unit-cell according to formula $AA'M_2O_5$. Suitably sized trivalent lanthanides (Ln) as A atoms and Ba as the A' atom are able to stabilize this arrangement for transition metals M like Mn, Fe and Co. The implied non-integer average valence $M^{2.5+}$ and an entire vacant oxygen site are the main ingredients for a multitude of structural, electronic, magnetic and electric properties changing along a wide solid-state redox-stability range. $LnBaM_2O_{5+w}$ phases with selected combinations of Ln = Nd, Sm, Gd, Y and M = Fe, Co are studied on quenched samples with *w* varied between 0.00 and 0.80. Structural consequences are investigated by powder neutron and synchrotron x-ray diffraction and involve distortions of the tetragonal (S.G. *P4/mmm*) prototype and/or further ordering schemes for significant compositions in terms of *w*. Valence and spin states of M are studied by ^{57}Fe Mössbauer spectroscopy (for M = Co, 1% of it is replaced by ^{57}Fe). A mixed-valence AF state $Fe^{2.5+}$ is observed at room temperature for the prototype composition and fades away with increasing *w*. Upon cooling below the transition temperature of around 200 K, the $Fe^{2.5+}$ state separates into a high-spin Fe^{3+} state and Fe^{2+} with unusually low internal magnetic field. The transition is associated with a small change in magnetic susceptibility and a weak thermal effect, implying a charge ordering into an electron localized state. Samples with the most reduced M = Fe and the most oxidized M = Co have a silver luster appearance at room temperature, and optical reflectivity spectra as well as electrical conductivity measurements illustrate changes in the occurrence of the metallic character as a function of *w* and temperature. The $Fe^{2.5+}$ valence state mixing coincides with the metallic state and is therefore closely reminiscent of the Verwey transition in magnetite, Fe_3O_4, one of the earliest examples of charge ordering in a transition metal oxide.

M11.OF.003 ORDERED AND DISORDERED STRUCTURAL CONTROL OF PEROVSKITE PROPERTIES. J. P. Attfield, Department of Chemistry and IRC in Superconductivity, University of Cambridge, Cambridge CB2 1EW, UK.

Many transition metal oxide perovskites and related materials show remarkable conducting properties such as colossal magneto-resistances at the metal-insulator transition in $Ln_{1-x}M_xMnO_3$ and superconductivity in $Ln_{2-x}M_xCuO_4$. Changes in electronic behaviour with hole doping level x have been extensively studied, but there are also variations in property when different Ln^{3+} (lanthanide) or M^{2+} (Ca, Sr, Ba) cations are used. We have shown that these cation effects may be described by two quantities, the mean radius of the Ln/M cations (equivalent to the well known perovskite tolerance factor) and the disparity in their radii, parameterised by the statistical variance in the radius distribution. Experiments reveal that both the metal-insulator transition temperature in $Ln_{1-x}M_xMnO_3$ perovskites [1] and the critical temperature of $La_{2-x}M_xCuO_4$ superconductors [2] are very sensitive to changes in either of these quantities. The results enable simple quadratic relationships for the size and disorder effects to be derived [3]. Powder neutron diffraction has been used to determine how both ordered and disordered structure change with cation size and variance giving insight into the structure-property relations.

M11.OF.004 NEW SUPERCONDUCTING BISMUTH-ATES IN PEROVSKITE RELATED SYSTEMS. C. Bougerol-Chaillout and P. Bordet, Laboratoire de Cristallographie CNRS, BP166, 38042 Grenoble cedex 9, France; S.M. Kazakov, J. Pshirkov, S.N. Putilin, and E.V. Antipov, Chemistry Department, Moscow State University, Moscow 119899, Russia and M. Hanfland, ESRF, BP220, 38043 Grenoble cedex France.

Following the discovery of $BaPb_{1-x}Bi_xO_3$ (T_c~12K) in 1975 by Sleight et al. [1] and that of $Ba_{1-x}K_xBiO_3$ (T_c~40K) by Mattheiss et al. [2], we have been able to synthesize a new bismuth-based oxide, $SrBiO_3$, and to induce superconductivity by K or Rb doping [3] performed under high pressure. T_c maximum is about 12K when the K-substitution is larger than 45%, the solubility limit being around 60%. These new compounds have a distorted perovskite-based structure. Powder synchrotron and neutron diffraction have shown that, as a function of K doping, the symmetry changes from monoclinic (space group $P2_1/n$) to tetragonal (space group I 4/mcm) and remains the same down to 4K. Above room temperature, $SrBiO_3$ keeps the same structure until decomposition around 700°C, whereas the K-doped phases decompose around 300°C. An increase of T_c was observed when resistivity was measured as a function of pressure. On a structural point of view, powder synchrotron studies carried out at room temperature indicate that pressure induces an increase of the tetragonal distortion. In the case of $SrBiO_3$, no noticeable change was observed. By increasing the Sr/Bi ratio above 1, it has been possible to obtain a new cubic perovskite phase having a double lattice parameter.

Recently, we focussed on the search for Rudelsden Popper type compounds containing bismuth. $(Sr,A)_3Bi_2O_7$ compounds with A=K, or Rb have been obtained. The average structure was refined in the tetragonal I4/mmm space group, however, superstructure reflections observed by electron microscopy indicate that the real structure has a larger unit cell.

M11.OF.005 ANION- AND CATION-DEFICIENT HEXAGONAL PEROVSKITES. R.V. Shpanchenko, Department of Chemistry, Moscow State University, 119899 Moscow, Russia.

Mixed anion- and cation-deficient hexagonal oxides with perovskite-like structures have been synthesised and studied by X-ray diffraction and high resolution electron microscopy. Anion and cation vacancies in such compounds are localised in a structural block containing two or three face shared octahedra.

Anion-deficient perovskites $AnBnO_{3n-d}$ (A = Ba, Sr; B= rare earth, Zr, Al) were obtained for different rare earth elements. Their structures consist of alternating BaO_3 and BaO_2 layers. The presence of Al atoms with a stable tetrahedral co-ordination provides a possibility for anion ordering with a formation of Al_2O_7 groups.

Cation deficient hexagonal perovskites $AnB_{n-d}O_{3n}$ (A= Ba, Sr, La; B = Ta, Zr, Ti, Ni) were obtained in the $Ba_5Ta_4O_{15}$ - ABO_3 systems. An electrostatic interaction between B-cations located in the neighbouring octahedra is an important parameter influencing a type of close-packing and cation ordering. A presence of two cations with different charges in the B-framework results in their ordering among different positions. Inter-growth structures ($Ba_5Ta_4O_{15}$ ´ n(Ba,Sr)ZrO_3) are obtained only with Zr. In this case compounds with general formula $(Ba,Sr)_{5+n}Ta_5Zr_nO_{15+3n}$ (n=1,2) form. However, a replacement of Zr^{4+} by Ti^{4+} results in a formation of new structures: $Ba_{10}Ta_{7.04}Ti_{1.2}O_{30}$ (10H) and $Ba_8Ta_4Ti_3O_{24}$ (8H), where only pairs of face shared octahedra are present instead of columns of three face shared octahedra. In the latter structures, the B-cations and vacancies are located in the (10H) and (8H) compounds in a disordered and ordered manner, respectively. The further ordering in the B-sublattice takes place upon replacement of Ti^{4+} by Ni^{2+} in the $Ba_8Ta_6NiO_{24}$ structure due to the larger charge difference.

M11.OF.006 STRUCTURAL AND MAGNETIC PHASES TRANSITIONS IN THE NEW PEROVSKITE $HoBaCo_2O_5$. E.Suard, Institut Laue Langevin, Av. des Martyrs, F-38042 Grenoble, F.Fauth, Swiss Light Source (SLS), Paul Scherrer Institute, CH-5232 Villigen PSI, V.Caignaert, Laboratoire CRISMAT-ISMRA, Bd du M^{al} JUIN, F-14050 CAEN, I.Mirebeau, Laboratoire Léon Brillouin, CE-Saclay, F-91191 Gif sur Yvette.

In the new ordered oxygen deficient perovskite $HoBaCo_2O_5$, we have observed by neutron powder diffraction two structural phase transitions at 350K and 210K, corresponding to the occurrence of magnetism and charge ordering, respectively. In the paramagnetic domain ($T_N \approx 350K$), the crystal structure is tetragonal with P4/mmm space group and derives from the perovskite structure. Cell parameters are $a=b\approx a_p$, $c\approx 2a_p$ where a_p is the cell parameter of the cubic perovskite. The structure is described with an alternate stacking of holmium and barium layers along *c* direction, and rows of CoO_5 pyramids as in $YBaCuFeO_5$ structure [1]. When cooling down, a magnetic moment appears on the Co sites resulting in an AF structure with a propagation vector k=(½ ½ 0). The Co spins point along a crystallographic direction in the *ab* plane and therefore induce an orthorhombic distortion of the nuclear structure. In the temperature range $210K<T<350K$, the space group is Pmmm. For $T<210K$, we have observed a doubling of the cell in the b direction and solved the nuclear structure in the Pmmb space group, leading to the existence of two different sites for the Co atoms. It is interpreted by a charge ordering of the Co^{2+}/Co^{3+} cations over these two sites, which also induces a perturbation in the magnetic ordering due to the existence of two magnetic sublattices with Co^{2+} HS and Co^{3+} HS. Both transitions have been confirmed by DSC and resistivity measurements.

P11.OF.001 *IN-SITU* NEUTRON DIFFRACTION STUDY OF PZN-PT PIEZOELECTRIC SINGLE CRYSTAL UNDER AN APPLIED VOLTAGE. J. S. Forrester and E. H. Kisi, The University of Newcastle, Callaghan, NSW, 2308, Australia, and R. Piltz, Australian Nuclear Science Technology Organisation, PMB 1, Menai, NSW, 2234, Australia.

A new class of piezoelectric ceramics known as PZN-PT have recently been discovered. Unlike typical piezoelectric ceramics (*e.g.* lead zirconate titanate (PZT)) which can show strains of only 0.17% in a strong electric field (1), the new single crystal, $Pb(Zn_{1/3}Nb_{2/3})O_3$-$PbTiO_3$ can exhibit strains of up to 1.7% in an electric field of 120 $kVcm^{-1}$ (2). The underlying cause for this phenomenon is poorly understood, but is likely to be related to a field induced crystal structure transformation. Recent studies of the piezoelectric and dielectric properties (3) have suggested that the initially rhombohedral symmetry becomes tetragonal during application of the field.

The current work aims to determine details of the crystal structure, and using *in-situ* neutron diffraction experiments in an electric field, to examine structural changes and phase transformations. Diffraction data is being collected while the crystal is subjected to increasing applied voltage in the range 0-120 $kVcm^{-1}$ and the results will be discussed in detail.

P11.OF.002 POINT DEFECTS AND EXTENDED DEFECTS IN THE PEROVSKITE-STRUCTURED TITANATES. R. Waser, Institut für Werkstoffe der Elektrotechnik II, RWTH Aachen University of Technology, D-52056 Aachen, and Institut für Festkörperforschung, Forschungszentrum Jülich, D-52425 Jülich, Germany

A large variety of dielectric and ferroelectric ceramic components today is build upon alkaline earth and lead titanates and solid solution derivatives. A key to understand, to tune, and to tailor the electronic properties of the components is the control of the defect structure of the crystal lattice. This control has to cover the bulk of the ceramic grains as well as the region in the vicinity of interfaces such as grain boundaries and surfaces.

Recent research results have shown that point defect models in combination with the Poisson relation and the continuity equation permit to describe the grain boundary impedances in titanate ceramics in all details. At the surface, additional phase separation processes may occur which seem to be accompanied by the formation of extended defects.

The present understanding of the interrelationship of the extended defects and the point defects in titanates as well as their impact on the electrical properties will be discussed.

P11.OF.003 SYNTHESIS, STRUCTURE AND ELECTRON DENSITY DISTRIBUTION OF $SrFeO_{3-x}$ AND (Sr-Ba)TiO_3 B.N. Kodess[1,5], V.K. Ovcharov[1], A. Bush[2], V.G. Smotrakov[3], V.A.Sarin[4], A.M. Balagurov[6], L.A Butman[5], A.Y. Boyko[5] [1] Department of Crystal Metrology, VNIIMS, 119361 Moscow, Russia, [2] MIREA, 119 382 Moscow, Russia, [3] RSU, Rostov/Don, Russia [4] INR, 117312 Moscow, V-312, [5] ICS&E, Aurora, CO 80015, USA, [6] JINR, Dubna, Russia,

Strontium titanate ($SrTiO_3$) shows a displacive phase transition of cubic to tetragonal phase transitions at 110 K. T_c for system of $Sr_xBa_{1-x}TiO_3$ single crystals with x=0.025 is ~ 28 K. Oxygen-deficient perovskite of Sr exist in tetragonal symmetry at temperatures above 270 K.

Synthesis of stochio- and non-stochiometric monocrystalls of solid solutions of perovskite with variable composition and oxygen has been conducted. Verneuil methods has been used for titanate strontium and barium and zone melting with radiant heating for ferrate strontium. Determination of structural parameters of these and Standard References Materials has been conducted using accurate x-ray measurements in full sphere on four-circle CAD-4 and KM-4 diffractometers as well as time-of-flight neutron diffraction on High-Resolution Fourier Diffractometer on the IBR-2 reactor. Lattice parameters of ferrate strontium a=в=3.8535(3) and c=3.8781(3) Å correspond to $SrFeO_{2.79}$ composition. Their value is non-dependent from order of reflection; this is evident from stacking fault. Similar distortion of the cubic system were observed for $SrTiO_{2.7}$ with a=b=3.918, c=3.881. Substitution of Sr with Ba produces extra space around ions of Sr and increases lattice parameters from 3.905(1) to 3.920(1) for values of x = 0.25.

Deformation density maps and atomic displacements in pure perovskite and solid solutions were studied by high-precision X-ray diffraction analysis of single crystals. Also analysis of main features of electron distribution was performed. Electron density maps show distinct aspherity of charge both near transition-metals atoms as well as near strontium and barium atoms.

P11.OF.004 EXPERIMENTAL STUDIES OF OCTAHEDRAL TILTING IN PEROVSKITES. C.J. Howard, Australian Nuclear Science and Technology Organisation, Private Mail Bag 1, Menai, NSW 2234, Australia, and B.J. Kennedy, School of Chemistry, The University of Sydney, Sydney, NSW 2006, Australia and B.C. Chakoumakos, Solid State Division, Oak Ridge National Laboratory, Oak Ridge, TN 37831, USA.

Following a recent group theoretical study of octahedral tilting in perovskite [1], a number of related experimental studies have been completed, and the results are reported here. The interest in this work has been to examine the rotation and/or distortion of the oxygen atom octahedra in metal oxides having perovskite type structures. Neutron diffraction was used to determine the oxygen positions from which the octahedral rotations and distortions were derived.

Results are given for a number of compounds, including $SrZrO_3$, $SrHfO_3$, $CaTiO_3$, $NaTaO_3$ and $LaGaO_3$. In each case, the crystal structures have been followed to high temperatures, and intermediate phases between the room temperature orthorombic and high temperature cubic phase identified.

Close attention has been paid to temperature regimes in which only a simple octahedral tilt (tilt around a single symmetry axis) pertains. Each of the first four compounds transforms to cubic from a tetragonal phase (with octahedral tilt around the fourfold axis), and in each case, as far as can be determined from our measurements, the tilt angle in the tetragonal phase decreases continuously towards zero as the temperature is raised. There are interesting differences, however, in the functional form of this variation, suggesting the transition may be second order in some cases and of tricritical type in others. The $LaGaO_3$ transforms at modest temperature to a rhombohedral phase, but though the tilt angle in this phase decreased slowly with increasing temperature, the sample reacted with the sample can before the supposed transformation to cubic.

11AA DRUG DISCOVERY AND DESIGN (sponsored by 3-Dimensional Pharmaceuticals)

M11.AA.001 WHY ARE β-LACTAMS SO SPECIAL? - STABLE AND UNSTABLE ACYL-ENZYME COMPLEXES OF SERINE PROTEASES. R.C. Wilmouth, I.J. Clifton, N.J. Westwood, S. Kassamally, C.V. Robinson and C.J. Schofield, The Oxford Centre for Molecular Sciences and The Dyson Perrins Laboratory, University of Oxford, South Parks Road, Oxford OX1 3QY, UK.

Comparison of the crystal structures of the acyl-enzyme complexes formed between a serine protease, porcine pancreatic elastase (PPE), and peptidic or lactam-derived inhibitors demonstrates why certain complexes may be resistant to hydrolysis and gives insights into the success of β-lactams as enzyme inhibitors.

Mass spectrometric screening revealed that a natural heptapeptide, human β-casomorphin-7 (BCM7), reacted with PPE to form an unusually stable acyl-enzyme complex. The X-ray structure[1] of this complex showed that the ester carbonyl was located in the oxyanion hole and, above it, in an optimal position for attack a well defined 'hydrolytic' water molecule was identified.

β-Lactam containing antibiotics remain amongst the most important therapeutic agents in clinical use and, more recently, β-lactams have been developed as inhibitors of serine proteases. The structure of the stable complex formed between PPE and a monocyclic β-lactam[2] showed that, in comparison to the PPE:BCM7 complex, the ester carbonyl had rotated out of the oxyanion hole with concomitant displacement of the hydrolytic water. A series of γ-lactam inhibitors based upon the monocyclic β-lactam were synthesised to investigate further the 'special' nature of the β-lactam ring. In the crystal structure of the acyl-enzyme complex formed between PPE and one of these monocyclic γ-lactams, displacement of the hydrolytic water was again observed but without rotation of the ester carbonyl. The combined knowledge of these structures suggests ways in which these γ-lactams and similar inhibitors might be modified to improve their inhibitory properties.

M11.AA.002 DISCOVERY & X RAY STRUCTURE DETERMINATION OF NOVEL CYCLOPHILIN LIGANDS. G. Kontopidis, P. Taylor, and M. Walkinshaw. Structural Biochemistry Group, ICMB, University of Edinburgh, Edinburgh EH9 3JR

We have used cyclophilin A as a template for the design and discovering of novel small molecule ligands. Putative ligands were selected by two different methods; by structure similarity and using the docking program LIDAEUS. Twenty nine small molecules were selected from a small molecule database and were tested with a fluorescence assay and PPIase assay for binding activity. Six new ligands have been discovered which bind to Cyp-A. The X-ray structures of a number of the ligands including 3-acetyl-1 methyl piperidine, ethyl-piperidine glyoxylate, dimethyl sulfoxide, tetramethylene sulfoxide and cyclopentanone have been solved and refined.

The structural analysis of the native and ligand structures revealed a hydrophobic pocket surrounded by residues Asn 102, Met 61, Arg 55 and His 122, a hydrogen bond donor site of the main chain nitrogen Asn 102, and another hydrogen bond donor site of the guanidinium of Arg 55. Some significant side chain movements are observed on binding of some of the ligands. The ligands can be classified into 2 different families of compounds.

The piperidine family shares structural similarities with natural dipeptide substrates of Cyp-A. Dimethyl sulfoxide (DMSO), tetramethylene sulfoxide and cyclopentanone form the DMSO family.

M11.AA.003 IRREVERSIBLE HIV-1 PROTEASE INHIBITOR: STRUCTURE, DESIGN AND KINETICS OF CYCLIC UREA EPOXIDES. Chong-Hwan Chang, Indawati De Lucca, Ronald Klabe, Jodie Duke, Edward Huston, Nicolas Hodge, Paul Aldrich, David Nugiel, George DeLucca, James Meek, DuPont Pharmaceuticals Company, Experimental Station, Wilmington, DE 19880

The human immunodeficiency virus (HIV) encodes an aspartic protease (PR) that cleaves the *gag* and *gag-pol* viral proteases into replicative enzymes and structural proteins. We have previously described the design and synthesis of cyclic ureas (CUs) as a novel, potent, non-peptide inhibitors of HIV PR. The CU with its seven-membered ring heterocycle is a very efficient chemical scaffold for many varieties of substituents at the S1, S2, S1', S2' binding sites of protease. To overcome difficulties of a necessity of a large molecule to fit the all the binding sites for a potent inhibitor, of a plasma protein binding, and of a drug resistant mutation, a irreversible inhibitor has been designed while keeping the CU-scaffold.

The designed cyclic urea epoxides should react with the aspartic acid in the active site to form a covalent bond. Kinetic studies indicate that the second order rate constant (k_{inact}/K_I) ranges from $1.4x10^3$ to $3.3x10^6$ M^{-1} min^{-1}.

The three-dimensional structure of HIV PR complexed with a irreversible CU has been determined with 1.8 Å diffraction data. The inhibitor binds covalently with the catalytic aspartate. While forming the bond, the aspartate residue shifts toward the center of the active site. The largest shift, 1.7 Å, occurs at the side chain of aspartate while the shifts of CU is considerably small.

The details of the binding mode and kinetics data will be discussed.

M11.AA.004 NOVEL MODES OF ANTIBIOTIC INTERACTIONS WITH ELONGATION FACTOR Tu. F. Jurnak, S.E. Heffron, S. Mui, K. Abel, A. Auroa, S. Watkins Department of Physiology and Biophysics, University of California, Irvine, CA 92697

The laboratory has solved the three-dimensional structures of two EF-Tu-antibiotic complexes and several additional complexes are in progress. All structures have been solved by molecular replacement methods. The first structure is that of a trypsin-modified EF-Tu-GDP-tetracycline complex. The complex crystallizes in space group P21, with a = 69.7 Å, b = 156.1 Å, c = 134.8 Å, b = 95.4° and six molecules per asymmetric unit. The structure has been refined to a crystallographic R factor of 18.7% at a resolution of 2.7 Å. The structural analysis reveals that the active phenylidiketone moiety of tetracycline binds to the GTPase center of EF-Tu. The results suggest a novel, but overlooked, mechanism of tetracycline inhibition of protein synthesis. The second structure is that of an EF-Tu-GDP-GE2270A complex. GE2270A is a member of the cyclic thiazolyl peptide antibiotic class. The antibiotic inhibits bacterial protein synthesis by binding to EF-Tu, with such a strong affinity that the protein must be denatured to release the antibiotic. The complex crystallizes in C2, with a = 133.47 Å, b = 45.17 Å, c = 144.00 Å, b = 94.64° and two molecules per asymmetric unit. The structure has been refined to a crystallographic R factor of 20.0% at a resolution of 2.3 Å. The structural analysis reveals that the GE2270A binds to the second domain of EF-Tu, primarily through hydrophobic interactions. The extraordinary high affinity of the antibiotic for the protein is due to the formation of a protein salt bridge formed over the antibiotic. A comparative analysis of all conformations of EF-Tu suggests that GE2270A inhibits protein synthesis by preventing the conformational change associated with the GTP state as well as sterically competing with the binding site of the aminoacyl group of charged tRNA. If completed, the results of other EF-Tu-antibiotic structures will also be presented.

M11.AA.005 POTENT, BIOAVAILABLE THROMBIN INHIBITORS: DRUG CANDIDATES FROM STRUCTURE BASED DRUG DESIGN, COMBINATORIAL CHEMISTRY AND CHEMI-INFORMATICS. John C. Spurlino, F. Raymond Salemme, Martin McMillan, Roger Bone, Richard M. Soll, Bruce Tomczuk, Tianbao Lu, Carl R.Illig, Larry Murphy, Anna Radzicka, Troy Randle, Stephen Eisennagel, and Frank Lewandowski. 3-Dimensional Pharmaceuticals, Inc., Eagleview Corporate Center, 665 Stockton Drive, Exton, Pennsylvania 19341, USA.

Efficient drug discovery is facilitated greatly by the knowledge of three dimensional molecular structures of protein-inhibitor complexes gained from crystallographic methods. Structure-activity relationships (SAR) need not be inferred in a limited fashion simply from the regiochemistry of an inhibitor and pharmokinetic data when direct structural information is available. Crystallography is an essential technique of modern drug discovery but to be most effective it needs to be coupled in an iterative, high throughput loop with the parallel synthetic methods of combinatorial chemistry, and high throughput screening assays. The huge amounts of information generated in this loop need to be assessed and then used to guide the drug design through the next cycle. The realm of chemi-informatics gives tools to correlate individual pieces of physicochemical properties or observations and categorize trends in similarity or diversity among a vast number of compounds.

Here we present some results of successful efforts to design potent, bioavailable thrombin inhibitors based heavily on SAR from the x-ray crystallographic studies of dozens of thrombin-inhibitor complexes. This information was coupled intimately with parallel high throughput analysis, synthesis, screening, and further structural elucidation to give an efficient, shortened drug discovery process.

P11.AA.001 DISPLACEMENT OF WATER IN THE DNA MAJOR GROOVE BY A DNA INTERCALATOR AT ATOMIC RESOLUTION. A.K.Todd[a], J.H.Thorpe[a], A.Adams[b], W.A.Denny[c], and C.J.Cardin[a], [a]Chemistry Department, University of Reading, Whiteknights, Reading RG6 6AD, U.K., [b]Biochemistry Department, University of Sydney, Sydney 2006, Australia. [c]Faculty of Medicine and Health Sciences, University of Auckland, N.Z.

The X-ray structure of compound *N*-[2-(dimethylamino)ethyl-9-amino-5-bromo-4-carboxamide (**1**), was determined by MAD methodologies. It is a derivative of the antitumour agent *N*-[2-(dimethylamino)ethyl]-4-carboxamide (**2**) which is currently undergoing clinical trials in the UK. Compound (**1**), although slightly less potent than (**2**) displays similar biological activity and like (**2**) is known to be a mixed topoisomerase type I and II poison. The acridine chromophore intercalates preferentially between CpG bases with the side chain; $(CO)NCH_2CH_2NH^+(CH_3)_2$, which appears to be a critical structural feature in the activity of this class of compounds, protruding into the major groove and forming a hydrogen bond between the dimethylamino terminus of the side chain and the O6 of an adjacent guanine group. The roughly symmetrical intercalation site allows binding of the drug in two orientation, this results in orientational disorder in the crystal. The disorder of the bound drug is translated via water H-bonded interactions to

produce disorder of the nearby 5-bromouridine group, illustrating the side chain's ability to disrupt the highly conserved major groove hydration.

P11.AA.002 CRYSTAL STRUCTURES OF HUMAN SQUALENE SYNTHASE ENZYME:INHIBITOR COMPLEXES. J.Pandit, D.E. Danley, G.K. Schulte, S.M. Mazzalupo, T.A. Pauly, F.M. DiCapua, C.M. Hayward, E.S. Hamanaka, J.F. Thompson and H.J. Harwood Jr. Pfizer Central Research, Groton, CT 06340, USA.

We have determined the crystal structure of recombinant human squalene synthase (rhSQS) to assist in the discovery of selective, potent inhibitors of SQS which could be developed as potential anti-hypocholesterolemic drugs.

Squalene synthase catalyzes the biosynthesis of squalene, a key cholesterol precursor, through a reductive dimerization of two C_{15} farnesyl diphosphate (FPP) molecules. Since FPP is located at the final branchpoint in the isoprenoid biosynthesis pathway, its conversion to squalene through the action of SQS represents the first committed step in the formation of cholesterol.

The structures of rhSQS complexed with different inhibitors, in combination with biochemical and mutagenesis data have also provided insights into critical features underlying the unique two-step reaction mechanism of this enzyme. The first half-reaction is a prenyl transfer reaction, leading to the formation of a stable intermediate, presqualene diphosphate (PSPP). In the second half reaction, PSPP loses inorganic pyrophosphate, incorporates a hydrogen from NADPH and rearranges to form squalene.

The protein is folded as a single domain, with a large cleft in the middle of one face. One end of this cleft is exposed to solvent, and lined by conserved aspartate and arginine residues, which are known from mutagenesis experiments to be involved in binding FPP. The other end of the channel leads to a completely enclosed pocket surrounded by conserved tyrosines and phenylalanines. These observations, along with mutagenesis data identifying residues that affect substrate binding and activity, suggest that two molecules of FPP bind at one end of the channel, where the active center of the first half-reaction is located, then the stable reaction intermediate moves into the deep pocket, where it is sequestered from solvent and the second half-reaction occurs.

Examination of the co-crystal structures has allowed, for the first time, for a detailed examination of the binding mode of SQS inhibitors at both active centers, and should aid in the design of more potent and specific inhibitors.

P11.AA.003 STRUCTURE OF SHV-1 β–LACTAMASE AND ITS COMPLEX WITH TAZOBACTAM. J.R. Knox, A.P. Kuzin, M. Nukaga, Y. Nukaga, A.M. Hujer†, and R.A. Bonomo†. Department of Molecular Biology, University of Connecticut, Storrs, CT 06269; †Department of Veterans Affairs, Cleveland, OH 44106.

The SHV-1 β-lactamase is prevalent in clinical strains of *Klebsiella* resistant to penicillin and cephalosporin antibiotics. SHV-1 is the prototype of 11 natural mutants that have arisen in the last 10 years in response to the heavy use of new cephalosporins. The x-ray structure of SHV-1 has been determined to 1.97 Å resolution. The 28.8 kDa enzyme crystallizes from PEG6000 at pH 7 in $P2_12_12_1$ with cell dimensions a = 49.6, b = 55.6, c = 87.0 Å. A molecule of the Cymal-6 detergent required for crystallization is clearly seen linking enzyme molecules in the crystal lattice. The structure was solved by MR and has been refined with XPLOR to an R factor of 0.18 (R_{free} = 0.25) for all non-zero data from 8.0 to 1.97 Å. Deviations of bonds and angles from ideal values are 0.018 Å and 1.8°, resp. Overlay of all 263 Cα atoms in the SHV-1 and TEM-1 β-lactamase results in a deviation of 1.4 Å (rms). Largest deviations occur in the H10 helix (218-224) and in the loops between strands in the β-sheet. All atoms in residues 70, 73, 130, 132, 166, and 234 in the catalytic site of SHV-1deviate only 0.23 Å from atoms in TEM-1. However, the width of the substrate-binding cavity in SHV-1, as measured from the 104-105 and 130-132 loops on one side to the 235-238 β-strand on the other side, is 0.7 to 1.2 Å wider than in TEM-1. A structural analysis of the highly different affinity of SHV-1 and TEM-1 for the β-lactamase-inhibitory protein BLIP focuses on interactions at position 104 (Asp or Glu). An intermediate in the reaction of SHV-1 with the suicide inhibitor tazobactam has been mapped at 100°K and is being refined with 2 Å data.

Work supported by U.S Department of Veterans Affairs and NIH AG-00634.

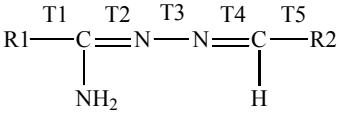
P11.AA.004 THE STRUCTURE OF THE CATALYTIC SUBUNIT OF CDC25B AT 1.9 RESOLUTION. R.A. Reynolds, Physics Dept. Grand Valley State Univ., Allendale, MI 49401 USA, A.W. Yem, C.L. Wolfe, M.R. Diebel and K.D. Watenpaugh, 7255-209-102, Pharmacia and Upjohn, 301 Henrietta St., Kalamazoo, MI 49001 USA.

Cdc25 dual-specific phosphatases are responsible for the dephosphorylation and activation of cyclin-dependent protein kinases resulting in cell cycle progression. Blockage of this progression is a strategy being pursued for the design of novel anit-cancer drug templates. A domain of cdc25b containing the catalytic subunit has been crystallized and the structure solved using MIR techniques. This recombinant human subunit incorporates residues 356-556 and was determined to be stable for crystallization at 4°C using dynamic light scattering techniques. Mercury and Tungstate derivatives were used to determine initial phases. Data collected at 100K were over 95% complete to 1.92 with the resulting structure having an R_F = 13.8% (R_{free} =18.6%) for data greater than $2\sigma_F$. The protein consists of six α-helical regions, three strands of parallel β-sheet, and a considerable amount of less well defined structure. The signature motif (HCX_5R) of the catalytic site was observed with both sulfate and tungstate bound. A second sulfate binding site encompasses residues which are highly conserved in the cdc25 family. In addition to binding two sulfates, two cysteine residues are observed as beeing modified by β-mercaptoethanol and an additional strong electron density peak in a charged pocket is consistent with the binding of a chlorine ion. Although this construct has disorder at both ends, the C-terminal end forms a helical region which lays against the rest of the subunit forming a groove which was not observed in the cdc25a structure

Fauman *et al.,* Cell **93**, 617-625, 1998

P11.AA.005 CRYSTALLOGRAPHIC AND COMPUTATIONAL COMPARISON OF ISOMERIC ANTI-MYCOBACTERIAL AMIDRAZONES. C. H. Schwalbe, C. Gallagher, P. R. Lowe, D. C. Billington, D. L. Rathbone & K. J. Tims, Pharmaceutical Sciences Institute, Aston University, Aston Triangle, Birmingham B4 7ET, U.K.

Crystal structures [1] of four 2-heteroarylcarboxamidrazones consistently revealed intramolecular N...H-N-H...N hydrogen bonds from each amino group, and small twists along the chain (torsion angles T1 to T5) which incline the planes of R1 and R2 at ca. 10°.



We report here two structures bearing a common R2 = *p*-benzyloxy-*m*-methoxyphenyl but with R1 attached differently: R1

= 2-pyridyl in **I**, 4-pyridyl in **II**. Paradoxically, some 2-pyridyl and 4-pyridyl isomers (e.g. when R2 = *p-t*-butylphenyl) are equi-active against *Mycobacterium fortuitum*, but **I** is nearly as active as isoniazid while **II** is inactive. Replacement of N...H-N-H hydrogen bonding in **I** by C-H...H-N-H clash in **II** alters T1 but still leaves H atoms only 2.22(3) Å apart. T3 in both **I** and **II** disagrees with the averaged absolute values from [1]. T1-T5 in degrees are tabulated below:

Source	T1	T2	T3	T4	T5
<|1|>	175.5	178.3	173.3	176.6	5.6
I	-168.7	176.5	157.6	177.6	3.8
II	154.6	172.4	147.9	173.4	-13.4
3-21G	153.6	178.8	178.3	179.9	0.2
AM1	131.7	178.3	175.4	179.1	19.0

Ab initio 3-21G molecular orbital optimisation of **II** with R2 simplified to phenyl corroborated the short H...H contact and the T1 twist. It removed the anomaly in T3, which may be due to packing requirements of R2. The semi-empirical AM1 method widened the H...H contact via greater T1 twisting and a partially pyramidal amino group, a trend exaggerated by PM3 and MNDO.

11BB MACROMOLECULES AT HIGH RESOLUTION: REFINEMENT AND VALIDATION

M11.BB.001 THE RELATIONSHIP BETWEEN R_{free} AND R IN A CORRECTLY REFINED PROTEIN STRUCTURE. Ian J Tickle, Roman A Laskowski and David S Moss, Department of Crystallography, Birkbeck College, Malet Street, London WC1E 7HX, UK.

The last five years have seen a large increase in the use of cross-validation in the refinement of macromolecular structures from X-ray data. In this technique, a test set of reflections is set aside and used to calculate a free R-factor. Although this R-factor is frequently quoted in presenting experimental results and is expected to be higher than the R-factor from the working set, no theory has existed to say how much higher it should be. We have derived the statistically expected values of the ratio of the free R-factor to the R-factor calculated from the working set for a structure where weights correctly account for experimental and model errors. These estimates have been compared with the observed ratios from 725 macromolecular structures in the Protein Data Bank and the results have been related to resolution and the number of reflections per atom.

Tickle, I J, Laskowski, R A and Moss D S, R_{free} and the R_{free} ratio. Part I: Derivation of expected values of cross-validation residuals used in macromolecular refinement, Acta Cryst., (1998), D54, 547-557.

M11.BB.002 SUBTILISIN AT ATOMIC RESOLUTION. R. Bott, G. Ganshaw, Genencor International, Palo Alto CA 94304, Mark Knapp, LLNL Livermore CA 94550, Peter Kuhn and Mike Soltis, SSRL, Menlo Park CA 94025

Subtilisin a serine protease of the "subtilase" class is one of the most extensively studied enzymes and a target for protein engineering. The three-dimensional structure has been determined by both X-ray crystallography and NMR. Subtilisin has a very ordered structure in NMR experiments[1]. There are numerous non exchanging hydrogen atoms. X-ray cryo-crystallographic data can be collected well beyond 1.0 Å.

We have previously reported determination of the structure of Bacillus lentus subtilisin at 0.78 Å from a crystal grown at pH 5.9 [2]. At pH 5.9, the enzymes displays approximately 10% of its optimal activity while at pH 8.6 the enzyme is fully active. We have collected data from crystals at pH 8.6 to a resolution of 0.85Å. While the overall structure is unchanged we can detect subtle changes in difference maps that are attributed to the specific ionization of a carboxylate group. These results, along with a comparison of the refine coordinates, currently in progress, will be presented .

M11.BB.003 ANISOTROPIC REFINEMENT AND OTHER ADVANCES OF USING FFT PROCEDURES. Murshudov, G.N.[1,2,*], Lebedev, A.[3], Vagin, A.A.[1] and Dodson, E.J.[1], [1]Chemistry Department, University of York, [2]CLRC, Daresbury Laboratory, [3]MPG-ASMB c/o DESY, Hamburg, [*]e-mail: garib@yorvic.york.ac.uk

Refinement of individual atomic anisotropic atomic displacement parameters (ADP) using FFT has already been proven to be fast [1]. For example for 5 000(x9 = 45 000 parameters) atoms with 450 000 reflections (at 0.89Å resolution) one cycle of refinement using an O_2 SGI takes approximately 30 minutes of CPU time. Various tests of anisotropic refinement implemented in the program REFMAC [2] (available from CCP4 [3]) will be discussed. The merits of mixed refinement where some parts of structure have isotropic and some anisotropic ADPs will also be presented.

Usually individual atomic anisotropic refinement is performed at high resolution. In these cases anomolous pairs should be considered as separate observations, and although they represent dependent random variables the dependence is not linear. Maximum likelihood equations which use FFT and take this into account have been derived. It is expected that this technique will increase the power of the refinement even at relatively low resolutions, especially in the presence of strong anomolous scatterers.

M11.BB.004 ULTRA HIGH RESOLUTION STRUCTURE OF CRAMBIN: FIRST CHARGE DENSITY ANALYSIS OF A PROTEIN. Christian Jelsch §, Martha M. Teeter *, Virginie Pichon-Pesme §, Robert H. Blessing # & Claude Lecomte §. § Laboratoire de Cristallographie et Modelisation des Materiaux Mineraux et Biologiques LCM3B-UHP-CNRS BP 239. 54506 Vandoeuvre-lès-Nancy Cedex FRANCE, * Department of Chemistry, Boston College, Chestnut Hill, MA 02167, USA, # Hauptman-Woodward Medical Research Institute, Buffalo, NY USA

Diffraction data of crambin crystals have been collected at ultra high resolution (0.54 Å) using synchrotron radiation at the EMBL Outstation in Hamburg. After a first refinement using SHELXL-97 [1], the structure has been refined with an adapted version of MOLLY, a program [2] which uses a charged non-spherical atom model describing the electron distribution on the molecule.

First, the charges and electron density multipoles of the protein atoms were taken from our database [3] of transferable average parameters obtained from several small peptides and amino acid charge density analyses.

Then, the average charge density parameters of the polypeptide mainchain atoms have been refined. The average peptide unit deformation electron density, which reveals the effect of bonding aspherical electron density, is comparable but slightly weaker to the one obtained from parameters transfer and compares very well with that obtained by ab initio calculation on a small peptide.

The high diffraction power of the crambin crystals is due to the low thermal displacement parameters of the protein atoms [4]. This study on the protein crambin shows that biological macromolecules start now to be accessible to charge density experiments.

Dr. Lamzin, Dauter & Wilson are gratefully acknowledged for their contribution in the diffraction data collection.

P11.BB.001 ATOMIC RESOLUTION STRUCTURES OF ADH. R. Meijers and V. S. Lamzin, EMBL c/o DESY Notkestraße 85 D-22603 Hamburg, FRG, E.S. Cedergren-Zeppezauer, Biokemi, Kemicentrum, Box 124, 22100 Lund, Sweden, H.W. Adolph, Fachrichtung 12.4, Biochemie, Postfach 151150, Universität des Saarlandes, D-66041 Saarbrücken, FRG, Z. Dauter, Brookhaven Nat. Lab., Bldg. 725A-X9, Upton, NY 11973, USA, K. S. Wilson, Dept. of Chemistry, York University, Heslington YO1 5DD, UK.

The atomic resolution structures of ADH give new and intriguing insights into the mechanism of hydride tranfer. Alcohol dehydrogenase (ADH) is a NAD+-dependent oxidoreductase acting on electron donors containing a CHOH-group such as primary and secondary alcohols. The catalytic dehydrogenation proceeds by a mechanism of hydride ion transfer from substrate to NAD+ combined with proton transfer from substrate to solution. The horse liver ADH is a 80kDA dimer [1] containing 4 zinc ions which can be substituted by cadmium. 4Cd-ADH is a useful enzyme probe when measuring ligand binding to Cd in the active site with perturbed angular correlation of gamma rays (PAC) [2]. A crystalline abortive complex of 4Cd-ADH with NADH and methyl pentane diol MPD was prepared to check the feasibility of the replacement of zinc by cadmium. Cryo data extending to 1.1 Å were collected for complexes with cadmium and zinc respectively. A glutamate near the active site extends partly towards the metal in the cadmium complex but not in the zinc complex. The nicotinamide ring of NADH that is involved in hydride transfer is severely distorted in both complexes.

P11.BB.003 PATTERNS IN WATER-PROTEIN DISORDER SUBSTATES & PEPTIDE GEOMETRY IN CRAMBIN CRYSTALS AT 0.54 Å RESOLUTION. M. M. Teeter, Dept. of Chemistry, Merkert Chemistry Building, Boston College, Chestnut Hill, MA 02167.

Refinement of X-ray data, collected to 0.54 Å and 100 K at the EMBL Hamburg Outstation of the DESY synchrotron, reveals crambin substates not only of side chains but also for the backbone. Further, disordered protein positions are correlated in space with water substates, for this mixed sequence form of crambin. The interrelations of modelled water substates to each other are analysed and origins of the disorder are discussed.

Comparison of disorder in this crystal structure is made with the pure sequence forms of crambin (Yamano and Teeter, 1994; Yamano, *et al.*, 1997.) Surprisingly, although protein substates are reduced by half in the pure form crystals, considerable water substate disorder remains. A hypothesis for this residual water disorder is advanced. The implication of crambin's water and protein disorder for crystal structures at lower resolution is discussed. A template for modelling such water and a strategy for refinement is being developed.

Complete disorder modelling improves protein geometry statistics and suggests improved values for target peptide geometry in proteins.

Acknowledgements: Dr. Christian Jelsch contributed to refinement of the 0.54 Å data. Dr. Victor Lamzin provided invaluable help in data collection.

P11.BB.004 MULTI-PURPOSE EXTERNAL REFERENCE FILE FOR MACROMOLECULES. Vagin, A.A.[1,*], Greaves, R.[1], Dodson, E.J.[1], Wilson, K.S.[1] and Murshudov, G.N.[1,2], [1]Structural Biology laboratory, University of York, [2]CLRC, Daresbury Laboratory, [*]e-mail: alexei@yorvic.york.ac.uk

The external reference file (ERF) for the chemical description of the structural units of the macromolecules (proteins, DNA/RNA, sugars etc) as well as small inorganic and organic molecules and the programs to manage it will be presented. This ERF can be used for several purposes: refinement, graphics, validation. The extended mmCIF dictionary format makes the ERF self-explanatary, simple to correct and add new information.

An automated procedure to create list of restraints corresponding to the input coordinates in the PDB or mmCIF formats using the ERF has been implemented in the program MAKECIF. The LIBCHECK program has also been developed to manage and check the content of the ERF. It can create new ERF entries from different sources: PDB, CDS, CIF, SMILE.

Its application for refinement will be discussed.

P11.BB.005 ON BUILDING A DATA BANK OF TRANSFERABLE EXPERIMENTAL ELECTRON DENSITY PARAMETERS: APPLICATION TO VERY HIGH RESOLUTION PROTEIN STRUCTURES. C. Lecomte, C. Jelsch and V. Pichon-Pesme, LCM^{3}B, UPRESA CNRS 7036, Université Henri Poincaré, Nancy I, Faculté des Sciences, BP 239, 54506 Vandoeuvre-lès-Nancy Cedex.

Very precise electron distribution obtained from very high resolution X-ray diffraction on small peptides is used to calculate new scattering factors which contains aspherical features due to chemical bonding[1-4] like covalent bonds, d electrons or lone pairs. It will be shown that these scattering factors can be transferred to refine high resolution oligopeptide and protein structures[5].

Application to small proteins and the limits of applicability in terms of resolution, B factors, disorder[6] will be given. Some applications in the future in like deriving partial atomic charges, electrostatic potential or d electron population in the case of metallo proteins will be discussed.

11CC NEW FRONTIERS IN HIGH PRESSURE CRYSTALLOGRAPHY

M11.CC.001 NEW SINGLE-CRYSTAL DIFFRACTION TECHNIQUES AT HIGH PRESSURE. M.I. McMahon. Department of Physics and Astronomy, The University of Edinburgh, Edinburgh EH9 3JZ, UK.

Recent advances in 2-dimensional detectors have enabled great progress to be made in refining high-pressure crystal structures from powdered samples. However, considerably more detailed structural information on high-pressure phases could be obtained if single-crystal samples were utilised. Unfortunately, the strongly first-order nature of the phase transitions experienced by many materials at high-pressure means that single-crystal samples rarely survive intact into the high-pressure phase.

While single-crystal samples of high-pressure phases can be obtained by annealing at high temperature or by slow cooling from the melt, we have recently found that systems such as InSb, Ce and Ba have high-pressure phases that recrystallise spontaneously at room temperature. Although such samples are not normally mono-crystalline, but contain many crystallites, some of these are sufficiently large to enable (in principle) single-crystal data sets to be collected. The problem then becomes one of identifying which of the many observed reflections in a spotty powder pattern come from the same sample crystallite.

Methods for overcoming this problem, and allowing reflections from a single-crystallite to be identified, will be presented. The merits of CCD-based area detectors over conventional 4-circle diffractometers will be discussed, and results will be given for test single-crystal studies with multi-crystallite samples. Work is also in progress to grow single-crystal samples under pressure at high temperature and the latest results will be shown.

M11.CC.002 MAGNETIC NEUTRON DIFFRACTION IN THE 50 GPA PRESSURE RANGE. Goncharenko I.N. [1], Mirebeau I. [2], Ochiai A. [3], [1] Laboratoire Leon Brillouin, CEA Saclay, 91191; Gif-sur-Yvette, France and Russian Research Center "Kurchatov Institute", 123182 Moscow, Russia, [2] Laboratoire Leon Brillouin, CEA Saclay, 91191 Gif-sur-Yvette, France, [3] Niigata University, Ikarashi-Ninocho 8050, Niigata-shi, Niigata-ken 950-2181, Japan

Magnetic neutron diffraction is the most powerful method to study magnetic order in solids. Therefore, progress in high pressure magnetic crystallography is closely related with developments in high pressure neutron techniques. We report here recent results on neutron diffraction studies of magnetic structures and magnetic phase transitions in the 50 Gpa pressure range.

The experiments have been performed in the Laboratoire Leon Brillouin, in collaboration with the RRC "Kurchatov Institute". We developed a specialized high pressure powder diffractometer for magnetic studies. We use sapphire or diamond anvil cells, adapted for neutron measurements. We discuss the current stage of the project and the future developments, bringing neutron studies to the same pressure range as for X-ray crystallography. The progress in the neutron instrumentation and pressure techniques allowed us to study various magnetically ordered materials in the wide range of pressures (50 GPa) and temperatures (down to 1.5 K). The talk includes several examples of high pressure neutron diffraction studies, like studies of magnetic order in the "model Heisenberg magnets" EuX and GdX (X =chalcogen or pnictogen). The drastic increase of the available pressure range changed crucially knowledge about magnetic interactions in the "model" semiconductors under pressure. We observe new pressure induced magnetic phases and abnormal enhancement of the ferromagnetic interactions with pressure.

M11.CC.003 PRESSURE DEPENDENCE OF DISORDER: COMPUTER SIMULATION OF RECONSTRUCTED DENSITIES. Karsten Knorr, Institut für Geowissenschaften, Mineralogie / Kristallographie, Universität Kiel, Olshausenstr. 40, D 24098 Kiel, Germany and Fritz Mädler, Hahn-Meitner-Institut Berlin GmbH, Glienicker Str. 100, D 14109 Berlin, Germany.

Recently, the structure of KPF_6 at ambient conditions and the pressure dependence of the electron-density distribution of the disordered PF_6^- ion in the cubic phase have been studied experimentally by X-ray single crystal diffraction [1]. We analysed the density distribution resulting from a maximum entropy reconstruction by using a flexible evolutionary algorithm which imitates mechanisms of the biological evolution in order to optimise a suitable cost function [2]: To fit the rigid PF_6^- anion to the density maxima, its orientation angles (θ, ϕ, ψ) were mutated at random. In order to evaluate possible re-orientation paths of the fragment we allowed congruent mappings of the PF_6^- octahedron within the space available in the structure. Thus, we found two different pathways for the reorientation which together fully explain the shape of the electron density found experimentally [1].

For a ``virtual pressure experiment'' we simulated the steric hindrance experienced by the octahedra during reorientation by confinement of the available space. The change in the shape of the density distribution under increasing pressure can be explained by ordering and a superposition of the differently oriented PF_6^- octahedra, in excellent agreement with the experimental findings [1].

M11.CC.004 STREAM-LINING DATA ANALYSIS AND GOING FURTHER. A P Hammersley, T Günzel, A Fitch, European Synchrotron Radiation Facility, BP 220, 38043 Grenoble Cedex, France

The enormous increase in cheaply available computing power means:

i. Existing analysis methods can be applied quickly

ii. Much larger problems can be tackled

iii. New forms of analysis can be undertaken and new problems tackled

To realise the full potential of the computing power new and more flexible software is needed.

Examples of software developments will be presented in the field of High Pressure powder diffraction. FIT2D allows integration of 2-D images to 1-D ``2-theta'' scans. This is now used routinely with huge images, and automation has been added which allows routine treatment of hundreds of images. FIT2D is useful for time-resolved in-situ studies (e.g. mineralogy), and with weakly scattering samples of intermediate crystallinity (e.g. fullerenes). The program ``CINDEX'' has been developed to faciliate interactive indexing of 2-theta scans. This provides a

stream-lined interface to a number of standard indexing algorithms. On recent PC's the whole process is fast enough make the analysis interactive; the fast feed-back simplifying the analysis process.

The challenge is to develop software to tackle more difficult problems automatically. Indexing of mixed phase samples is such an area. Algorithms will be enhanced with more powerful search techniques. Similar techniques may be useful for mixed phase single crystal indexing, whilst the availability of cheap 3-D graphics may provide alternative interactive techniques.

M11.CC.005 NUCLEAR RESONANT SCATTERING OF SYNCHROTRON RADIATION - A NEW TOOL FOR HIGH PRESSURE RESEARCH. H.F.Grünsteudel, A.Barla, R.Rüffer, A.I.Chumakov, J.Metge, O.Leupold* and K.Quast. European Synchrotron Radiation Facility, BP 220, F-38043 Grenoble Cedex *on leave from II. Institut f. Experimentalphysik, Univ.Hamburg, Luruper Chaussee 149, D-22761 Hamburg

The central idea to excite nuclear levels using synchrotron radiation is to combine its advantages like high brilliance, pulsed time structure and high degree of linear polarization with the high energy resolution of the Mössbauer effect (e. g. $\approx 10^{-13}$ in the case of ^{57}Fe). In the nuclear decay following the pulsed excitation, intensity modulations (``quantum beats'') can be observed in a simple transmission geometry (Nuclear Forward Scattering). Quantum beats originate from nuclear level splitting due to electric and/or magnetic hyperfine interactions, the beat frequencies being characteristic for the splitting. Background radiation originating from scattering by the electronic system of the sample (instantaneous) is separated from the (delayed) nuclear scattering and is discriminated by means of a fast detector system and fast electronics, leading to an excellent signal to noise ratio. The well established diamond anvil cell technique is therefore especially suited, as scattering by the diamond anvils does not spoil the signal. Further techniques are on the horizon to explore high pressures and high temperatures simultaneously.

We present the method and discuss major achievements compared to traditional energy resolved Mössbauer spectroscopy. Recent experiments will be discussed and latest developments for the resonance energies of ^{57}Fe, ^{151}Eu and ^{119}Sn will be shown.

M11.CC.006 INELASTIC X-RAY SCATTERING UNDER HIGH PRESSURE. K. Hämäläinen, Department of Physics, POB 9, FIN-00014 University of Helsinki, Finland

Inelastic scattering at high momentum transfer, usually referred as Compton scattering, is a unique tool to probe directly the electron ground state properties. For example, the measured Compton profile gives the momentum density of the scattering electrons, which is directly related to the charge density, band structure and the wavefunctions. The advent of synchrotron radiation has recently made it possible to use crystal analyzers to significantly improve the momentum resolution. This has opened up new possibilities to study fine structures related to the Fermi surface topology. Recently, several studies have been done on novel materials varying the sample environment (temperature, magnetic field) or crystal direction or doping. We will report Compton scattering studies on sodium under high pressure accomplished at beamline ID15 at ESRF using both large volume and diamond anvil cell.

Sodium 3s electrons form within very good approximation a free electron gas. Several fundamental properties of solids can be understood surprisingly well by treating the system as a non-interacting electron gas. However, in many solid state systems the electron-electron correlation effects can play a crucial role in determining the system behavior. Separating these effects from the other overlapping solid state contributions experimentally via a direct measurement is not that simple task. The Compton scattering can in principle be utilized to directly produce the quasiparticle renormalization constant Z_F that is given by the jump of momentum density at the Fermi break. The correlation effects depend on the free electron density and the various theories predict significantly different density dependencies. Only few experiments have been done to access different electron densities using different elements (typically Li, Be and Na). However, in this way it is very difficult to separate the band structure effects, for example, from the correlation effects. Therefore, we have studied sodium at different pressures to directly modify the free electron density without a major change of the atomic structure.

P11.CC.001 INSTRUMENTATION FOR NUCLEAR RESONANT SCATTERING IN HIGH PRESSURE RESEARCH. H.F.Grünsteudel, A.Barla, L.E.Schröder, M.Mezouar, K.Quast, J.Metge, R.Rüffer, A.I.Chumakov, O.Leupold* and H.Grünsteudel**. European Synchrotron Radiation Facility, BP 220, F-38043 Grenoble Cedex, *on leave from II. Institut f. Experimentalphysik,Univ. Hamburg, Luruper Chaussee 149, D-22761 Hamburg, **on leave from Kemisk Institut, Odense Universitet, Campusvej 55, DK-5230 Odense

In Nuclear Resonant Scattering low-energy nuclear transitions are excited by synchrotron radiation pulses. Specially adapted X-ray optics, fast detectors, various machine timing modes and demanding sample environment are necessary. The natural linewidth of such transitions is of the order of $\approx 10^{-9}$eV while an undulator has typically a bandwidth of the order of $\approx 10^{2}$eV. The incident radiation (energy $\approx 10^{4}$eV) can be monochromatised to the meV range by high resolution monochromators based on perfect silicon crystals. We present several designs for the resonance energies of ^{57}Fe (14413eV) and ^{151}Eu (21542eV).

For high pressure experiments focussing techniques are employed to match the small sample sizes of typically 100x100 μm^2 or smaller. We present our recent developments to achieve variable focal spot size at several distances from the source for the resonance energies mentioned above.

Further on we present new installations and developments for high pressure experiments at low temperature ($\approx$ 2K) in external magnetic fields up to 6T. First high pressure high temperature experiments have been carried out and will be discussed.

P11.CC.002 NUCLEAR RESONANT SCATTERING OF SYNCHROTRON RADIATION BY ^{119}Sn. A.Barla[1], H.F.Grünsteudel[1], R.Rüffer[1], A.I.Chumakov[1], J.Plessel[2], M.M.Abd-Elmeguid[2], (1) European Synchrotron Radiation Facility, BP 220, F-38043 Grenoble Cedex, (2) II. Physikalisches Institut, Universität zu Köln, Zülpicherstrasse 77, D-50937 Köln

Nuclear Resonant Scattering became a new tool in high pressure for the investigation of electronic and magnetic properties of a wide variety of systems using Nuclear Forward Scattering (NFS) as well as the dynamics using Nuclear Inelastic Scattering (NIS). So far most of the work has been performed on iron containing samples. We report here on the development of this technique for tin compounds. Our NFS measurements on β-Sn and SnO_2 at room temperature (RT) allowed an accurate determination of hyperfine parameters and Lamb-Mössbauer factor. A first application to high pressure has been carried out on UNiSn. This system shows a triple transition at $T_N \approx 45$K from semiconducting, paramagnetic and cubic (for $T > T_N$) to a metallic, antiferromagnetic and tetragonal phase. High pressure is an important tool to understand the relationship between the disappearance of the semiconducting gap and the onset of antiferromagnetism. We present our first high pressure test NFS measurements on UNiSn.

Finally, NIS is valuable for the investigation of dynamical properties especially of phase transitions. It measures the phonon density of states (DOS) as well as the Lamb-Mössbauer factor. The thermodynamic properties of Sn have recently drawn considerable interest due to its ambivalent behaviour at the borderline between covalent and metallic bonding [1]. Here we present our NIS measurements at RT and at T ≈ 100K on β-Sn, together with the DOS obtained at the lower temperature.

P11.CC.003 ANHARMONIC EFFECTIVE PAIR POTENTIAL OF α-AgI TYPE CuBr DETERMINED BY EXAFS UNDER PRESSURE. Maki Okube, Akira Yoshiasa, Osamu Ohtaka, Tomokazu Ito, Graduate school of Science, Osaka University, Toyonaka, Japan, Osamu Kamisima, Research Institute for Scientific Mesurements, Tohoku University, Sendai,Japan, Yosimori Katayama, SPring-8, Akoh, Hyogo, Japan.

The anharmonic effective pair potentials

$$V(u) = [(\alpha u^2)/ 2!]+[(\beta u^3)/ 3!]+[(\gamma u^4)/ 4!]$$

for Br-Cu bond in α-AgI type CuBr have been investigated by the EXAFS technique. The EXAFS spectra near the Br K-edge were measured at 773, 873 and 973 K under the pressure of 7 GPa using synchrotoron radiation from SPring-8. In the parameter fiting, we have directly carried out the numerical integration of EXAFS function and evaluated the precise anharmonic effective pair potentials [1,2]. The Grüneisen parameters γ_G are calculated from the obtain values of α and β. The statistical distribution of Cu in α-AgI type CuBr and superionic conduction mechanisum have been discussed based on the effective pair potential and distribution of Br-Cu distances. The time spent on a lattice site is greater than the time spent between the potential-energy minima. However, the probability of finding mobile ions at saddle-point position can be regard as siginificant and is several per cent in the superionic conducting phase.

P11.CC.004 NEUTRON SCATTERING STUDY OF STRUCTURE AND DYNAMICS OF AMMONIUM HALIDES UNDER HIGH PRESSURE. D.P.Kozlenko, A.M.Balagurov and B.N.Savenko, Frank Laboratory of Neutron Physics, Joint Institute for Nuclear Research, 141980 Dubna Moscow Reg., Russia, and V.P.Glazkov and V.A.Somenkov, RRC "Kurchatov Institute", 123182 Moscow, Russia and S.Hull, ISIS Facility, CLRC Rutherford Appleton Laboratory, Chilton, Didcot, Oxon OX11 0QX, UK.

Structural changes in ammonium halides ND_4Cl, ND_4Br and ND_4F at pressures up to 40 kbar and ND_4I at pressures up to 86 kbar have been studied by means of neutron diffraction at room temperature. The pressure dependencies of the lattice parameter *a* and the deuterium position parameter *u* were obtained. It was found that the order - disorder II-IV phase transition in ND_4Br and ND_4Cl occurs at equal critical values of *u*, u_{cr}=0.152(2). For ND_4F, *u* is initially higher than u_{cr} and only the ordered CsCl type phase III (analogous to the phase IV of the other ammonium halides) exists at high pressure. For ND_4I, no II-IV phase transition was observed. A phase transition into the recently discovered high pressure phase V was detected in ND_4I at $80 < P < 86$ kbar. The structure of ND_4I(V) was found to be the same as the structure of the low temperature phase ND_4I(III) - tetragonal one with antiparallel ordering of ammonium ions, space group *P4/nmm*. The critical value of *u* for the II-V phase transition in ND_4I, *u*=0.148(2) is close to the u_{cr} for the II-IV transition in ND_4Cl and ND_4Br. Under pressure N-D bond length remains nearly constant for all the investigated compounds.

Vibrational spectra of NH_4I and NH_4F have been studied by means of incoherent inelastic neutron scattering at pressures up to 40 kbar. Libration and transverse optical (TO) modes frequencies as functions of pressure were obtained. Both frequencies increase under pressure. For NH_4F, libration frequency was found to be considerably larger in comparison with the one for the other ammonium halides.

P11.CC.005 MODELLING HIGH PRESSURE STRUCTURES USING THE BOND VALENCE (IONIC) MODEL I.D.Brown, Brockhouse Institute for Materials Research, McMaster University, Hamilton, Ontario, Canada L8S 4M1.

In the ionic model, the cohesive force supplied by the electrostatic attraction between charged ions provides an internal pressure which is opposed by the repulsive contact forces that prevent the solid from collapsing to a point. The internal pressure is of the order of 10 GPa. The behaviour of a crystal under hydrostatic pressure can therefore be simulated by increasing the ionic charges in order to increase the internal pressure. Changing these charges changes the bond flux or bond valence allowing the length of the compressed bonds to be calculated from the bond valence - bond length correlation. This leads to a simple formula for the bond compressibility.

The model also predicts that for the NaCl type structures the product of the bond force constant and the bond compressibility is equal to B - R/2, where B is the bond valence paramter (generally taken as 0.37Å) and R is the bond length, a relationship that is obeyed within the accuracy of available results.

The model is being tested on a number of compounds. Preliminary results of comparisons with experiment will be presented.

P11.CC.006 P-V EQUATION OF STATE OF MINERALS BY BRILLOUIN SCATTERING:GH PRESSURE MINERALOGY. Jay D. Bass, Stanislav V. Sinogeikin [1] and Jennifer M. Jackson [2], [1] Department of Geology, University of Illinois, 1301 W. Green St., Urbana, IL 61801 USA, [2] Department of Civil Engineering and Geology, University of Notre Dame, Notre Dame, Indiana

High pressure crystallography and acoustic measurements provide highly complimentary information. Both provide the bulk modulus (K) and its pressure derivatives, which are necessary to model the composition of planetary interiors. Brillouin scattering is a type of vibrational spectroscopy in which sound speeds are obtained from the frequency shift of light scattered by acoustic phonons. Only small (tens of microns) samples are required, so it can be performed at high-P using diamond cells and the pressure derivatives of moduli and velocities can be measured. This allows the P-V EOS to be accurately calculated without actual volume measurements. Our Brillouin scattering studies on minerals include MgO, garnets, pyroxenes, and the spinel-structured high-P gamma-phase of olivine. For $MgSiO_3$ orthoenstatite, XRD observations of a change in the atomistic at 4 GPa are found to have no effect on the EOS parameters as determined by Brillouin. High-P Brillouin experiments on garnet and gamma-phase utilizing a diamond cell suggest that the variation in bulk modulus and sound speeds with P are significantly less than those in the transition zone of the Earth (410-660 km depth). The seismologically determined properties of the transition zone are therefore likely due to phase transitions in minerals within this depth range.

11DD STRUCTURE SOLUTION FROM POWDER DATA – MOLECULAR COMPOUNDS (sponsored by Clariant GmbH)

M11.DD.001 CRYSTAL STRUCTURES OF PHARMACEUTICALS SOLVED FROM POWDER DATA BY GLOBAL OPTIMISATION METHODS K. Shankland and W.I.F. David, ISIS Facility, Rutherford Appleton Laboratory, Chilton, Didcot, Oxon. OX11 0QX, UK.

Powder diffraction has, in recent years, been increasingly and more ambitiously applied to the study of pharmaceutical compounds. While several years ago, a pharmaceutical company would use powder diffraction as a simple signature for polymorph recognition, there is now the real potential of complete structure determination for moderately complicated molecular structures. However, pharmaceuticals represent a challenging class of compounds for the application of traditional techniques of structure solution such as direct methods to powder diffraction data. This is because there are normally a large number of atoms to be located and seldom any atoms heavier than chlorine to assist with the phasing process.

Recent developments in global optimisation methods of structure solution [1] exchange these old issues and traditional methods for a new set of problems and algorithms which though difficult are proving more tractable. Complications in these new global optimisation methods arise because pharmaceuticals generally exhibit a significant amount of torsional flexibility and are often marketed as salt forms. These factors combine to increase the number of variables that need to be optimised in any search procedure that seeks to locate the entire molecule within the crystallographic unit cell *via* a stochastic optimisation process.

Efficient algorithms have been implemented for both the search methods employed and the evaluation of candidate solutions. These algorithms will be illustrated with the structure solutions of pharmaceuticals ranging from polymorph pairs to multiple salt forms.

David, W.I.F., Shankland, K. and Shankland, N., *Chem Commun*, 1998, 931.

M11.DD.002 DIRECT METHODS AND SYSTEMATIC OVERLAP J.Rius, Institut de Ciència de Materials de Barcelona, CSIC. Campus de la UAB. E-08193 Bellaterra, Spain

Besides accidental overlap, systematic overlap constitutes one of the principal limitations for the solution of crystal structures from powder diffraction data. Unlike accidental overlap which affects all type of structures, systematic overlap is restricted to high-symmetry ones (e.g. 65% of the space groups compatible with a hexagonal lattice). It will be shown how the direct methods sum function can be adapted to cope with data extracted from patterns containing systematic overlap. Preliminary results indicate that at least for moderate sized inorganic structures, systematic overlap should not represent a serious drawback for the direct methods application. In contrast to the usual two-stages procedures employed for solving structures with accidental overlap, here both multiplet decomposition and phase refinement are carried out simultaneously. This procedure will be discussed with two examples.

M11.DD.003 ROUTINE STRUCTURE SOLUTION OF MOLECULAR SOLIDS USING POWDER DIFFRACTION: THE MALARIA PIGMENT. S. Pagola and P. W. Stephens, Dept. of Physics and Astronomy, SUNY at Stony Brook, Stony Brook, NY 11794, USA; D. S. Bohle and S. K. Madsen, Dept. of Chemistry, Univ. of Wyoming, Laramie, WY 82071-3838, USA.

The crystal structure solution of molecular solids of moderate complexity is currently achieved using synchrotron X-ray powder diffraction as a routine procedure. The high resolution and high ratio signal to noise allow the easier determination of the unit cell, systematic absences and space groups. Based in the knowledge of the molecular geometry and cell contents is possible to postulate different trial solutions in the direct space. The agreement between the calculated and observed integrated intensities is used as a cost function to minimise in the simulated annealing method. Using this procedure it was possible to solve the crystal structure of several organic small molecules [1].

Malaria pigment (beta-Hematin) is a solid material formed from the degradation of hemoglobin in red cells by the plasmodium parasite that causes malaria. It was thought it was a biopolymer of heme units linked by iron-carboxylate bonds [2]. New chemical methods of synthesis of beta-Hematin allowed its preparation as a powder of enough crystallinity to determine the unit cell (triclinic symmetry, Z=2), to corroborate the equivalence with the pigment obtained from infected red cells [3], and now to solve the crystal structure using simulated annealing. The structure shows Fe-O interheme bonds giving rise to heme dimers. The remaining carboxylate of each heme is involved in hydrogen bonds with neighbor dimers in the crystal. Since the action of antimalarial drugs is not completely understood, this unanticipated structure is a significant result in the understanding and design of antimalarial compounds.

M11.DD.004 SOLUTION OF FLEXIBLE MOLECULAR STRUCTURES FROM POWDER DIFFRACTION DATA USING SIMULATED ANNEALING. Y. G. Andreev and P. G. Bruce, School of Chemistry, University of St. Andrews, St. Andrews, Fife KY16 9ST, Scotland.

Structure solution is one of the most challenging and fashionable topics in powder diffraction at present. Recently developed direct-space methods of simulated annealing and genetic algorithms mark a breakthrough in *ab initio* solution of molecular structures using powder data. Simple molecular structures represented by a single rigid or semi-rigid molecule in the asymmetric unit can be routinely solved in a matter of hours. Difficult structures containing several flexible molecular moieties in the asymmetric unit require much more effort.

We present a method of simulated annealing for structure solution from powders using full-profile fit of powder patterns. The issue of what type of structure should be considered as difficult-to-solve, with regards to number of atoms in the asymmetric unit, molecular flexibility and the number of independent moieties, is addressed. The method is illustrated by examples of *ab initio* solution of previously unknown molecular structures containing highly flexible molecules. Among the examples is the structure of the polymer/salt complex $(CH_2CH_2O)_6$:$LiAsF_6$ the solution of which involved 79 variable parameters including 23 bond lengths, 25 bond lengths and 15 torsion angles.

M11.DD.005 DO MICROCRYSTAL DIFFRACTION FACILITIES MAKE STRUCTURE SOLUTION FROM POWDER DIFFRACTION DATA OBSOLETE? C.S. Frampton, Roche Discovery Welwyn, Broadwater Road, Welwyn Garden City, Hertfordshire AL7 3AY, UK.

A major step in the development of any pharmaceutical material is the study and quantification of its polymorphic behaviour. The methods of choice for the structural characterisation of the various polymorphic forms, including

solvates and hydrates, are the combined techniques of single crystal X-ray diffraction and powder X-ray diffraction.

In many cases however, it is extremely difficult to produce single crystals that are of a suitable quality with which to obtain a full single crystal X-ray structural analysis. It is for these samples that the prospect of obtaining a full structure from *ab-initio* methods using the X-ray powder diffraction pattern alone is particularly exciting. One drawback of this methodology at the present time is that its application is restricted to relatively simple systems. With the advent of CCD detectors for small molecule crystallography and their subsequent installation on synchrotron beamlines, *e.g.* Station 9.8 at Daresbury SRS, the ability to obtain structures from microcrystalline samples has become feasible with no real limits on structural complexity.

This presentation will focus on the structural characterisation of several polymorphic forms of an α-TNF Converting enzyme inhibitor using both *ab-initio* structure solution from powder diffraction data methods and microcrystal X-ray diffraction techniques.

P11.DD.001 MOLECULAR CRYSTAL STRUCTURES FROM LABORATORY POWDER DIFFRACTION DATA: RELIABILITY AND REPRODUCIBILITY OF THE RESULTS. V.V. Chernyshev, A.V. Yatsenko and L.A. Aslanov, Moscow State University, Department of Chemistry, 119899 Moscow, Russia, E.J. Sonneveld and H. Schenk, University of Amsterdam, Laboratory of Crystallography, Nieuwe Achtergracht 166, Amsterdam 1018 WV, The Netherlands

On the basis of dozen unknown molecular crystal structures of C-nitro heterocycles and anthracene-derived dyes, successfully solved from laboratory X-ray powder diffraction data, the practical aspects of structure determination are discussed. The abundance of degrees of freedom, pre-assumptions and applied corrections in crystal structure determination from low-resolution powder data generate the problem of reliability and reproducibility of the obtained results. The comparison of the crystal structures solved from laboratory powder diffraction data with those obtained from synchrotron and neutron data, clearly show the real and reliable possibility of molecular crystal structure solution from laboratory X-ray data with sufficient accuracy in a case of only one rigid fragment in the asymmetric unit. As a consequence of the crystal structure solution the correct molecular structures of some of the investigated compounds were obtained distinguishing between several isomers which were indistinguishable by spectroscopic and quantum chemical methods. As follows from our results the most effective way in crystal structure solving of a series of small molecule organic compounds is to use mainly an X-ray laboratory diffractometer, in transmission mode preferably, and to use synchrotron and neutron facilities in any 'non-standard' cases.

P11.DD.002 USING STRUCTURE ENVELOPES AS MASKS IN STRUCTURE SOLUTION FROM POWDER DATA. S. Brenner, L.B. McCusker, Ch. Baerlocher, Laboratory of Crystallography, ETH, Zurich, Switzerland

A structure envelope, which effectively describes the coarse features of a crystal structure, can be used to advantage as a mask in direct-space methods of structure determination from powder data. It is generated from just a few (1-9) of the strongest, low-index reflections (i.e. precisely those reflections that are generally well-separated in a powder diffraction pattern).

However, to generate the structure envelope, the phases of these reflections must first be determined. To do this, a combination of the Sayre equation, the pseudoatom method and phase permutation has been developed. A pseudoatom is used to describe a prevelant building unit in the structure (e.g. $SiO_{4/2}$ in a zeolite), so *pseudo* atomic resolution can be achieved (e.g. at 3.0 Å). All reflections up to this resolution are involved in the process. Phase sets are generated by permutation (the Golay code is used to improve efficiency) and then extended with the Sayre equation. The resulting phase sets are ranked according to several criteria. For zeolite structures, the FOM from the Sayre equation is generally sufficient to phase the 1-5 reflections needed, but for organic structures, where more reflections are usually necessary, additional criteria (e.g. sign statistics, appearance of the Fourier map) must also be taken into consideration.

The use of a structure envelope as a mask in the FOCUS approach to zeolite structure determination from powder data proved to be beneficial, so it was then combined with a simulated annealing approach for application to organic structures. This combination allowed the structure of a tripeptide ($C_{32}N_3O_6H_{53}$, $P2_12_12_1$, a = 61.03, b = 11.18, c = 5.08 Å) to be solved. The phases of nine reflections were estimated for a centrosymmetric projection along [001] and a 2-dimensional envelope generated. This was used to find favorable starting positions and configurations for simulated annealing runs. Eight torsion angles were varied without restriction and three more were allowed to move within a range of 40°. The peptide linkages and the phenyl ring were kept planar, and the rotation and translation of the whole molecule was subjected to a penalty function calculated from the fit of the molecule to the envelope.

P11.DD.003 STRUCTURE DETERMINATION FROM POWDER DATA. Gerhard Engel, Steffen Wilke, Olaf König, Frank Leusen, Molecular Simulations Ltd., 230/250 The Quorum, Barnwell Road, Cambridge CB5 8RE, UK.

Increasingly powerful methods have been developed recently to facilitate the crystal structure determination from powder data. Based on earlier work at Molecular Simulations [1], we have developed a fast and efficient indirect structure solution package, called POWDER SOLVE, which is fully integrated into MSI's modelling environment.

Positions and orientations of structural fragments within the unit cell are modified to obtain optimal agreement between experimental and simulated powder patterns. An efficient global optimization algorithm allows the method to be applied to organic and inorganic systems. Validation work shows that the method can be applied successfully to systems with up to 18 degrees of freedom with moderate computational effort. At the same time, the package can also be used as a stable and powerful tool for rigid-body Rietveld refinement.

As for related techniques [2,3], the experimental powder pattern (not necessarily from a synchrotron source) must be successfully indexed prior to the simulation, and peak shapes and background parameters must be determined. For this purpose, we have implemented a modification to the Pawley method [4], which avoids the instabilities inherent to the original algorithm.

P11.DD.004 STRUCTURE DETERMINATION OF TWO LITHIUM 4-HALOGENOMETHYLBENZOATES FROM POWDER DIFFRACTION DATA. H. Ehrenberg[1,2], O. Herzberg, B. Hasse, M. Epple[3], [1] Darmstadt University of Technology, Materials Science, Petersenstr. 23, D-64287 Darmstadt, Germany, [2] Hamburger Synchrotron Radiation Laboratory (HASYLAB) at Deutsches Elektronen-Synchrotron (DESY), Notkestrasse 85, D-22603 Hamburg, Germany, [3] Institute of Inorganic and Applied Chemistry, University of Hamburg, Martin-Luther-King-Platz 6, D-20146 Hamburg, Germany

Poly(hydroxymethylbenzoic acid), an aromatic polyester, can be prepared by heating alkali salts of the corresponding chloromethylbenzoic acid above 100°C. An alkali halide is eliminated, and the organic remainder of the molecule polymerizes. The reaction takes place in the solid state. After this reaction, a composite of polymer and salt remains, out of which the salt can be removed by washing with water, leaving behind a highly porous polymer with pores in the sub-micrometer range. The reaction takes place in a number of combinations of alkali metal and halogen. Notable exceptions are the lithium salts of 4-chloro- and 4-bromomethylbenzoic acid that do not polymerize but only decompose.

A structural interpretation of this reaction is only possible with knowledge of the molecular packing in the starting compounds. Unfortunately, suitable single crystals of these compounds could not be obtained. Therefore, we have solved the structures of the two lithium compounds ab initio from synchrotron powder diffraction data. Both compounds are isostructural and crystallize in the monoclinic space group P21/c. The molecules are packed in parallel layers with the halogen atoms of every two layers pointing to each other. Layers of lithium cations are coordinated by oxygen atoms from carboxylic groups. The structure does not support a topochemical polymerization mechanism and therefore well explains the results of the chemical reactivity studies.

P11.DD.005 CRYSTAL STRUCTURES FROM X-RAY POWDER DATA. W. Lasocha, A.Rafalska-Lasocha, M.Michalec. Faculty of Chemistry Jagiellonian University,30-060 Krakow, ul. Ingardena 3, Poland, S.Boryczka. Silesian Medicine Academy, 41-200 Sosnowiec, Jagiellonska 4, Poland. H Schenk, Lab. v. Kristallografie, University Amsterdam, Nieuve Achtergracht 166, 1018WV Amsterdam, The Netherlands

Crystal structures of several compounds have been solved from a powder diffraction data using combination of different techniques. The complexity of the investigated compounds range from 12 to 27 atoms in the asymmetric unit. The samples represent: pure organic compound ($C_{25}O_2H_{18}$, Space Group P 2_1/c, 27 atoms in asymmetric unit), organic compounds with heavy atoms ($C_3H_6NS.ClO_4$, SG: $P2_1$/c, 20 atoms in asymm. unit, $C_3H_6NS.Br$, SG: $P4_22_12$, 12 atoms in asymm.unit) and organometallic compound ($VO_5C_{12}Cl_2.H_2O$, SG: C c, 21 atoms in asymm. unit). In most cases the pattern decomposition was performed by LSQPROF program, while the phase problem was solved using SHELXS, SIRPOW95, PATSEE or SIMPEL programs. The crystal structures were completed and refined by the Rietveld method using XRS-82 program. Most of the structures were solved from laboratory data. Obtained by different methods results will be compared. Important and useful observations will be pointed out and discussed.Support of Polish Committee of Scientific Research (KBN Grant No. 0312/TO9/98/15) is kindly acknowledged.

P11.DD.006 SOLVING MOLECULAR CRYSTAL STRUCTURES FROM POWDER DIFFRACTION DATA USING GENETIC ALGORITHMS. K.D.M. Harris, B.M. Kariuki and R.L. Johnston, School of Chemistry, University of Birmingham, Birmingham B15 2TT, U.K.

Many solids can be prepared only as microcrystalline powders and are not suitable for structural characterization by conventional single-crystal diffraction methods. For such materials, it is necessary to tackle structure determination using powder diffraction data. Although there are many examples in which traditional techniques for structure solution from powder diffraction data have been applied successfully, organic molecular crystals represent a particularly challenging case. For these reasons, we have focused in recent years [1–4] on the development and implementation of new methods for structure solution from powder diffraction data, with emphasis on addressing the specific challenges encountered for molecular crystal structures. Our methods are based on a direct-space strategy in which a hypersurface defined by the profile R-factor (R_{wp}) is searched using Monte Carlo [1,2] or Genetic Algorithm [3,4] techniques. As part of our recent research in this field, we have carried out systematic explorations to find the optimum ways of implementing the different operations (such as mating, mutation and natural selection) within the Genetic Algorithm technique. These studies have provided important information on the strategies for implementing Genetic Algorithms in structure solution, and have yielded important insights concerning the character of the hypersurfaces being explored. In this research, we have applied our methods to solve the crystal structures of complex molecular materials defined by a significant number of variable torsion angles.

The presentation will describe new developments in our understanding of fundamentals of the Genetic Algorithm technique and the optimum strategies for its implementation in powder structure solution. Recent results obtained from the application of this method to solve structures of molecular crystals will be presented.

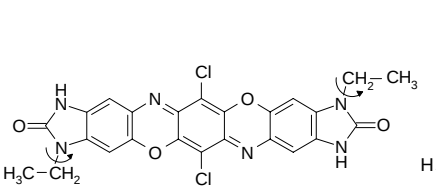
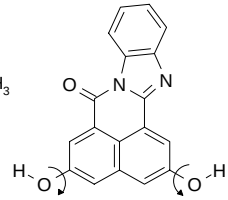
a)R_1=R_2=H, $P2_1$/c, Z=4.

b) R_1=R_2=CH_3, c) R_1=H, R_2=CH_3, both $P\bar{1}$, Z=1



2: $P\bar{1}$, Z=1



3: $Pna2_1$, Z=4

The crystal structures of five industrial organic pigments were solved by energy minimization techniques. The intramolecular degrees of freedom indicated by arrows were optimized together with the arrangement of the molecules. Subsequently the structures were refined by rigid body Rietveld methods, using synchrotron powder data. In cases 1a-c it was also possible to refine all non-hydrogen atoms individually without applying any constraints or restraints (44 independent atoms for 1a).

P11.DD.008 DIRECT SPACE STRATEGIES FOR STRUCTURE SOLUTION. M. Tremayne and C. Glidewell, School of Chemistry, The Purdie Building, University of St. Andrews, St. Andrews, Fife, KY16 9ST, UK.

The crystal structure determination of molecular materials from X-ray powder diffraction data is a rapidly expanding field and has grown substantially in the last few years mainly due to the development and application of direct space based techniques of structure solution [1-4].

In this paper we present results in which the performance of a direct space method (here based on the Monte Carlo approach) is enhanced by the use of good structure solution strategy for the system under consideration. Application of these techniques to powder data significantly affected by preferred orientation will be discussed. Structure solution strategies that combine reciprocal space with direct space methods, and X-ray powder diffraction with crystal structure prediction will also be demonstrated.

These methods will be illustrated by systems that exhibit polymorphism, and materials in which the primary interest is in the intermolecular aggregation, particularly the hydrogen bonding schemes. Examples such as cocrystals will also be presented in which the structure solution process is complicated by the presence of more than one molecule in the asymmetric unit.

11EE MAGNETIC AND INELASTIC SCATTERING

M11.EE.001 DETERMINATION OF MAGNETIC STRUCTURES USING NEUTRON SPHERICAL POLARISATION ANALYSIS. P.J. Brown, Institut Laue Langevin, Avenue des Martyrs, PO Box 156, 38042 Grenoble Cedex, FRANCE

Determination of magnetic structure from measurement of the intensities of neutrons (or X-rays) scattered by magnetic Bragg reflections is in some ways a more difficult problem than determination of the crystal structure. This is because the magnetic structure factor is a vector quantity so that directional as well as phase information is lost in measuring just the intensity. Spherical polarimetry provides a way of recovering some of this lost information. Magnetic neutron scattering is due to a magnetic dipole interaction between the neutron's magnetic moment and the fourier components of the magnetic induction in the crystal. This interaction gives rise to changes in direction of the neutron dipole moment (polarisation) which are highly dependent on their relative orientations. Spherical polarimetry consists in determining the direction of scattered neutron polarisation for any chosen incident polarisation direction. It has been implemented at ILL by developing a CRYogenic Polarisation Analysis Device which is now the second generation CRYOPAD II [1]. Spherical polarisation analysis using CRYOPAD has been able to solve a number of magnetic structure problems which were intractable by other means. For instance it has enabled the absolute orientation of the magnetic moments in magneto-electrics, relative to applied electric and magnetic fields, to be determined for the first time [2]. It is particularly valuable in the study of non-collinear magnetic structures where it has already shown that certain previously determined structures were incorrect [3,4]. Additionally it provides a means for precision determination of antiferromagnetic form factors.

M11.EE.002 MAGNETISM OF HIGHLY CORRELATED MULTILAYERS BASED ON CERIUM AND IRON. W. Felsch, M. Arend and M. Muenzenberg, I. Phys. Institut, Universitaet Goettingen, Germany, and G. Krill, LURE, Université Paris-Sud, 91405 Orsay, France.

The 4f-electron states of the rare-earth element Ce are at the borderline between localization and itinerancy. Both cases can be realized, depending on the degree of hybridization between the 4f- and conduction-electron states, either in the γ or α phase of the pure metal or in compounds with transition metals. Dramatic differences in the physical properties result, reflected in a magnetic and nonmagnetic ground state in the γ- and α-phase-like electronic Ce configurations, respectively. For Ce/Fe multilayers, experiments of X-ray absorption (XA) and X-ray magnetic circular dichroism (XMCD) signal strong electronic correlations at the interfaces, involving the Ce-4f and 5d, and the Fe-3d states. The result is an α-phase-like Ce configuration (4f states delocalized) with ordered 4f and 5d magnetic moments even at room temperature. While the 4f polarization is limited to the direct interface, the 5d polarization extends deeply into the Ce layers. Remarkably, magnetic order on the 5d states can exist without a polarization of the 4f states. There is evidence that the 5d states in these structures are very close to a ferromagnetic instability.

The introduction of hydrogen into Ce in these multilayers, resulting in structures $CeH_{2-\delta}$/Fe, leads to a relocalization of the 4f states, i.e. a γ-phase-like electronic configuration of Ce. A profound modification of the bulk magnetic properties results, like a reorientation of the magnetic easy axis from in plane to out of plane as the temperature is decreased [1]. Angle- and temperature-dependent XMCD experiments permit to trace down the microscopic mechanism of this transition to a perpendicular orientation of the Ce-4f magnetic moment at the interfaces, due to a crystal-field induced single-ion anisotropy. By a complex interplay of hybridization and exchange effects this orientation is transferred to the Fe-3d states via the Ce-5d states.

M11.EE.003 R_2BaNiO_5 COMPOUNDS: HALDANE SPIN CHAINS IN STAGGERED MAGNETIC FIELDS. Andrey Zheludev, Physics Department, Brookhaven National Laboratory, Upton, NY11973-5000, USA.

The quantum-disordered ground state and the famous Haldane gap in the magnetic excitation spectrum have kept S=1 one-dimensional Heisenberg antiferromagnets at the center of attention of condensed matter physicists for the last 15 years. Of particular interest is the behavior of such systems in staggered magnetic fields. In the past this problem was not given much attention in literature, as the required conditions were thought to be almost impossible to realize in an experiment. One clever trick to obtain a field oscillating on the microscopic scale is to make use of an intrinsic magnetic modulation in a material that, in addition to integer-spin Heisenberg chains, has other magnetic ions. Should the latter become ordered magnetically with an appropriate propagation vector, they will project an effective staggered exchange field on the Haldane spin chains. A neat

realization of this mechanism was recently found in a class of linear-chain rare earth nickelates with a general formula R_2BaNiO_5. Extensive neutron diffraction and inelastic neutron scattering studies of several compounds of this type allowed us for the first time to experimentally investigate the influence of a strong staggered field on the properties of S=1 quantum spin chains and particularly on the triplet Haldane-gap excitations.

M11.EE.004 SPIN DENSITIES IN FERROMAGNETS. J.A. Duffy, Department of Physics, University of Warwick, Coventry, CV4 7AL, UK.

Direct measurements of the spin density of a ferromagnet can reveal useful information about the distribution of spin moments, and about the electronic structure. These momentum space spin densities are obtained via synchrotron based Compton scattering experiments. Several examples of the recent work of the Warwick group are presented. Firstly, in the Gd-Y system, where magnetic ordering is believed to be driven by the polarisation of the Y electrons, the magnetic Compton profile revealed that there is an induced spin moment on the Y electrons. More recently, the spin densities in two magnetoresistive materials have been investigated. In $SmMn_2Ge_2$, a giant magnetoresistive material, negative polarisation of the Sm spin moment has been observed for the first time. The spin density of the colossal magnetoresistive perovskite, $La_{0.7}Sr_{0.3}MnO_3$, is also discussed. Finally, possible future applications of the technique are described.

M11.EE.005 DIRECT OBSERVATION OF ORBITAL ORDERING BY RESONANT X-RAY SCATTERING. Youichi Murakami, Photon Factory, Institute of Materials Structure Science, High Energy Accelerator Research Organization, Tsukuba, 305-0801, Japan

Over the last few years, magnetic-field-induced phenomena in perovskite-type manganites have attracted a great deal of attention. In the study of these materials, it has been recognized that the charge, spin and orbital degrees of freedom each play important roles in the electric and magnetic properties. Synchrotron X-ray diffraction is very powerful tool to observe such charge and orbital ordering. Here the direct observation of orbital ordering by resonant x-ray scattering will be presented.

Dipole resonant x-ray scattering from ordered Mn 3d orbitals has been observed near the Mn K-absorption edge in a layered, bi-layered, and three-dimensional perovskite-type manganites. The polarization of the scattered photons is perfectly rotated and the azimuthal angle dependence shows a characteristic twofold symmetry. A theory of the resonant scattering mechanism has been developed by considering the splitting of the Mn 4p levels due to the Mn 3d orbital ordering. The stability of the orbital ordering in these compounds will be discussed when the hole is doped or the external field are applied.

P11.EE.001 ANTIFERROMAGNETIC ORDERING OF THE RARE EARTH IONS R^{3+} IN $R_2Ba_4Cu_7O_{15-\delta}$ (R=Er, Dy). G. Böttger, Laboratorium für Kristallographie, ETH Zürich, 8092 Zürich, Switzerland, and P. Fischer, J. Mesot, B. Roessli, P. Allenspach and A. Furrer, Laboratorium für Neutronenstreuung, ETH Zürich & Paul Scherrer Institut, 5232 Villigen PSI, Switzerland, and A. Dönni, Department of Physics, Niigata University, Ikarashi-Ninomachi 8050, Niigata 950-21, Japan, and Y. Aoki and H. Sato, Department of Physics, Faculty of Science, Tokyo Metropolitan University, Hachioji-shi 192-03, Japan.

The structure and the magnetic properties of the high-temperature superconductor $R_2Ba_4Cu_7O_{15-\delta}$ (R=Er, Dy; $0.05 \le \delta \le 0.7$) have been studied by elastic and inelastic neutron scattering, specific heat and magnetic susceptibility measurements. The polycrystalline samples have been prepared by a sol-gel-technique at ambient pressure. The high transition temperatures to superconductivity T_c=89 K for $Er_2Ba_4Cu_7O_{14.92}$ and T_c=91 K for $Dy_2Ba_4Cu_7O_{14.95}$ indicate a good sample quality. Specific heat measurements show a magnetic phase transition for each of the investigated samples. The Néel temperature T_N is about 1 K for $Dy_2Ba_4Cu_7O_{15-\delta}$ and $0.50 \le T_N \le 0.54$ K for $Er_2Ba_4Cu_7O_{15-\delta}$. Except for the case of $Er_2Ba_4Cu_7O_{14.3}$ the specific heat data of the $R_2Ba_4Cu_7O_{15-\delta}$ samples can be interpreted with an anisotropic 2D-Ising model. The specific heat data for $Er_2Ba_4Cu_7O_{14.3}$ can only be understood by assuming two different types of magnetic clusters to be present in this sample. Such an interpretation is supported by the results of neutron crystal-field spectroscopy demonstrating the presence of at least two distinctly different surroundings of the rare-earth ions. Additionally, we have investigated the temperature dependence of the relaxation rate of the crystal-field transitions in $Er_2Ba_4Cu_7O_{14.92}$ and $HoBa_2Cu_4O_8$ by inelastic neutron scattering. These measurements give evidence for the opening of an electronic gap (pseudogap) in the normal state at about 200 K. The main observed features can be best reproduced by considering a strongly anisotropic gap function. The magnetic ordering of the rare-earth ions in $R_2Ba_4Cu_7O_{15-\delta}$ ($\delta \approx 0$) has been determined by neutron diffraction for R=Er, Dy. For the first a long-range antiferromagnetic order in $Er_2Ba_4Cu_7O_{14.92}$ has been observed time in a $R_2Ba_4Cu_7O_{15-\delta}$ compound. The magnetic Er moments are oriented parallel to the *b*-axis. They are coupled antiferromagnetically along the *a*- and *c*-axis and ferromagnetically along the *b*-axis. Finally, the results of a recent neutron diffraction experiment on the magnetic ordering in $Dy_2Ba_4Cu_7O_{14.95}$ will be presented.

11FF INTERMOLECULAR INTERACTIONS

M11.FF.001 PINPOINTING MOLECULAR INTERACTIONS VIA CRYSTALLINE THIN FILMS. Leslie Leiserowitz, Dept. of Materials and Interfaces, The Weizmann Institute of Science, Rehovot, Israel

Molecular Interactions may be elucidated from the structural properties of thin crystalline molecular films at the air-solution interface. We take advantage of the fact that it is now possible to establish, in favourable cases, the structures of such films to near atomic resolution with the use of grazing incidence X-ray diffraction using synchrotron radiation. The topics we shall cover include:

(1) Induced nucleation of ice using monolayers of long-chain alcohols from which we may glean information on the role played by the orientation of alcohol OH groups for promoting ice nucleation by epitaxy [1].

(2) The role played by N-H...O hydrogen bonds and molecular conformation in the spontaneous separation of racemic mixtures of amphiphiles on water into onolayer crystallites of opposite handedness [2,3].

(3) The effect on polymorphic behaviour of inter- and intra-layer forces involving long chain alkanes in thin crystalline films [4]

(4) The interplay between acid-base interactions, molecular conformation and chirality, in determining the formation of interdigitated bilayers at the air-solution interface [5]

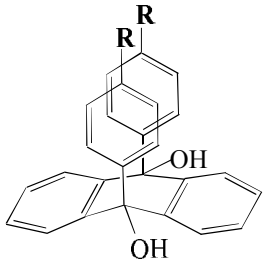
M11.FF.002 HALOGEN SUBSTITUENTS AS SUPRAMO-LECULAR SYNTHONS. I. Csöregh, Structural Chemistry, Arrhenius Laboratory, Stockholm University, Sweden; T. H. Brehmer, and E. Weber, Organische Chemie, TU Bergakademie Freiberg, Germany; and F. H. Cano, Instituto Química-Física, Rocasolano (CSIC), Madrid, Spain.

Intermolecular interactions involving halogen substituents, particularly chlorines, have been proved to enhance crystal formation, thus providing a tool for crystal engineering of both homomolecular and heteromolecular solids. In order to study the effect of various halogens on the crystalline architecture, the *cis*-9,10-diphenyl-9,10-dihydroanthracene-diols **1-4,** differing only in the *p*-phenyl substituents **R** (*cf.* scheme), have been synthesised, crystallised and investigated using X-ray diffraction.



Host (R)	Solvent/ Guest	Stoichio-metry	V_{cell}/Å^3	Space group	
2 (Cl)	Toluene		4153(1)	P-1	0.051
2 (Cl)	DMSO	(2 : 3)	5472(1)	I2/a	.057
2 (Br)	toluene		4217.0(15)	P-1	.048
2 (Br)	toluene/trace of $CHCl_3$		4198.6(1)	C/c	.065
2 (Br)	chloroform	(1 : 1)	5080.1(4)	Pbcn	.075
2 (Br)	DMSO	(2 : 3)	5463.4(4)	I2/a	.087
3 (I)	toluene		1096.7(2)	P-1	.018
3 (I)	ethanol	(1 : 2)	2638(2)	$P2_1$	
4 (CH_3)	toluene		2023.5(5)	$P2_1/c$	.036
4 (CH_3)	THF	(1 : 1)	2551.0(9)	$P2_1/c$	.066

*refinement is in progress.

The crystals of **1-4** were grown from a variety of solvents, yielding crystalline compounds with or without inclusion of guest molecules, hence indicating also the influence of the solvents on the realised packing motif. Structural details with emphasis on the effects of various halogens on the balance of intermolecular interactions will be discussed.

M11.FF.003 SOLID STATE REACTIVITY IN POLYMORPHS OF *ORTHO*-ETHOXY-*TRANS*-CINNAMIC ACID. Demetrius C. Levendis and Manuel A. Fernandes, Centre for Molecular Design, Department of Chemistry, University of the Witwatersrand, Private Bag 3, PO Wits, 2050, South Africa.

The crystal structures of three polymorphs of *ortho*-ethoxy-*trans*-cinnamic acid have been established for the first time. In this paper we report how weak intermolecular interactions determine which polymorph crystallizes and also determine the products and probable mechanisms of the [2,2] solid state photodimerization.

In the crystals, hydrogen bonded dimers of cinnamic acid form layers that are held together in the lattice by weak C-H...O=C interactions, very similar to those found in *p*-toluic acid[1]. In the case of the alpha polymorph, neighbouring ethylene groups are not ideally aligned for [2,2] photodimerization. A shift of one molecule along the C=C direction would be required. During irradiation, the crystal shears along the <-101> direction. This cracking gives vital clues to the mechanism of the solid state reaction.

The beta 'polymorph' is actually a solvated crystal where channels in the crystal with 3-fold symmetry are occupied by benzene molecules. Weak interactions between the benzene and the cinnamic acid molecules stabilise this form. Crystals of Ortho-EtO-cinnamic acid (thiophene) are isomorphous to the beta polymorph and appear to be thermodynamically and photochemically more stable than the benzene form.

M11.FF.004 CRYSTALLINE POLYMERS OF METALLOPORPHYRINS TAILORED BY SPECIFIC INTERACTIONS. Israel Goldberg, School of Chemistry, Tel Aviv University, 69978 Tel Aviv, Israel.

In light of the tremendous versatility of porphyrins and metalloporphyrins in mediating electron and energy transfer, their utility as redox catalysts, and their dynamic photophysical properties, there has been a widespread interest in the design and synthesis of multiporphyrin architectures. In this context, the ability to control the supramolecular organization of such molecular entities by noncovalent interactions is a crucial step on the road to formulation of new materials for specific applications.

Recent investigations have shown that predictable architectures of oligomers and polymers from metallomacrocyclic building blocks can be rationally designed by selection of the coordination geometry of metals, suitable functionalization of the porphyrin framework, and the structure of multitopic ligands involved in the supramolecular synthesis. Relevant examples of successful attempts to assemble crystalline multiporphyrin (often porous) domains will be discussed. They include: (i) the generation of polymeric patterns sustained by external metal centers or multidentate bridging ligands, (ii) the formation of large arrays by utilizing hydrogen-bonding forces (e.g., β-molecular networks with hollow architectures), (iii) the construction of homogeneous as well as heterogeneous coordination polymers of varying dimensionality and crystalline porosity, propagated by metal-to-ligand interactions. [1,2]

Current efforts are directed at the construction (by combination of the different modules of supramolecular design in the same material) of more structurally robust porous molecular crystals, and assessment of potential utility of such structures as molecular sensors and solid state catalysts.

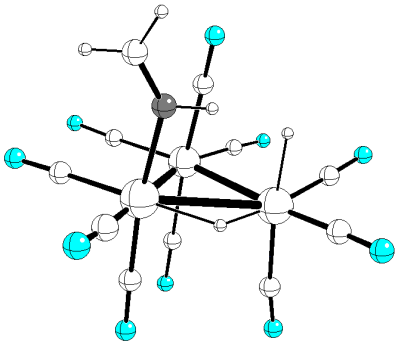
M11.FF.005 SUPRAMOLECULAR CHEMISTRY OF BENZENE POLYCARBOXYLATES. Mark R.J. Elsegood, William Clegg, Simon J. Richards, Matthew J. Hemmings, Katy E. Holmes and Colette Harvey. Department of Chemistry, Bedson Building, The University of Newcastle-upon-Tyne, Newcastle-upon-Tyne, NE1 7RU, UK.

Benzene polycarboxylates are excellent candidates for the study of intermolecular interactions and use in crystal engineering applications since their solid state structures exhibit both extensive hydrogen bonding and π-stacking between layers. The rigid shapes of the acids and their predisposition to form intermolecular hydrogen bonding motifs with regular geometries additionally leads to the formation of cavities within the structures, reminiscent of zeolites. Such cavities may be filled with host solvent or other molecules, or may act as templates for shape specific reactions.

We are currently investigating a number of aspects of this chemistry: (a) Alkali metal complexes of 1,3,5-benzenetricarboxylic acid and 1,2,4,5-benzenetetracarboxylic acid for which we have obtained structural results for the monosodium salt of the former and the disodium salt of the latter. (b) Organic salts of the 1,3,5 acid and guanidinium, which both have 3-fold molecular symmetry. These have extended structures with several cations and anions in the asymmetric unit. (c) We have structural data on a number of alcohol clathrate compounds, some with related hydrogen bond motifs and layering. (d) Transition metal complexes exhibiting both molecular and framework structures. Data sets were measured at low temperature using a Bruker SMART CCD area detector diffractometer.

Leading up to the Congress we hope to obtain structural results obtained with a newly installed Bede Scientific Microsource X-ray generator, and conduct some exploratory high resolution studies investigating the detailed electron density distributions in some of these compounds using the SMART diffractometer. Any results obtained by then will be presented in preliminary form.

P11.FF.001 UNCONVENTIONAL N-H···H-Os HYDROGEN BOND IN AN IMINO TRIOSMIUM COMPLEX. D. Viterbo, S. Aime, R. Gobetto, M. Ferritz, M. Milanesio, E. Valls - Dip. di Chimica IFM, Università di Torino, and Dip. di Scienze e Tecnologie Avanzate, Università del Piemonte Orientale (Alessandria), Italy



Imino metal complexes are often obtained by modification of a previously coordinated ligand such as nitriles, oximes, amines, etc. In trinuclear derivatives this reactivity leads to systems in which the organic ligand occupies a bridging position. Until now, there has been no example of terminal imino ligands in polynuclear systems. Here we show that the stabilization of a coordinated imine may be obtained on the surface of a triosmium cluster possibly stabilized by the formation of an unconventional intramolecular hydrogen bonding interaction between the N-H moiety and a terminal hydride ligand [1]. The crystal structure of the $H(\mu\text{-}H)Os_3(CO)_{10}(HN{=}CPh_2)$ complex is shown in the figure (Ph groups substituted by H). Because of the rather severe absorption effects the hydrogen atoms can not be located with certainty in the difference maps, but they can be reasonably located by geometrical considerations. Indeed in the Os-H···H-N system the H···H distance (≈2.0Å) is much shorter than the normal 2.4Å vdW contact. This result is in keeping with the NMR analysis, based on longitudinal relaxation time measurements, which also indicate a short H···H contact (≈2.1Å). In order to obtain a more accurate localization of the H atoms and to gain some insight of the nature of this new type of hydrogen bond we are currently performing some *ab-initio* theoretical calculations on this complex.

P11.FF.002 ESTIMATION OF EFFECTS OF SUBSTITUENTS ON CRYSTAL PACKING BY FORMING MIXED CRYSTALS. D. Hashizume, N. Takashima, R. Miki, M. Yasui and F. Iwasaki Department of Applied Physics and Chemistry, The University of Electro-Communications, Chofu, Tokyo 182-8585, Japan

4-(4-X-Phenylmethyleneamino)-TEMPO radicals (TEMPO; 2,2′-tetramethylpiperidyl-1-oxyl) have been studied as organic magnets. In the course of the studies, we found that Me, Cl and Br derivatives are crystallized into different crystal forms although the size or character of the substituents are similar. In order to elucidate effects of these substituents on the packing of the crystals, we prepared mixed crystals composing of Me and Cl derivatives, and Cl and Br derivatives.

By mixing the both components in methanol, mixed crystals were obtained from the resultant solutions in any mixing ratio. Crystal structures of the mixed crystals are isomorphous to those of either components, and the both crystal forms of components were observed at the intermediate component ratio. The molecules are disordered only at the substituents but the other moieties are ordered.

We focus on the changes of the contacts between the substituents as the component ratio in the mixed crystals, and will discuss the effects of these substituents on the crystal formation.

P11.FF.003 STRUCTURE, FORMATION AND INTERACTION OF COILED-COILS: FROM LEUCINE ZIPPERS TO INTERMEDIATE FILAMENTS. P. Burkhard[1], R. Kammerer[1], M. Steinemtz[1], S. Strelkov[1], H. Herrmann[2], and U. Aebi. [1]M.E. Müller Institut, Biozentrum der Universität Basel, 4056 Basel, Switzerland, [2]German Cancer Research Center, Heidelberg, 69120, Deutschland.

Subunit oligomerization of many proteins is mediated by coiled-coil domains. Although the basic features contributing to the thermodynamic stability of coiled coils are well understood, their assembly kinetics have not yet been dissected. Here we report a 13-residue sequence pattern - xxLExchxcxccx - which occurs with limited sequence variation in many parallel 2-stranded coiled coils (cf. kinesin, myosin, tropomyosin, plectin), and which is a prerequisite for the assembly of the Dictyostelium actin-bundling protein cortexillin I and the yeast transcriptional activator GCN4. In contrast to arbitrarily chosen heptad repeats, coiled-coil "trigger" sequences form relatively stable monomer helices and thus represent autonomous folding units mediating coiled-coil formation. Last but not least, trigger sequences will be useful in *de novo* protein design.

We have also crystallized the entire 18 heptad-repeat long dimer rod (termed Ir) of cortexillin I and solved its atomic structure. Strickingly, the structure of the trigger sequence can be distinguished from the rest of the Ir dimer rod by its unique intrahelical ion pairing pattern. In pursuit to understand intermediate filament (IF) structure and assembly at atomic detail, we are exploring the different modes of dimer-dimer interactions implicated in IF assembly by X-ray crystallography of "mini-constructs" engineered from IF proteins, so that each mini-construct harbors the central IF dimer rod segment(s) specifying a particular homo- or hetero-typic dimer-dimer association mode.

P11.FF.004 THE HYDROGEN BOND STRENGTH IN TERMS OF THE TOPOLOGICAL PROPERTIES OF THE ELECTRON DENSITY DISTRIBUTION. E. Molins[1] E. Espinosa[1,2] and C. Lecomte[2]. [1]Institut de Ciència de Materials de Barcelona (CSIC). Campus de la UAB, 08193 Cerdanyola (Barcelona), Spain. [2]Laboratoire de Cristallographie et Modélisation des Matériaux Minéreaux et Biologiques, UPRESA CNRS 7036, Université Henri Poincaré, Nancy 1, BP 239, 54506 Vandoeuvre-lès-Nancy CEDEX, France.

Interatomic interactions such as hydrogen bonds (HB's) can be adequately described and classified by the topological properties of the electron density $\rho(r)$ at the (3,-1) critical points r_{CP}, where the gradients of $\rho(r)$ vanish [1]. We have analysed [2] the topological properties of $\rho(r)$ at the intermolecular critical points of 83 experimentally observed HB's [X-H...O (X= C, N, O)] on a large set of compounds, obtained from accurate X-ray diffraction experiments. In spite of different models, methods and experimental conditions employed to obtain the topological properties of $\rho(r)$, we show that, for closed-shell interactions, the kinetic energy density $G(r_{CP})$ and the potential energy density $V(r_{CP})$ at the critical point, depend exponentially on the H...O distance. We point out the positive correlation found between the $V(r_{CP})$ and the HB energy when their functionalities against the H...O distance are compared. Recently [3], we have also observed that the positive and the negative curvatures of $\rho(r)$ at the H...O critical point exhibit linear relationships against, respectively, $G(r_{CP})$ and $V(r_{CP})$. The proportional behaviors found between those quantities show that the strength of the hydrogen bond interaction can be indistinctly interpreted in terms of any of them.

P11.FF.005 MOLECULAR COMPLEXES FOR THE STUDY OF ENANTIODISCRIMINATIVE PROCESSES. F. Bachechi [1], M. Flieger [2], M. Sinibaldi [3], [1] Istituto di Strutturistica Chimica Area della Ricerca di Roma, C.N.R., C.P. 10, 00016 Monterotondo St. (Roma), Italy, [2] Institute of Microbiology, Academy of Scieces of the Czech Republic, 142 20 Prague 4-Krc, Czech Republic, [3] Istituto di Cromatografia, Area della Ricerca di Roma, C.N.R., C.P. 10, 00016 Monterotondo St. (Roma) Italy

The resolution of optical isomers by liquid chromatography requires a chiral selector able to form reversible interactions with the enantiomers and labile diastereoisomeric complexes with different degrees of stability. Since the stability difference between the complexes affects the degree of chiral discrimination and the efficiency of the chiral selector, studies of the mechanism of chiral recognition are particularly relevant, as they provide the basis for the development of new chiral stationary phases.

Recently a chiral selector, based on the ergot alkaloid terguride, (+)1-(3-allylpropyl)-(5R,8S,10R)-terguride, have been developed to resolve optically active isomers. This new chiral stationary phase is successfully used for the separation of several classes of carboxylic acids racemates as dansyl derivatives of amino acids, halogen-substituted 2-aryloxypropionic acids (herbicides), 2-arylpropionic acids and the structurally similar flobufen (anti-inflammatory drugs).

Crystals from molecular complexes, that the selector forms with the more retained enantiomer of a racemic mixture, are not easily obtained, but their crystal structures allow a clear insight into the enantiodiscriminative mechanism. Here the crystal structure of the complex between (+)1-(3-allylpropyl)-(5R,8S,10R)-terguride and (R)-N-dansylserine will be discussed together with analogous complexes, that the selector forms with other analytes to illustrate the interactions at the basis of the chiral recognition.

11GG BULK CRYSTAL GROWTH AND SURFACE PHENOMENA

M11.GG.001 RAPID CRYSTAL GROWTH FROM SOLUTIONS: MECHANISMS OF GROWTH AND DEFECT FORMATION. N.Zaitseva, I.Smolsky, L.Carman, R.Ryon, Lawrence Livermore National Laboratory, University of California, P.O.Box 808, Livermore, CA 94550, USA. E-mail: zaitseva1@llnl.gov

The technique of rapid crystal growth [1] gave a base for the successful development of the technology for production of large KDP and DKDP crystals (more than 50 cm in size) for the National Ignition Facility (NIF) laser being built at Lawrence Livermore National Laboratory.

High growth rates, 1-2 orders of magnitude faster than in conventional methods, became possible due to increased solution stability and the shift of the growth process into the region of high supersaturations. This condition emphasized new mechanisms of growth which have not been observed on the large scale or have not been explained previously.

One of such mechanisms is growth on steps generated by the corners and edges of a growing crystal. In faceted crystals this works as a correction mechanism for preserving the crystallographic shape of the faces and edges deviated from the singular directions by the existence of vicinal hillocks. It also explains the phenomena of fast regeneration of the seed from any shape to the right crystallographic habit of minimum surface energy.

Another mechanism is connected with the observation of large crystal facets which grow in the absence of dislocations at a normal growth rate of about one order of magnitude less than growth on dislocation sources under the same conditions. This phenomena is more pronounced in crystals with a low number of dislocations growing at high temperature. Two-dimensional nucleation, when quasi-molecular units attach to the growing surface directly, is a possible explanation of this phenomena.

The growth mechanisms, together with the other factors, such as impurities, hydrodynamics and crystal size, influence the growing surface structure, which at the end determines the optical quality of the crystals. The connection between the defect formation process and the surface structure will be presented.

N.P.Zaitseva, J.J.DeYoreo, M.R.Dehaven, R.L.Vital, K.E.Montgomery, M.Richardson, L.J.Atherton, J.Cryst.Growth 180 (1997) 255.

M11.GG.002 SOLUTION GROWTH OF MIXED ALUM CRYSTALS AND STUDY OF THEIR OPTICAL INHOMOGENEITIES. A.G.Shtukenberg and Yu.O.Punin, Crystal Genesis Laboratory, Geological Faculty, 199034 St.Petersburg State University, St.Petersburg, Russia, E-mail: sasha@as3607.spb.edu; H.Klapper and E.Haegele, Mineralogisch-Petrologisches Institut, University of Bonn, D-53115 Bonn, Germany.

We have carried out detailed investigations of optical anomalies in mixed crystals of alums ($(K,NH_4)Al(SO_4)_2 \cdot 12H_2O$ and $K(Al,Cr)(SO_4)_2 \cdot 12H_2O$) using *in-situ* observation of crystal growth at controlled conditions as well as *ex-situ* optical and X-ray topographic methods. The large mixed crystals (up to 10 cm diameter) were grown from aqueous solutions by lowering the temperature under strong stirring with reversal of rotation. The crystals display a pattern of strong optical inhomogeneities. The

aim of this work is to clarify the origin of these inhomogeneities. Optical anomalies in mixed crystals arise by three causes: 1. Mismatch strains due to compositional inhomogeneities; 2. Strain caused by dislocations; 3. Kinetic ordering of atoms (growth dissymmetrization). It was shown that all three sources of optical anomalies occur in alum mixed crystals, forming the observed complex optical pattern. Even stationary growth conditions lead to optical inhomogeneities in the shape of growth sector-zoning (induced by growth dissymmetrization) and of optical anomalies along dislocation bunches (induced by elastic strain). Non-stationary growth conditions lead to some additional optical effects: zoning and sub-sector zoning. Three interrelated factors determine these additional effects: (1) Compositional inhomogeneities lead to significant inhomogeneous mismatch strain and (2) to different degree of ordering of the mixing atoms; (3) Different directions, heights and velocities of growth steps induce different degrees of ordering of mixing atoms. All kinds of inhomogeneities are discussed in detail in connection with growth conditions. The results obtained can be used for other mixed crystals with optical anomalies.

This work is supported by Russian RFBR grant # 98-05-64151 and German DAAD grant # A/97/53466.

M11.GG.003 GROWTH AND CHARACTERISATION OF NEARLY PERFECT BISMUTH GERMANATE CRYSTALS. Krishan Lal[a], R.V.Anantha Murthy[a], M.Ravikumar[a], A.Choubey[a], G. Bhagavannarayana[a], Lyudmila Kharachenko[b], V. Shleguel[b], V. Guerasimov[b] and Yu. Shubin[b], [a]National Physical Laboratory, Dr. K. S. Krishnan Road, New Delhi 110012, India, [b]Institute of Inorganic Chemistry, SB RAS, Novosibirsk, Russia.

Bismuth Germanium Oxide (BGO) $Bi_3Ge_4O_{12}$ are grown from melt to meet the stringent requirements as scintillators for X-rays and γ-rays. Till recently, Bridgman method had been employed to grow BGO crystals with good degree of perfection. Recent efforts have shown that nearly perfect BGO single crystals can be grown by Low Thermal Gradient (LTG) Czochralski method with Automatic Weight Control Process [Murthy et al, J. Crystal Growth 1999]. For structural characterization, high-resolution X-ray diffractometry and topography methods were employed. Point defects and their clusters have been investigated by diffuse X-ray scattering measurements. The crystal growth system has been developed at IIC, Novosibirsk and the multi-crystal X-ray diffractometers employed in this study were developed at NPL. The crucible weighing system has an accuracy of 10 mg in 1 kg range and 50 mg in 25 kg range. The diameter control is effected through crucible weight control. The temperature gradient above the crystal – melt interface is negligible in a zone of ~4 cm. Platinum crucible was used to melt the charge, which was heated at a rate of 250^o C/h. Nearly perfect crystals were grown under following growth conditions: pulling rate - 2.5 mm/h, seed rotation rate - 38 rpm, growth rate - 30 g/h and post growth cooling rate - 150^o C/h. Crystal dimensions were ~ 80 mm long and ~ 40 mm in diameter [weighing ~ 800g]. Diffraction curves were quite sharp with typical half width values of ~9 arc sec in the central region. Some regions at the periphery had *very* low angle grain boundaries with angular tilts of only ~33 arc sec. Thermal annealing at elevated temperatures reduced the tilt angles and improvements in crystalline perfection were observed. Diffuse X-ray scattering measurements showed significant differences in defect structure with direction of growth. Variations in trace impurities in starting materials, which apparently led to different tinges, did not produce appreciable effect on the point defect clusters.

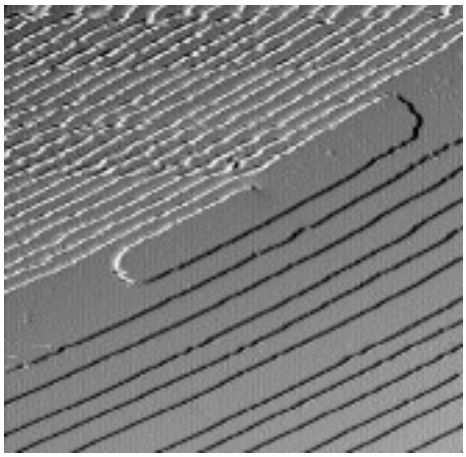
M11.GG.004 ATOMIC FORCE MICROSCOPY OF ORGANIC CRYSTALS. M. Plomp, F.F.A. Hollander, K. Waizumi, P.J.C.M. van Hoof and W.J.P. van Enckevort, RIM Laboratory of Solid State Chemistry, University of Nijmegen, Toernooiveld 1, 6525 ED, Nijmegen, the Netherlands.

Atomic Force Microscopy (AFM) is a powerful method for imaging crystal surfaces from a microscopic to a molecular scale, which has been applied to metal, semiconductor, ionic, and, as in this presentation, organic crystals. We investigated both *in situ* and *ex situ* growth patterns on the surfaces of fat, protein and paraffin crystals. All crystals showed monomolecular step patterns on their faces.

Different polymorphs of tripalmitate fat crystals were examined. On a microscopic scale very anisotropic growth spirals (see figure) and stacking faults were discriminated. On a smaller scale molecular resolution images could be made.

Insulin protein crystals showed growth both via screw dislocations and 2D nucleation.

On n-$C_{23}H_{48}$ paraffin crystals growth and etching took place during *ex situ* imaging. This was caused by tip-induced local melting of the surface. Measurements on n-$C_{40}H_{82}$ crystals showed the occurrence of crossing steps. This phenomenon was caused by post-growth stress in the crystals, leading to slip movement of screw dislocations.



Growth spiral as observed on the (001) face of a tripalmitate crystal.

All these investigations provide insight into the growth of organic crystals. This is important for various industries and for X-ray structure determination.

M11.GG.005 ATOMIC FORCE MICROSCOPY INVESTIGATION OF TRENDS IN SURFACE DYNAMICS DURING GROWTH FROM SOLUTIONS. J.J. De Yoreo, T.A. Land, C.A. Orme [1], H.H. Teng, P.M. Dove [2], M.T. Mc Bride, T.L. Martin, G.T.R. Palmore [3], [1] Department of Chemistry and Materials Science, Lawrence Livermore National Laboratory, Livermore, CA 94550, [2] School of Earth and Atmospheric Sciences, Georgia Institute of Technology, Atlanta Georgia 94550, [3] Department of Chemistry, University of California at Davis, Davis, CA 94671.

Using force microscopy to image crystal surfaces during growth from solutions, we investigated the dependence of growth mechanism, surface morphology, step kinetics and impurity effects on supersaturation in a variety of systems including simple ionic solids (KH_2PO_4, $CaCO_3$ and Ca_3PO_2), hydrogen bonded organic compounds (2,5-diketopiperazines), and Van der Waals bonded macromolecules (proteins). From the dependence of critical step length and step speed on supersaturation, we determined the step edge free energy, kinetic coefficient of elementary steps, and free energy barrier to 1D nucleation at step edges. The wide variety of molecular sizes and bonding allowed us to examine differences in the behaviour of systems for which the step edge energy and the

kinetic coefficient vary by over three orders of magnitude. Here we present a comparative analysis in terms of standard thermodynamic models. We find that the supersaturation at which two-dimensional nucleation occurs is well correlated with the magnitude of the step edge energy and that there is a systematic trend in step kinetics with increasing complexity of growth units. We also show that the magnitude of step edge roughness and step fluctuations varies dramatically among these systems, and that the near-equilibrium step kinetics is often dominated by impurity effects. We then examine the interaction of Fe^{3+}, Al^{3+} and Cr^{3+} impurities with steps on the {100} face of KDP as it enters and emerges from the "dead zone. Within the "dead zone", the surface consists of an intertwined array of immobile elementary steps and macrosteps. As the supersaturation increases, contrary to what is expected from standard models, the surface emerges from the dead zone by propagation of macrosteps which are unhindered by the impurities while the elementary steps remain immobile. As the supersaturation is increased further, the elementary steps begin to advance, but at a slower speed than the macrosteps. At sufficiently high supersaturations, both step types are highly mobile, but the effect of impurities on step motion results in a progressive doubling of steps heights with distance from the step source until macrosteps containing many hundreds of elementary steps dominate the surface.

M11.GG.006 IN SITU ATOMIC FORCE MICROSCOPY STUDIES OF MACROMOLECULAR CRYSTAL GROWTH. A. Malkin, Yu.G. Kuznetsov, A. McPherson [1] Department of Molecular Biology and Biochemistry, University of California, Irvine, CA 92697-3900, USA.

Crystal growth, defects structure and cessation of growth. The growth of twelve protein and virus crystals was investigated in situ using AFM. It was revealed that all the classical growth mechanisms such as growth on dislocations, growth by two- and three-dimensional nucleation and normal growth mechanism operate in macromolecular crystals. Supersaturation dependencies of tangential, normal growth rates and rates of two-dimensional nucleation were measured and several fundamental crystallization parameters were determined. Point defects, dislocations, stacking faults and inclusions were observed and mechanisms of their formation were revealed. The defect density in several different macromolecular crystals was calculated and these data were correlated with the ultimate resolution to which a crystal diffracts. We have observed how the crystals stopped to grow due to the formation of adsorption layer of impurities on the crystalline surface.

Molecular resolution imaging. AFM images at the molecular level have been obtained and structure of the surface layer was resolved for a number of macromolecular crystals. For several crystals molecular structures of the growth step edge and its advancement due to formation of one-dimensional nuclei on the step edge were revealed. High-resolution images of the surface layer of turnip yellow mosaic virus (TYMV) crystals allowed the first direct visualization of the capsomere structure of a virus by AFM. Hexameric and pentameric capsomers of the T=3 capsides are readily discriminated from one another and are clearly visible. Adsorption of individual virus particles and formation of clusters of virus particles on the crystalline surface were visualized. Surface transitions on the (101) face of TYMV crystals were revealed. Three entirely different lattice structures of the surface layer were observed and these patterns transformed sequentially from one to another under specific supersaturation conditions

M11.GG.007 KDP PRISM FACE GROWTH AT LOW STEP VELOCITIES L.N.Rashkovich, O.A.Shustin, T.G.Chernevich, Physics Department, Moscow State University, Moscow 119899, Russia

Research of crystallization processes when velocity of elementary growth layers is under 100 A/s, i.e. close to the non-investigated dead zone of supersaturations, is now possible only with application of atomic force microscope. Up to now this work was never done although being important for understanding of interaction mechanism between steps and impurities adsorbed at the surface or other defects, as well as for crystal growth technology.

Crystallization was conducted in moist media. Method is based on inverse proportionality of solubility to the thickness of solution film on crystal surface. Solution moistens measuring tip of the nanoscope, and therefore solution layer under the tip is thicker. For this reason growth proceeds only in the area of surface scanning and close to this area.

The work describes morphological modifications of preliminarily rough surface in process of generation of singular face and dislocational hillocks.

It was shown for complicated dislocational sources forming multi-thread spirals, that with changes of supersaturation the distance between threads of neighboring spirals is changing, being able to cause development of macrosteps.

Two mechanisms of encapturing obstacles by growing layer are discussed: formation of "sack" (in case of a big obstacle) and encapturing of impurity atoms during kinks movement. In the first case it is easy to determine size of critical nuclei.

Dependence of step velocity on supersaturation and dependence of inter- thread distance on the radius of critical nucleus were obtained through independent measurement of step velocity and rotation period of dislocational spiral.

Drastic surface morphology change with addition of aluminum ions to solution is discussed. These experiments were done in solution flow washing the surface.

12OA VIRUSES AND VIRAL PROTEINS

M12.OA.001 CRYSTAL STRUCTURE OF HUMAN HEPATITIS B CAPSID. A. G. W. Leslie, S. A. Wynne and R. A. Crowther, MRC Laboratory of Molecular Biology, Hills Road, Cambridge CB2 2QH, U.K.

The crystal structure of human hepatitis B capsid with T = 4 icosahedral symmetry has been determined at 3.3Å resolution, using heterologous expression in *Escherichia coli* of capsid protein with the basic C-terminal region (aa 150-185) deleted. The structure was solved using phases derived from a 7.4Å resolution map determined by electron cryomicroscopy (Böttcher *et al*., 1997). Icosahedral averaging and solvent flattening were used to extend the phases to 3.3Å resolution. The capsid protein fold is largely helical, as predicted by spectroscopic measurements, and is in excellent agreement with the fold derived by electron cryomicroscopy. The monomer fold is stabilised by an extensive hydrophobic core formed by residues which are highly conserved amongst human variants. The capsid protein forms very stable dimers by the association of two amphipathic α-helical hairpins, producing a four helix bundle which corresponds morphologically to the spikes on the capsid surface. The dimer-dimer interactions which result in capsid formation involve residues located towards the C-terminus of the truncated protein, which helps to explain the observed dependence of shell formation on the exact length of the construct. The hepatitis B capsid is highly antigenic, and is very effective as a carrier for foreign epitopes. The major immunodominant region (aa 78 - 83) lies at the tips of the spikes. There is a cluster of conserved residues in the same location, which may play a role in specific interactions with the surface antigen during envelopment of the capsid.

M12.OA.002 PROBING THE INTERIOR OF THE BLUETONGUE VIRUS CORE PARTICLE. J. M. Diprose, P. Gouet, J. M. Grimes, R. Malby and D. I. Stuart, Laboratory of Molecular Biophysics, Oxford University, Oxford OX1 3QU, UK, and S. Zientara, C.N.E.V.A. Alfort, Laboratoire Central de Recherches Veterinaires, BP67, 94703 Maisons Alfort Cedex, France, and J. N. Burroughs and P. P. C. Mertens, Institute for Animal Health, Pirbright Laboratory, Pirbright, Woking GU24 0NF, UK.

The bluetongue virus core particle is the active transcriptional unit of the virus, consisting of an icosahedral capsid surrounding the enzymatic components and segmented dsRNA genome. The structure of the core was recently solved [1], revealing much about the high-symmetry capsid components but less about the low-symmetry minor proteins and RNA.

An analysis of the structural restraints imposed by the capsid allows us to estimate the concentration of RNA within the core at 410 mg/ml, indicating the genome may be organised as a liquid crystal. Further evidence for this comes from the observation of powder rings of correct spacing in the diffraction patterns collected. Cross-averaging between the structure of serotype 1 (space group $P2_12_12$) and serotype 10 (space group $P4_12_12$) has allowed the identification of structure internal to the capsid conserved between serotypes. Layers of electron density are seen, consistent with the suggested organisation of the genome segments. Density located on the 5-fold icosahedral axis just inside the capsid has been putatively assigned to the polymerase/transcriptase and capping enzymes. Solvent contrast variation experiments reinforce this picture of the internal arrangement of the core particle.

M12.OA.003 ABSTRACT NOT AVAILABLE. W.A. Hendrickson

M12.OA.004 THE CRYSTAL STRUCTURE OF ADENOVIRUS KNOB BOUND TO ITS CELLULAR RECEPTOR CAR. M.C.Bewley, P. Freimuth, K. Springer and J.M. Flanagan. Biology Department, Brookhaven National Laboratory, Upton, New York, 11973, USA.

Understanding the mechanism of adenovirus entry onto host cells is key to designing viable Adeno-based gene therapy vectors. The first step in this pathway is the attachment of the fibre knob domain to its cellular receptor. We have solved the crystal structure of Ad12 knob in complex with domain 1 of its cellular receptor CAR (Coxsackie and Adenorirus Receptor) to 2.6Å resolution. The knob-CAR interface buries a large surface area, but there are few specific contacts between the two proteins, resulting in the formation of a 170$Å^3$ cavity. There are many features of the interface that are similar to that of HIV gp120 in complex with its receptor CD4. CAR is also the cellular receptor for subgroup B of Coxsackie virus. The two viruses compete for binding on CAR, indicating that at least part of the site is shared

The structure of the knob-CAR complex will be presented and compared to that of HIV gp120-CD4. Mutagenesis data, which provides supporting evidence of the validity of the complex, will also be presented. In addition, we will present an explanation for the inability of certain adenovirus serotypes to bind to CAR and we will discuss the implications of our structure on the Canyon hypothesis, presenting possible binding sites for Coxsackie B.

M12.OA.005 WHEN BIG THINGS REFUSE TO CRYSTALLIZE: COMBINING EM AND X-RAY CRYSTALLOGRAPHIC DATA. Jordi Bella, Yizhi Tao and Michael G. Rossmann, Department of Biological Sciences, Purdue University, West Lafayette, IN 47907, USA

In spite of the spectacular successes of virus crystallography, both past and present, a considerable number of interesting problems in virology still elude tackling by crystallographic techniques. Hard-to-crystallize examples include non-icosahedral viruses, antibody-virus, or receptor-virus complexes. Cryo-electron microscopy (cryo-EM) techniques may prove invaluable in such cases, and the combination with data obtained from X-ray diffraction experiments can provide models at near-atomic resolution.

The interaction between the major group of Human Rhinoviruses (HRVs) and their cellular receptor, Intercellular Adhesion Molecule-1 (ICAM-1), has been studied by this combined approach [1]. Cryo-EM reconstructions of complexes between HRV and fragments of ICAM-1 have been interpreted by fitting coordinates obtained from crystal structures of the individual components. This fit has been optimized by rigid-body refinement against structure factors from the cryo-EM map. Fragments of ICAM-1 used in the reconstruction have different degrees of glycosylation. Whereas glycosylation sites show conformational disorder, they can still be identified in the cryo-EM reconstructions, and thus help to refine the orientation of the ICAM-1 fragment model.

The study of the assembly pathway of ϕ29, a dsDNA tailed bacteriophage, provides another example of synergism between cryo-EM and X-ray data [2]. The cryo-EM reconstruction of the prolate head of ϕ29, with only 5-fold symmetry, has allowed for the visualization in situ of the head-tail connector, the central component of the DNA packaging machinery. Crystallographic data indicates that this connector has 12-fold symmetry, thus incommensurate with that of the head. This mismatch may be required to rotate the connector during DNA packaging.

P12.OA.001 STRUCTURE OF THE 2A CYSTEINE PROTEINASE FROM HUMAN RHINOVIRUS 2. J.F.W. Petersen [1], M.M. Cherney [1], H.-D. Liebig [2] T. Skern [2], E. Kuechler [2] and M.N.G. James[2], [1] Department of Biochemistry, U. of Alberta, Edmonton, Alberta, T6G 2H7, Canada, [2] Institute of Biochemistry, U. of Vienna, A-1030 Vienna, Austria.

The crystal structure of the 2A proteinase from human rhinovirus serotype 2 (HRV2-2A) has been solved to 1.95 Å resolution by MAD phasing over the absorption edge of zinc. HRV2-2A is involved in the first cleavage of the viral polyprotein which is an intramolecular (cis) cleavage between the N-terminus of HRV2-2A and the C-terminus of the structural protein VP1. In addition HRV2-2A causes the shut-off of the host cell's protein synthesis by cleaving the eukaryotic initiation factor eIF4G. The structure has an unusual, although chymotrypsin-related, fold comprising a unique four-stranded β-sheet as the N-terminal domain and a six stranded β-barrel as the C-terminal domain. A tightly bound zinc ion essential for the stability of HRV2-2A is tetrahedrally co-ordinated by three cysteine sulphurs and one histidine nitrogen located at the junction of the N- and C-terminal domains. The active site consists of a catalytic triad formed by His18, Asp35 and Cys106 and is stabilised by an extensive hydrogen bonding network involving Asp35. Modelling studies reveal that productive substrate binding requires an induced fit in

a cleft formed by a flexible β-hairpin loop containing two tyrosine residues. This model of substrate binding explains furthermore the specificity of the subsites S4, S2, S1 and S1' as well as the cleavage of the host protein eukaryotic initiation factor eIF4G leading to the inability of the infected cell to translate its own capped mRNA. The structure of HRV2-2A suggests that self-processing of the picornaviral polyprotein occurs intramolecularly.

12OB PROTEIN-CARBOHYDRATE INTERACTIONS AND CELL ADHESION

M12.OB.001 MULTIVALENCY AND PROTEIN-CARBOHDYDRATE INTERACTIONS. James M. Rini[1], John R. Walker[1], Yuri D. Lobsanov[1], Bhushan Nagar[1], Jung-Kay Chiu[1], Martin Young[2], and Chi-Hung Siu[3]. [1]Departments of Molecular & Medical Genetics & Microbiology and Biochemistry, University of Toronto, Toronto, Ontario, M5S 1A8, Canada, and [2]Institute for Biological Sciences, NRC, Ottawa, Ontario, K1A OR6, Canada, and the [3]Banting and Best Department of Medical Research and Biochemistry, University of Toronto, Toronto, Ontario, M5S 1A8, Canada.

Both structural and biochemical analysis has shown that many, if not all, lectin types use multivalency to define the affinity and specificity for their carbohydrate ligands. Included among these are lectins responsible for mediating cell-cell and cell-matrix interactions, as well as molecular recognition processes.

The x-ray crystal structures of two new highly multivalent lectins - a decameric C-type lectin from Western diamondback rattlesnake venom (RSL) and discoidin from *Dictyostelium discoideum* - will be presented. RSL is a potent platelet activator and is found to be composed of two 5-fold symmetric pentamers related by a crystallographic 2-fold rotation axis. The ten carbohydrate-binding sites are solvent exposed and located on the "edge" of the decamer. Discoidin is developmentally regulated and important in mediating *D. discoideum* cell-streaming. The structure reveals a stalk-like trimer presenting 9 galactose binding sites. An array of three carbohdyrate-binding sites at each end of the trimer results in what appears to be a bifunctional cross-linker well suited to interacting with glycoconjugate containing surfaces.

In both cases the relative disposition of their carbohydrate-binding sites suggest structure-function relationships which will be discussed in light of that seen in other lectin structures.

M12.OB.002 STRUCTURAL BASIS OF A PEPTIDE MIMICKING THE OLIGOSACCHARIDE ANTIGEN OF AN ANTIBODY (SYA/J6). N.K. Vyas[a], M.N. Vyas[a], B.M. Pinto[b], J.K.Scott[b], S.L. Harris[b], M.A. Johnson[b], M.K. Chevernak[c], D.R. Bundle[c] and F.A. Quiocho[a,d], ([a])Dept.of Biochemistry, Baylor College of Medicine, One Baylor Plaza, Houston, TX 77030, USA, ([b])Department of Chemistry, Simon Fraser University, Burnaby, B.C., Canada, V5A 1S6, ([c])Department of Chemistry, University of Alberta, Edmonton, Alta, Canada, T6G 2G2, ([d])Howard Hughes Medical Institute, Baylor College of Medicine, One Baylor Plaza, Houston, TX 77030, USA

Understanding the molecular basis of peptide mimicry of oligosaccharide will be useful in rational drug design, vaccine development and places where substitution for natural ligand is desired. The monoclonal antibody (mAb) specific for oligosaccharide when screened against phage displayed peptide libraries, revealed an important fact that interacting peptides contain consensus sequence specific for the mAb and compete with the original antigen[1]. At present structural data for such polyspecificity is not well established. The crystallographic studies presented here are for a Fab segment of mAb (SYA/J6)[2], directed against the cell surface O-polysacchride of Gram negative bacteria, Shigella flexneri, in complex with two oligosaccharide epitopes (natural and synthetic) and the octa-peptide with very similar affinity for the SYA/J6 Fab, along with the unliganded Fab. All four structures were determined by the molecular replacement method. The final resolution of these structures ranges from 1.8 to 3 Å. All the data sets were collected at Synchrotron centers. The refinement using the CNS suites of programs (Axel Brunger, Yale University) gives crystallographic R factor for these structures below 0.25 (free R below 0.30). Analyses of results show, probably for the first time, that the peptide is bound in the combining site of the Fab where oligosaccharide, the natural epitope, binds. Peptide interacts with the CDRs of both heavy and light chains, but interacts with different regions of the CDRs. This suggests that peptido-mimetics is not a structural or stereo-mime but imparts its own specificity mimicking the biological role of oligosaccharide. The functional compatibility of peptide and oligosaccharide makes peptide a mime but not an inhibitor.

M12.OB.003 SUBSTRATE RECOGNITION BY ENDO-β-N-ACETYLGLUCOSAMINIDASES. Patrick Van Roey, Christopher A. Waddling, Anthony L. Tarentino and Thomas H. Plummer Jr. Wadsworth Center, New York State Dept. of Health, Albany, NY 12201-0509 USA.

Flavobacterium meningosepticum secretes three endoglycosidases, Endo F_1, F_2 and F_3. The three enzymes release asparagine-linked oligo- saccharides from glycoproteins by cleaving the β(1-4)-glycosidic link between the core N-acetylglucosamines. The three enzymes differ greatly in their substrate specificities. Endo F_1 only cleaves high-mannose oligosaccharides. Endo F_2 shows preference for biantennary complex glycans and Endo F_3 cleaves triantennary and α(1-6)-fucosylated biantennary oligosaccharides. We have determined the crystal structures of Endo F_1 and Endo F_3. The enzymes have an $(\beta/\alpha)_8$-barrel fold in which the catalytic glutamic acid residue is located at the end of β-strand 4. The geometries of the two enzymes differ greatly in the area of the loops of β/loop/α-units 2 and 3. In Endo F_1, the main feature in this area is a β-hairpin formed by loop 2. In Endo F_3, this hairpin is replaced by two short α-helices, one each from loops 2 and 3. The structure of Endo F_3 in complex with the biantennary octasaccharide, (Gal-GlcNAc-Man)$_2$-Man-GlcNAc, reveals unambiguously that this area functions as the primary recognition site by tightly binding the α(1-6)-mannose branch. Protein-carbohydrate interactions are similar to those seen in carbohydrate-lectin complexes. The α(1-3)-mannose branch lies over the surface of the protein in the areas of loops 1 and 8 and makes less specific interactions. O1 of the reducing end N-acetylglucosamine forms a bifurcated hydrogen bond with the carboxylate group of the catalytic residue, Glu128. Asp126 is within hydrogen-binding distance from the amine group of the N-acetyl- glucosamine and in position to stabilize the intermediate in a substrate assisted reaction mechanism. Research supported in part by NIH grants GM-50431 (PVR) and GM-34071 (ALT and THP).

M12.OB.004 STRUCTURES OF CHITOTRIOSIDASE AND HC gp39: A LEAD IN THE UNDERSTANDING OF HUMAN CHITINASES. Fabrizia Fusetti, Henriëtte J. Rozeboom, Tjaard Pijning, Annemarie S. de Haan*, Ebo S. Bos* and Bauke W. Dijkstra, University of Groningen, Department of Chemistry, Nijenborgh 4, 9747 AG Groningen,NL (*) NV Organon , Department of Analytical Chemistry , PO Box 20, 5340 BH Oss, NL

Chitinases are glycosyl hydrolases that are found in all organisms in which chitin is a structural component. Surprisingly, proteins highly homologous to chitinases have also been identified

in human. Among these the 39 kDa cartilage glycoprotein (HC gp39) and the enzyme chitotriosidase are particularly intriguing. Their precise physiological role is still unknown. They might be involved in defence mechanisms against pathogens, in tissue remodelling, and in cellular differentiation and high levels of both proteins have been associated with pathological conditions. Chitotriosidase is enzymatically active towards natural chitin but the physiological substrate has not been identified so far. This enzyme is a very reliable marker for the diagnosis of Gaucher disease, a genetic lysosomal storage disorder affecting glucocerebroside metabolism and resulting in mental retardation. In contrast, HC gp39 does not display any chitinolytic activity although it has maintained the ability to bind chitin. Overexpression of HC gp39 has been detected during inflammatory processes of the joints suggesting its potential use as a marker for rheumatoid arthritis.

To address the many questions on the function and the ligand binding properties of human chitinases, we have determined the crystal structures of HC gp39 and of the enzyme chitotriosidase. Both structures show an overall fold similar to that of other chitinases belonging to the glycosyl hydrolase family 18. They display a two domain structure consisting of a main $(\beta\alpha)_8$ barrel domain in which an $\alpha+\beta$ folded domain is inserted. The structure of a complex with a bound chitin fragment shows that HC gp39 holds the sugar chains in the groove present at the C-terminal side of the barrel, in a manner similar to bacterial and plant chitinases, confirming a close evolutionary relationship. These structures are a useful template to explain biochemical results and to discuss the suggested hypotheses on the role of human chitinases.

M12.OB.005 CRYSTAL STRUCTURE OF A MAMMALIAN GALACTOSYLTRANSFERASE Louis N. Gastinel, Christian Cambillau and Yves Bourne AFMB, CNRS-UPR 9039, 31 Chemin Joseph Aiguier 13402 cédex 20 Marseille, France

β1,4Galactosyltransferase, β4Gal-T1, catalyzes the transfer of galactose from UDP-Gal to terminal β-N-acetylglucosamine (GlcNAc) residues forming the poly-N-acetyllactosamine core structures present in glycoproteins and glycosphingolipids. In mammals, β4Gal-T1 associates with α-lactalbumin, a protein expressed exclusively in lactating mammary epithelial cells, to synthesize lactose. β4Gal-T1 is a member of a large family of homologous β4GalT where individual members appear to use different types of glycoproteins and glycolipids as substrates[1,2]. The 2.4 Å resolution crystal structure of the catalytic domain of bovine β4Gal-T1 (residues 133 to 402) consists of a single domain, composed of eleven β-strands, six α-helices and two short 3_{10} helices. The central part of the structure resembles the typical α/β Rossman fold found in a large number of nucleotide-binding protein structures. One face of the molecule contains a deep pocket of 13 Å in diameter. The bottom of the pocket contains the Arg228 side chain (F226NRA) and the signature sequences specific to the β4GalT family[3], Asp252 of DVD, Glu317 and Asp318 of WGWGG(R)EDD. UDP-Gal binds with the uracil moiety deeply buried between Phe226 and Arg191 side chains of the new motif PF(H)RXR, the phosphate groups are located near the DVD motif and the galactose moiety close to the EDDD motif and the Tyr286 side chain. The side chain of Trp314 located close to the EDDD motif, could be a good candidate for interaction with GlcNAc or other sugar acceptors. The only free cysteine Cys342, not conserved among β4GalT family, has is side chain buried and is unlikely to play a direct role in catalysis. A single patch of residues found at the surface and conserved only in β4Gal-T1 and β4Gal-T2 proteins is located in the α6 α-helix and involves residues Gln358, Arg362, His365, Thr369 and Met370. These residues are close to Trp314, suggesting that Trp314 may be involved in the GlcNAc binding site which may be used by glucose upon α-lactalbumin binding.

P12.OB.001 SUGAR BINDING, PLANT HORMONE BINDING AND NOVEL QUATERNARY STRUCTURE OF TWO LEGUME LECTINS. Thomas W. Hamelryck[1], Remy Loris[1], Julie Bouckaert[1], Minh-Hoa Dao Thi[1], Gerard Strecker[2], Anne Imberty[3], Elias Fernandez[4], Lode Wyns[1], Marilynn E. Etzler[4], [1]Laboratorium voor Ultrastructuur, Vlaams Interuniversitair Instituur voor Biotechnologie,Vrije Universiteit Brussel, Paardenstraat 65, B-1640 Sint-Genesius-Rode, Belgium, [2]Université des Sciences et Technologies de Lille, Bâtiment C9, 59655, Villeneuve D'Ascq CEDEX, France, [3]CERMAV-CNRS (affiliated to the University Joseph Fourier), BP 53, F-38041 Grenoble Cedex 9, France, [4]Section of Molecular and Cellular Biology, University of California, Davis, CA 95616, USA

The tetrameric *Dolichos biflorus* seed lectin (DBL) has an interesting specificity among the legume lectins because it binds GalNAc readily while it binds Gal very weakly. In addition, DBL is an adenine/cytokinin plant hormone binding legume lectin. DBL was crystallized with the blood group A trisaccharide GalNAc(α1-3)[Fuc(α1-2)]Gal (2.8 Å resolution), the high affinity ligand GalNAc(α1-3)GalNAc (Forssman disaccharide) (2.6 Å resolution) and adenine (2.65 Å resolution). The structure of DBL in complex with adenine shows that some legume lectins possess a hydrophobic binding site which depends on their quaternary structure. DB58, a dimeric vegetative lectin from the same plant, adopts a novel quaternary structure in which this site is strictly conserved. A sandwiched α-helix mediates quaternary structure and is part of the adenine/cytokinin plant hormone binding site in both DBL and DB58.

The DBL sugar complexes illustrate that specific binding of an *N*-acetylated sugar is achieved through a give-and-take mechanism: a lack of aromatic stacking against the sugar ring is compensated by a favorable interaction of the *N*-acetyl group with the lectin. The latter interaction not only depends on the presence of a specific subsite, but also on the correct positioning of the sugar ring by the specificity loop. High affinity binding of the Forssman disaccharide is solely mediated via the formation of a small, solvent shielded hydrophobic cavity and does not involve any additional hydrogen bonds.

P12.OB.002 THE COMPLEXES OF BOTH PARTS OF THE TRIMANNOSIDE MAN A1-3(MAN A1-6)MAN A1-OME WITH CON A. J. Bouckaert, R. Loris, L. Wyns, Ultrastructure, Vrije Universiteit Brussel, Paardenstraat 65, B-1640 Sint-Genesius-Rode, Belgium.

Man a1-6Man a1-OMe and Man a1-3Man a1-OMe, the two dimannoside parts of the highly specific epitope Man a1-3(Man a1-6)Man a1-OMe of concanavalin A, were crystallized in complex with this lectin. The structures were refined to a resolution of 2.0 Å and 2.9 Å respectively. The interactions between the sugar and the lectin as we observe them in the crystal structures largely explain the thermodynamic differences in enthalpy and entropy for the binding of the two dimannosides. In both structures, the first sugar unit binds in the monosaccharide (mannose or glucose) binding site. Man a1-6Man a1-OMe binds essentially the same way as is observed in the concanavalin A-trimannoside complex (1,2). The first mannoside binds in the

monosaccharide binding site. The second mannoside makes only one extra hydrogen bond and few van der Waals contacts compared to the monosaccharide. It occupies approximately the place of the core mannoside in the Man a1-3(Man a1-6)Man a1-OMe complex but its O2 hydroxyl makes no interactions in contrast to the trimannoside complex. Man a1-6Man a1-OMe binds with an almost equal affinity as Me- a-D-Man while Man a1-3Man a1-OMe and Man a1-3(Man a1- 6)Man a1-OMe bind respectively 4 and 60 times better. Man a1-6Man a1-OMe binding is accompanied by a slightly higher enthalpy change and a compensating entropy cost than binding of the monosaccharide Me- a-D-Man, however the same affinity as for Me- a-D-Man is maintained. The quasi absence of extra protein-carbohydrate interactions of Man a1- 6Man a1-OMe compared to Me- a-D-Man suggests that desolvation and the conformational restriction of the a1-6 glycosidic linkage may be the most important contributors to these differences. The first mannoside of Man a1-3Man a1-OMe binds in the monosaccharide binding site, in contrast to what is observed for the trimannoside complex, where it binds into a subsite formed by Pro13, Thr15 and Asp16. The second mannoside of Man a1-3Man a1- OMe makes strong van der Waals contacts with the protein along the side of the binding groove with Tyr12, Tyr100 and Leu99. Its large (negative) heat capacity change, enthalpy change and entropy cost probably reflect the importance of the expulsion of solvent during binding along this subsite build up of aromatic side chains.

P12.OB.003 DUAL AFFINITY LABELING OF THE ACTIVE SITE OF HUMAN LYSOZYME WITH AN N–ACETYL LACTOSAMINE DERIVATIVE. M. Muraki and K. Harata, National Institute of Bioscience and Human–Technology, Tsukuba, Ibaraki 305–8566, Japan, and N. Sugita and K.I. Sato, Kanagawa University, Yokohama, Kanagawa 221–0802, Japan.

The 2',3'–epoxypropyl β-glycoside of N–acetyllactosamine (Gal-β1,4–GlcNAc–Epo) doubly labelled human lysozyme (HL). This presented the first observation of dual binding of ligand to lysozyme. The labelled HL was crystallised (space group $P2_12_12_1$with unit cell dimensions a=56.45A, b=62.30A, c=32.98A) and the X–ray structure was determined at 2.3 A resolution, which identified the two Gal-β1,4-GlcNAc-Epo moieties inside the catalytic cleft of HL [1].

The attachment sites were the side–chain carboxylate groups of the catalytic residues Glu35 and Asp53 in HL. The first Gal-β1,4-GlcNAc-Epo moiety located virtually the same way as observed in the HL labelled with Gal-β1,4-GlcNAc-Epo molecule [2]. The second Gal-β1,4-GlcNAcEpo moiety was recognised via the carbohydrate–carbohydrate interaction with the first Gal-β1,4-GlcNAc-Epo moiety in addition to the protein–carbohydrate interaction with the catalytic cleft of HL through a number of hydrogen bonds as well as many van der Waals contacts. The two N–acetylglucosamine residues stacked with each other, while the two rings of galactose residues approximately shared the same plane.

The results demonstrated that the HL labelled with single Gal-β1,4-GlcNAc-Epo worked as a novel N–acetyllactosamine–binding protein, and the second labelling was performed by way of the first–ligand assisted recognition of the second ligand.

P12.OB.004 STRUCTURE OF ARTOCARPIN. M. Vijayan, K.Sekar*, P. Geetha Rani, A. Surolia and J.V. Pratap, Molecular Biophysics Unit and *Bioinformatics Centre, Indian Institute of Science, Bangalore, India.

Artocarpin, a homotetrameric, 66 kD *moraceae* lectin isolated from the seeds of jackfruit (*Artocarpus Integrifolia*), is specific to mannose. Among other things, it mediates the T-cell dependent B-cell maturation. The primary structure of artocarpin shows considerable similarity to jacalin, another lectin from the same source whose structure has been solved in this laboratory [1],although jacalin is specific to galactose. Moreover the jacalin monomer is made of two chains, while artocarpin is a single polypeptide chain. Two crystal forms, both belonging to space group $P2_1$, with one and two tetramers in the asymmetric unit respectively were obtained and intensity data were collected. The structures were solved by molecular replacement calculations using the jacalin tetramer as the search model and that with one tetramer in the asymmetric unit has been refined to an R value of 19.0%. The overall fold is similar to jacalin.

The carbohydrate binding region exhibits considerable differences compared to jacalin. The N-terminal glycine of the α chain of jacalin is now part of a linker region that connects the α and β chains of the jacalin monomer. Tyr A78, which stacks against galactose in jacalin, is replaced by Thr in artocarpin. Asp A125 is conserved, albeit with a different side chain conformation,as suggested by Rosa *et al.,*[2], although this difference does not appear to be a consequence of steric hindrance with the linker peptide. Modelling of galactose into the binding site does not show any substantial difference from the hydrogen bonding pattern observed in the crystal structure of jacalin. The loss of the stacking interaction provided by Tyr A78 in jacalin, might however be significant. A complete elucidation of the geometrical basis of the carbohydrate specificity of artocarpin should await the X-ray analysis of a complex of the lectin with a mannose derivative, which is in progress.

P12.OB.005 STRUCTURAL BASIS OF CARBOHYDRATE SPECIFICITY IN HUMAN GALECTIN-10 (CHARCOT-LEYDEN CRYSTAL PROTEIN). G.J. Swaminathan and D.D.Leonidas, Dept. of Biology and Biochem., University of Bath, Bath BA2 7AY, UK, and S.J. Ackerman, Dept. of Biochem. and Molecular Biology, University of Illinois at Chicago, Chicago, Illinois 60612, USA, and K.R.Acharya, Dept. of Biology and Biochem., University of Bath, Bath BA2 7AY, UK.

The autocrystallising Charcot-Leyden crystal (CLC) protein, a small hydrophobic protein exhibiting weak lysophospholipase activity, is a major constituent of human eosinophil and basophil granules [1]. The presence of typical CLC crystals in a variety of body tissues is considered to be a signature of eosinophil-associated inflammation. However, CLC shows no sequence similarities to any known lipolytic enzymes, and its role in eosinophil and basophil function remains speculative. The crystal structure of CLC determined at 1.8Å resolution showed striking similarities in overall structural fold with that of galectins [2], possessing a carbohydrate recognition domain (CRD) with 7 of 12 conserved residues among galectins, and 6 of 8 residues known to be directly involved in sugar binding. The carbohydrate-specificity of CLC is under study in our laboratory by crystallographic studies of CLC-sugar complexes using a wide variety of sugars. Our results indicate that although CLC has similarities with galectins in overall structural fold and a partially conserved CRD, it demonstrates affinity towards mannoside sugars unlike other galectins. The results of

our structural studies will be discussed in light of the possible function for CLC in the eosinophil granule.

P12.OB.006 3D STRUCTURE OF PLANT ASPARTIC PROTEINASE, A GLYCOSYLATED NATIVE CARDOSIN A. M. A. Carrondo, C. Frazão, I. Bento, J. Costa, C. M. Soares, I.T.Q.B. Apartado 127, 2780-Oeiras, Portugal and P. Veríssimo, C. Faro, E. Pires Dept. de Bioquímica, Univ. de Coimbra, 3000-Coimbra, Portugal.

Plant aspartic proteinases (AP) have been detected, extracted and characterized from seeds, leaves and flowers of a broad variety of plant species, and are involved in specific physiological roles [1]. Most of them contain in their cDNAs an insertion coding for a polypeptide segment of about 100 residues, known as PSI (plant specific insert). Cardosins are AP from the flowers of *Cynara cardunculus* L. [2] and their milk clotting activity have been exploited in Portugal since the Roman Era in the manufacture of traditional cheeses. Preliminary crystallographic data on cardosin A was published in [3]. The refined cardosin A crystallographic structure to 1.72 Å resolution includes two glycosylated molecules, built up by two (30 and 15 kD) peptide chains, in a total of 649 amino-acids. The base of the active site cleft is made of β-strands forming the typical, two abutting φ-like structures which contain the two catalytic aspartates (Asp 32 and Asp 215), with side chains held coplanar and within hydrogen bonding distances to involving main chain and conserved side chain groups. A water molecule is bound to both aspartate carboxyls by hydrogen bonds. The glycosyl content in cardosin A is described by 19 sugar rings attached to Asn 67 and Asn 257, localised on the molecular surface in two glycosylation sites, in each of the molecules, *i.e.* one site *per* polypeptide chain. An hydrogen bond between Gln 126 (Oε1) of the parent protein and Manβ4 (O2) renders the monosaccharide oxygen sterically unaccessible to accept a xylosyl residue, transferred by xylosyltransferase, as usually the case in glycans of the plant complex type.

This crystal structure [4] suggests a possible mechanism by which cardosin A might be orientated at the cell surface so that its RGD sequence could be recognised by the receptor from pollen.

12OC APERIODIC AND INCOMMENSURATE STRUCTURES (I)

M12.OC.001 QUASICRYSTAL OR RANDOM TILING? IN SITU SYNCHROTRON MEASUREMENTS OF DECAGONAL AL-CO-NI AT HIGH TEMPERATURE. T. Haibach, A. Cervellino and W. Steurer, Laboratory of Crystallography, Swiss Federal Institute of Technology, ETH Zurich, CH-8092 Zurich, Switzerland.

Stable $Al_{70}Co_{12}Ni_{18}$ represents a commensurate superstructure [1,2] of decagonal $Al_{72.5}Co_{17.5}Ni_{10}$. Both structures exhibit sharp Bragg peaks in X-ray diffraction experiments. Whether these two structures are exactly quasiperiodic or belong to the class of random tilings [3] is still not clarified.

We performed *in situ* high temperature X-ray measurements at the synchrotron source Hasylab. At various temperatures high-resolution one- and two-dimensional peak profiles of selected reflections were collected. Two-dimensional profile scans show that there is no phase transition to twinned approximants or nanodomain structures in the investigated temperature range. The analysis of the integral intensities, however, reveals a linear dependence with temperature whose coefficient is the perpendicular space norm of the main reflections. The results give evidence that the phasonic Debye-Waller factor of the basic structure is proportional to the temperature. The high temperature phase is proposed to belong to the class of random tilings.

M12.OC.002 REFINEMENT OF QUASICRYSTAL STRUCTURES. Akiji Yamamoto, Nat. Inst. Res. Inorg. Mat., Namiki 1, Tsukuba, 305 Japan.

A nontrivial problem in quasicrystal analyses is how to describe accurate quasicrystal structures or how to introduce structural parameters. One successful attempt for this problem is the use of cluster models in higher dimensional space. This model enables us to introduce more than 50 reasonable parameters for icosahedral quasicrystals and 100 for decagonal ones, which allow us to determine the detailed positions of atoms in the cluster and their thermal and occupational parameters. The first successful result was obtained in the analysis of the icosahedral Al-Pd-Mn quasicrystal. The cluster model assumes large clusters situated at the vertices of 3-dimensional Penrose pattern with an edge length of about 20Å. The clusters include more than 100 atoms. This model has 15 positional, 7 thermal and 28 occupational parameters and gave an R_w-factor of 0.106 for 1137 independent reflections [1]. Such a large cluster was shown to exist in the 2/1 approximant [2]. Recently, a decagonal Al-Mn-Pd quasicrystal was successfully analyzed with a noncentrosymmetric space group [3]. It consists of large columnar clusters with about 20Å diameter. The cluster model used includes 207 parameters and gave R_w=0.119 for 1428 independent reflections. The success of the analyses of typical quasicrystals implies that it is possible to analyze quasicrystal structures in detail with more than 1000 reflections when high quality single domain quasicrystals are used.

M12.OC.003 THE LOW TEMPERATURE SUPER-STRUCTURE OF NaV_2O_5. J. Lüdecke, A. Jobst, S. van Smaalen, Laboratory of Crystallography, University of Bayreuth, D-95440 Bayreuth, Germany, E. Morre, C. Geibel, MPI for Solid State Chemistry, D-01187 Dresden, Germany, H.-G. Krane, Hasylab, DESY, D-22603 Hamburg, Germany.

NaV_2O_5 displays magnetic ordering at temperatures below 35 K as shown by susceptibility measurements [1]. The magnetic ground state is connected with a commensurate distortion of the lattice leading to a ($2a\times2b\times4c$) supercell. Consequently it has been assumed that the phase transition is of spin-Peierls character [2]. Here a full determination of the modulated low temperature structure will be presented. The phase transition to the superstructure leads to a loss of the inversion symmetry. The displacements of all atoms could be determined. In agreement with magnetic ordering, the major displacements occur on the V

atoms. In contrast to the spin-Peierls compound $CuGeO_3$ the distortion pattern appears to be transverse to the one dimensional magnetic chains. The data cannot be understood in terms of a pure spin-Peierls transition, but additional charge ordering has to be assumed to explain the magnetic ordering. A complete understanding of the observed structure of the ground state of NaV_2O_5 has not been achieved yet but the proposed structure is in agreement with other experimental results.

M12.OC.004 INTERPRETATION OF MODULATED AND COMPOSITE STRUCTURES. M. Dusek and V. Petricek, Institute of Physics, Acad. Sci. of the Czech Republic, Na Slovance 2, 182 21 Prague, Czech Republic**.**

Contemporary structure analysis of modulated and composite crystals involves more and more complicated structures. The necessity of visualising crystal structures, usually described in the superspace, is obvious not only for presentation and interpretation of results but also for the solution during the structure analysis. The usage of standard crystallographic programs for this purpose is usually laborious and limited.

Here we present three topics: calculation of distances, visualisation of multidimensional electron density maps and plotting of modulated and composite structures. All of them are implemented in computing system JANA98[1] as programs CONTOUR and PICTUR and tested on examples of some hexagonal perovskites, hexamethylenetetramine sebacate and quininium (R)-mandelate. The distances calculation of modulated and composite crystals is based on the general theory as summarised in [2].

The plotting program PICTUR uses three dimensional cell expansion with calculation of translation-dependent positional, occupational and temperature modulation changes and successive calculation of distances. It works automatically also for sawtooth positional modulation and set of orthogonalized harmonic waves. The program has special mode for plotting structure fragments together with t-sections by electron density map and for making "animated" plots as a function of varying t coordinate. Program CONTOUR plots sections by multidimensional electron density maps and visualises modulation functions.

M12.OC.005 AN INTERPRETATION ON THE DIFFUSE SCATTERING IN $Cd_5(PO_4)_3Br_{1-x}$. Sven Lidin, Marat Moustiakimov and Peter Henning. FOOS kemi, Arrhenius Laboratory, Stockholm University, 106 91 Stockholm, Sweden

Single crystals of cadmium phosphate bromide grown from a cadmium bromide melt exhibit highly structured diffuse scattering in addition to the Bragg scattering from the basic apatite structure. This additional scattering occurs in layers perpendicular to **c***, and takes the shape of hexagonal honeycomb nets. It shows pronounced, Bragg-like, maxima at the positions *h+1/3 k+1/3 l* and *h+2/3 k+2/3 l* where *l* is close to 0.78 **c***, and may therefore to a first approximation be treated as an incommensurate modulation with a modulation wave vector **q**=1/3 1/3 0.78. This implies that the 3D space group of bromapatite, $P6_3/m$, should be replaced by the 4D superspace group R:$P\bar{3}$:-11. The remaining, rational, part of the modulation wave vector is then $\mathbf{q}^i$ = 0 0 0.78.

This behaviour can also be studied in the corresponding vanadate bromide and iodide, but here the Bragg-like ordering is weaker, and the diffuse nature of the scattering is more pronounced.

The scattering from a single crystal specimen was measure on a STOE imaging plate system, and the data obtained was refinable down to an R-value of 5% for main reflections and 12% for satellites using a saw-toot type displacive modulation for Br. The halogenide is simply to large for the cavity in which it resides, and spills over into the regime that should be occupied by the next Br which is displaced away from its ideal position, pushing the next Br even further away. This displacement accumulates until the accompanying strain becomes to great and a Br vacancy results.

The average structure agrees well with earlier reports, but the local Br ordering is intriguing; while the ordering in the individual Br channels is easy to understand simply from a steric point of view, the additional rhombohedral ordering between the channels is unexpected. The atoms surrounding the Br channels seem unaffected by the modulation, and the ordering may be attributed to an electrostatic effect. The diffuse streaks that join up the Bragg-like spots that are treated in this analysis may be attributed to imperfections in this electrostatic ordering. There is no reason to believe that the intra channel ordering is altered, since all diffuse scattering resides in the same plane perpendicular to **c***, but the rhombohedral ordering is weak, and several other ordering modes will yield electrostatically neutral solutions, as in monoclinic ClAp and OHAp.

P12.OC.001 STUDIES ON VARIATION OF CLUSTER DISTRIBUTION IN INCOMMENSURATE Co-ÅKERMANITE BY A SIMULATION. M. Ohmasa, K. Kusaka, K. Hagiya and N. Haga, Department of Life Science, Himeji Institute of Technology, Hyogo 678-1297, Japan, and K. Iishi, Department of Mineralogical Science and Geology, Yamaguchi University, Yamaguchi 753-8512, Japan.

The variation of the wave length or the component *q* of the modulation wave due to temperature change has been described in studies on åkermanite since Seifert et al. found the phenomena [1]. To know a change of the modulated structure with such variation of *q* or temperature, we usually need new data collection and refinement processes, although the new structure is essentially similar to the old one. A new simulation method was thus developed to get structure information without such processes and to look successive changes of the structure caused by the change of *q* or temperature. The displacement u_{ij}^T (i=1, 2, 3 corresponding to *x*, *y*, *z*) of jth atom at temperature *T* can be approximately expressed as

$$u_{ij}^T = \sqrt{I^T / I^{R.T.}} \sum_k A_{ijk}^{R.T.} trig(s,t),$$

where $I^T / I^{R.T.}$ is the ratio of intensity at *T* to intensity at *R.T.* (room temperature), $A_{ijk}^{R.T.}$ *k*th amplitude of the modulation wave and $trig(s,t)$ a trigonometric term with phases *s* and *t* at *T*. The atomic positions at *T* can be then calculated with the above formula.

The method was applied to study variation of the incommensurate structure of Co-åkermanite. The structure is characterized by clusters formed with four coordination polyhedra of the six-coordinated Ca together with a Co-tetrahedron and by the octagonal arrangement (an octagon) of the clusters [2]. The simulation with different *q*'s displayed that distribution of the octagons changes with q-values sensitively and ordered distributions of the octagons are formed for rational *q*'s (*e.g.* q = 2/7). The number of the octagons in a unit area also changes with *q*'s. The histogram of the numbers of the octagons versus *q*'s indicate a maximum at q = 0.294.

12OD STRUCTURE SOLUTION FROM POWDER DATA – INORGANIC MATERIALS

M12.OD.001 OVERVIEW OF COMPUTER PROGRAMS FOR STRUCTURE SOLUTION FROM POWDER DATA AND THEIR APPLICATION TO INORGANIC MATERIALS. Xavier Solans. Departament de Crista·lografia, Universitat de Barcelona. Spain.

In the issue of the November 1998 of *Scientific Computing World*, David Bradley (pages 16-17) states that standard methods for crystal structure determination from powder diffraction data are error prone and often produce incorrect structural predictions and he concludes his manuscript indicating that the crystal structure determination from powder data is not at present routine.

All computer programs for crystal structure determination have well-defined methodology and strategy. The successful use of a computer program depends on the crystal structure of the sample, the pattern measured and the user's strategy, which must agree with those defined in the computer program.

An overview of the computer programs used for structure solution from powder data will be carried out, where the experimental conditions of intensity collection will be emphasised.

M12.OD.002 SOLUTION OF FRAMEWORK CRYSTAL STRUCTURES FROM POWDER DIFFRACTION DATA BY MONTE CARLO METHODS. Michael W. Deem and Marco Falcioni, Chemical Engineering Department University of California Los Angeles, CA 90095-1592 USA.

We describe a new, biased Monte Carlo scheme to determine the crystal structures of zeolites from powder diffraction data [1]. We test the method on all publicly known zeolite materials, with success in all cases. We show that the method of parallel tempering is a powerful supplement to the biased Monte Carlo.

[1] Marco Falcioni and Michael W. Deem, ``A Biased Monte Carlo Scheme for Zeolite Structure Solution," J. Chem. Phys. 110 (1999) 1754-1766.

M12.OD.003 ZEOLITE STRUCTURE DETERMINATION FROM POWDER DATA USING THE "FOCUS" METHOD. R.W. Grosse-Kunstleve [1], L.B. McCusker & Ch. Baerlocher [2], [1] Yale University, New Haven, Connecticut 06520-8114, U.S.A., [2] Laboratory of Crystallography, ETH Zentrum, CH-8092 Zurich, Switzerland.

The technologically and industrially important zeolites are often synthesized and used in polycrystalline form. However, the determination of a zeolite structure from powder diffraction data is generally a non-trivial matter, because these materials tend to crystallize with relatively high symmetries and large unit cells. This automatically leads to a high degree of reflection overlap. Furthermore, the only structural information known *a priori* for zeolites are typical bond lengths and bond angles, and the fact that they can be described as having 3-dimensional, 4-connected framework structures.

To address the problem posed by zeolite structures, the program FOCUS, which integrates both the crystal chemical information and powder diffraction data into the structure determination process, was developed. FOCUS combines automatic Fourier recycling with a topology search specific to zeolites. Experience shows that this approach of using chemical and geometrical knowledge can compensate for some of the information that is lost as a result of the overlap problem.

Four examples of the application of FOCUS serve to illustrate its potential and its limitations. The solutions of the structures of two aluminophosphate molecular sieves, YUL-89 (AWO topology) and YUL-90 (ZON topology), demonstrate routine applications of the procedure. The high silica zeolite ZSM-5 (MFI topology), which has 12 Si-atoms (38 framework atoms) in the asymmetric unit, and the gallophosphate Cloverite (-CLO topology), whose framework is not fully 4-connected, provide examples of extremly difficult cases, which challenge the limits of the FOCUS algorithm.

M12.OD.004 STRUCTURE SOLUTION FROM POWDER USING PARETO-OPTIMIZATION OF PATTERN DIFFERENCE AND POTENTIAL ENERGY. H. Putz, German National Research Center for Information Technology (GMD), Scientific Computation and Algorithms Institute (SCAI), Schloss Birlinghoven, D-53754 Sankt Augustin, Germany and J.C. Schön, Inst. f. Anorg. Chemie d. Uni Bonn, Gerhard-Domagk-Str. 1, D-53121 Bonn, Germany.

Most of the "classical" methods for "ab initio" solution of crystal structures from powder diffraction diagrams depend on the knowledge of the intensity for each reflection I(hkl), in analogy to single crystal methods. Unfortunately, in many cases a severe overlap of different reflections makes it difficult to determine these values with sufficient accuracy [1, 2].

For this reason, the so called "direct space methods" propose a structural model independent of the powder diffraction diagram. Beginning with some arbitrarily chosen atomic starting configuration, the difference between the calculated and the measured diffraction pattern (costfunction) is minimized through repeated change of the atomic arrangement.

In practice for most crystalline solids this prescription results in the system quickly getting trapped in some minimum that does not correspond to a physically reasonable atomic arrangement. The reason for this lies in the landscape of the costfunction which includes numerous deep local minima.

Our concept implies a combined optimization of the difference between the calculated and the measured diffraction pattern and of the potential energy of the system ("Pareto-optimization"). Merging both hypersurfaces blurs the minima that belong to only one of the two surfaces, and strengthens those which belong to both of them. Thus, conventional global optimization methods (e.g. Simulated Annealing) can be used. This concept was tested successfully on a large variety of ionic, metallic and molecular compounds.

[1] K.D.M. Harris, M. Tremayne, Chem. Mater. **8**, 2554 (1996)
[2] D. Louër, Acta Cryst. A**54**, 922 (1998)

M12.OD.005 USING TEXTURE TO FACILITATE STRUCTURE SOLUTION. T. Wessels, C. Baerlocher and L.B. McCusker, Lab. f. Kristallographie, ETH-Zentrum,CH-8092 Zürich, Switzerland

The limiting factor for *ab initio* crystal structure solution from powder data arises from the collapse of three-dimensional single-crystal data onto the single dimension of a powder diffraction pattern, and the resulting peak overlap in 2-theta.

This problem can be reduced significantly if textured rather than random powder samples are used. A sample with pronounced preferred orientation can be regarded as being something between a completely randomly oriented powder and a single crystal with a corresponding increase in the information contained in the diffraction data. Using a textured sample and exploiting the high intensity and parallel nature of synchrotron radiation, a single-crystal-like set of intensities can be extracted,

and crystal structures as complex as those routinely solved by single-crystal methods can be determined.

To test the viability of the method, a measurement on a textured sample of ZSM-5 was performed. The extracted pseudo single crystal data set was input to a direct methods program, and all 12 of the Si and 19 of the 26 O positions were found in the top 40 peaks of the E-map. In a second test, measurements on a textured sample of the aluminophosphate Mu-9 with unknown crystal structure were performed. Intensity extraction followed by the application of direct methods revealed a rather unusual aluminophosphate structure (framework formula $Al_{66}P_{72}O_{288}$ per unit cell). All P atoms are tetrahedrally coordinated and 4-connected (i.e. form oxygen bridges to four Al atoms), whereas the Al atoms are 4- and 6-connected to P atoms of the framework. Finally, the method was applied to a sample of the as synthesized form of UTD-1, prepared using a modification of the published synthesis procedure. The structure was solved in the space group $P2_1/c$ (for Rietveld refinement the symmetry had to be lowered to Pc). In the initial E-map all 16 Si atoms and 17 of the bridging oxygens could be found. Subsequent electron density maps allowed the remaining 15 oxygens and the Co to be located.

P12.OD.002 STRUCTURE DETERMINATION OF GUEST-HOST SYSTEMS USING POWDER REFINEMENTS AND COMPUTER SIMULATIONS. G.Nalini, S.Yashonath and T.N.Guru Row, Solid State and Structural Chemistry Unit, Indian Institute of Science, Bangalore-560012.

The use of Rietveld technique for the determination of structures where the starting models are available is extensively used with accurate powder diffraction data. In guest-host systems, the model of the host molecule is generally available based on earlier crystallographic studies. The guest molecule is constrained within the matrix generated by the host with weak interactions which render the guest molecule to be in more than one configuration at a given temperature. The basic idea is to locate the guest molecule using molecular dynamic simulations at the given temperature and identify the resulting electron density distribution on a difference Fourier map generated based on the powder diffraction data. Examples involving Zeolite NaY as the host and rare gases like Argon and Xenon as guests provide valuable insight into these features. The data sets have been generated on a STOE-STADI/P diffractometer using an Oxford Cryo- system to enable data collection at required temperatures. The simulations have been performed using a locally developed CBMC methodology.

P12.OD.003 CRYSTALLOGRAPHIC THERMAL PARAMETERS FROM POWDER NEUTRON DATA: A STUDY OF ISOTOPICALLY SUBSTITUTED CuO. Paul F. Henry, Mark T. Weller, Chemistry Department, Southampton University, Highfield, Southampton, Hampshire, SO17 1BJ, UK, Chick C. Wilson, ISIS Facility, CLRC Rutherford Appleton Laboratory, Chilton, Didcot, Oxon., OX11 0QX, UK.

The evolution of the anisotropic thermal parameters in copper (II) oxide with temperature has been studied in detail both theoretically and experimentally using x-rays. However, extraction of similar quality information from powder diffraction data has proved problematical. In this work we have employed powder neutron diffraction, using isotopically substituted CuO, to extract detailed crystallographic information from powdered samples. The contrast in neutron scattering lengths between ^{63}Cu (6.43 fm) and ^{65}Cu (10.61 fm) allows collection of multiple data sets which can then be refined using a single crystallographic model to obtain extra structural information.

A major problem with structure refinements using powder diffraction data is the estimation of background and thus extraction of accurate peak intensities. For time-of-flight neutron sources and instruments, such as POLARIS, this is a particular problem due to relatively high backgrounds, non-linear backgrounds and, at short time-of-flights/low d-spacing, total overlap of peak profiles completely eliminating true background values. This generally produces strong correlation between refined thermal parameters and the choice of background. One way of overcoming this problem is to study chemically identical materials (thus with identical thermal parameters and producing identical backgrounds) but with different isotopes, yielding different intensity reflections. Simultaneous refinement of these data sets allows a much more accurate deconvolution of background (constant) and peak intensity (dependent on isotope) and thus thermal parameters. Comparison of the anisotropic thermal parameters with those from single crystal x-ray studies and theoretical measurements are presented.

P12.OD.005 DO PARAELECTRIC CRYSTALS NECESSARILY HAVE A NON-POLAR SYMMETRY GROUP? Xavier Solans, Jorge Mata, M.Teresa Calvet and Mercè Font-Bardia, Departament de Cristal-lografia, Universitat de Barcelona. Spain.

The crystal structures of $LiNH_4SO_4$ at 298, 423, 483, 523 and 571 K have been solved. The three ferroelectric structures (at 298, 423 and 483 K) and the two paraelectric structures at 523 and 571 K show the same group $P2_1nb$, which is polar. According to Neumann's principle the value of a physical parameter should remain invariant if it is subjected to a symmetry operation of its point group. From this, a ferroelectric crystal, which shows spontaneous polarization, requires a polar group for this crystal-type. All crystals with a non-polar space group are paraelectric; but does this imply that all paraelectric crystal must have a non-polar point group?. The experimental results presented here, together with the computation of the spontaneous polarization in each solved structure, using an ionic model, which vanishes at 523 and 571K, show that the non-polar space-group, although it is sufficient condition, is not a necessary condition for paraelectric crystals.

12OE X-RAY OPTICS (sponsored by Microsource, a division of Bede)

M12.OE.001 HIGH ENERGY X-RAY MICROOPTICS FOR DIFFRACTION, IMAGING AND SPECTROSCOPY A. Snigirev, ESRF, BP 220, 38043 Grenoble, France

The last several years have seen a tremendous breakthrough in the development of microoptics for high energy X-rays. Micro- and submicro-meter beams can be generated with Bragg-Fresnel Optics [1], Fresnel Zone Plates and Compound Refractive Lenses [2] in the energy range from 5 to 100 keV. Use of this optics along with high brilliance and spatial coherence of the X-ray beam provided by the third generation synchrotron radiation sources such as ESRF makes possible to realize high energy X-ray microscopy techniques. X-ray micro- diffraction [3], fluorescence [4] and imaging [5,6] are very powerful techniques for the nondestructive studies in material science and biology. The micro- fluorescence, imaging and diffraction beamline (micro-FID) has been successfully commissioned at the ESRF and various microscopy applications to study samples from biology, geology and material science have been performed.

M12.OE.002 PHASE-CONTRAST IMAGING AND PHASE RETRIEVAL USING X-RAYS. S.W. Wilkins[a], D. Gao[a], T.E. Gureyev[b], A. Pogany[a], and A.W. Stevenson[a] , [a]CSIRO, Manufacturing Science & Technology, PB33 Clayton Sth MDC, Clayton, Vic 3169 Australia [b] CSIRO, Forestry & Forest Products, PB10 Clayton Sth MDC, Clayton, Vic 3169 Australia.

Conventional X-ray radiography which has prevailed for the past 100 years relies on differential absorption in a sample to produce contrast. Recently a variety of methods for producing X-ray contrast via refractive (i.e. phase) effects have been proposed, see [1] and [2] and references therein. Our emphasis is on *in-line imaging* using high spatial coherence sources both in the laboratory [3] and at SR facilities [4]. Discussion of some of the key theoretical aspects of this work will be presented, including:i) non-interferometric methods for phase/amplitude retrieval [5-7], ii) the effects of *partial coherence* [6], and iii) factors affecting *contrast and resolution* [6]. Experimental results will also be presented demonstrating the very significant levels of new information that can be gained by these techniques, pointing to exciting new imaging applications for X-rays in science, medicine, and industry.

M12.OE.003 X-RAY WAVEGUIDES: A NOVEL OPTICS FOR NANO-DIFFRACTION. S. Lagomarsino and A. Cedola, Istituto Elettronica Stato Solido (IESS) - CNR, 00156 Roma, Italy and S. Di Fonzo and W. Jark, Sincrotrone Trieste - 34012 Basovizza - Trieste, Italy and C. Giannini and L. De Caro, CNRSM, 72100 Brindisi, Italy

Sub-micrometric X-ray beams can be produced by waveguides for medium-high energy x-rays (13-30 KeV). The waveguides consist in a multilayer structure constituted of: an ultra-flat substrate; a metal layer few tens of nm thick; a layer of low-density material (for ex. C) having a thickness of the order of 100 nm; a thin (few nm) metal film. A collimated x-ray beam impinging at grazing incidence on such a structure is subjected, at given incidence angles, to a resonance effect which can enhance the e.m. intensity inside the C film of tens or hundreds times with respect to the incident intensity[1]. When the resonance condition is met, the beam can travel along the film and come out at its end. The beam is highly coherent and in the first resonance has a divergence of about 1 mrad. In a vertical section it can be well approximated to a Gaussian beam originated by a point source[2]. With this beam we obtained phase contrast images with record resolution of 140 nm.[3] Here we will concentrate on the diffraction application. We demonstrate the possibility to measure Reciprocal Space Maps with a spatial resolution down to 100 nm or less. We applied this technique to the evaluation of local strain generated on the Si substrate by the edges of oxide stripes of different widths. A discussion on the potentialities of this novel technique will be given.

M12.OE.004 MULTILAYER MIRRORS. James H. Underwood, Center for X-ray Optics, Lawrence Berkeley National Laboratory, University of California, Berkeley, CA USA 94720

Using modern vacuum deposition technology, structures consisting of alternating layers of high- and low-Z materials, with individual layers having thicknesses of the order of nm, can be fabricated on suitable substrates. These structures act as multilayer interference reflectors for x-rays, soft x-rays and extreme ultraviolet (EUV) light. Their high reflectivity and moderate energy bandwidth ($10 < E/\Delta E < 100$) make them a valuable addition to the range of optical components available to construct instrumentation for x-rays with photon energies from a few keV to tens of keV. They are particularly useful in synchrotron radiation beamlines as mirrors and dispersive elements. They may be used to for produce focal spots with micrometer scale sizes, for applications such as fluorescent microprobing, microdiffraction and microcrystallography. Multilayer reflectors also have a wide range of applications at lower photon energies, in particular in the EUV region, where normal incidence multilayer reflectors allow the construction of space telescopes and optics for EUV lithography. This paper outlines the principles of the design of multilayer reflectors, in particular the choice of materials and the limitations imposed on performance by substrate and layer roughness. A representative variety of applications is discussed.

M12.OE.005 TUNABLE X-RAY POLARIZATION FILTER WITH PERFECT CRYSTALS. Y. Amemiya and Y. Hasegawa, Engineering Research Institute, University of Tokyo, Yayoi, Bunkyo, Tokyo 113, Japan, Y. Ueji, The Graduate University for Advanced Studies, Oho, Tsukuba, Ibaraki 305, Japan, K. Okitsu, National Research Laboratory of Metrology, Umezono, Tsukuba, Ibaraki 305, Japan, J. M. Ablett and D. P. Siddons, NSLS, Brookhaven National Laboratory, Upton, NY 11973, USA.

Conventionally, x-ray linear polarizers have been based on near-45 degree Bragg-case reflections from highly perfect crystals. Typically, they have been realized as multiple-reflection channel-cut devices. Even though such instruments perform well, they suffer from the disadvantage that the polarized beam is non-stationary as the energy is scanned.

The possibility of a transmission-type x-ray linear polarizer is investigated using a thin Bragg reflector as a polarizing filter. In this device, the transmitted beam (rather than the Bragg-reflected beam) is the useful output of the device. Consequently, the position and the direction of the transmitted beam are unchanged as the energy is changed, or even when the polarization direction to be filtered out is changed. Theoretical considerations as well as preliminary transmissivity measurements are presented. We examine the cases in which perfect crystals of silicon and diamond are used. A polarization ratio, defined as IH/IV, higher than 105 was observed in experiments to measure the performance characteristics of the proposed x-ray polarizing

reflector. The transmission-type x-ray linear polarizer is well suited for spectroscopic measurements with polarized x-rays. Future applicaitons of this polarization filter are presented.

M12.OE.006 X-RAY DIFFRACTION IN FINITE PERFECT CRYSTALS. G. Thorkildsen, Department of Mathematics and Natural Science, Stavanger College, Ullandhaug, 4004 Stavanger, Norway.

The boundary-value Green function technique has been used along with the Takagi-Taupin equations [1] to investigate diffraction phenomena in finite perfect crystals subject to an incoming plane wave. This includes extinction, absorption and rocking curve calculations [2]. Starting from Maxwells equations in a periodic dielectric medium, the differences and similarities between the present approach and the fundamental theory of dynamical scattering [3] are discussed. The geometrical region structures associated with point sources [4], the surface integrations necessary to calculate diffracted power and the concept of extended volumes [5] are explored. The displacement fields are handled either by series expansions or in the case of straight line boundaries by analytical functions provided by Uragami [6]. Anomalous scattering are included using a complex expansion parameter. Scattering planes with circular, rectangular and triangular shapes are studied. Examples of numerical results are related to silicon and germanium.

P12.OE.001 THE STANDING WAVE FORMED BY GRAZING-INCIDENCE X-RAYS IN A MULTILAYER WITH PLANES NORMAL TO SURFACE. P.A. Bezirganyan (Jr.), Dep. of Computer Science, State Engineering University of Armenia, #6, Korjune St., Yerevan 375009, Armenia, and A.P. Bezirganyan and S.E.Bezirganyan, Dep. of Physics, Yerevan State University, #1, A. Manoogian St., Yerevan 375025, Armenia, and H.A. Bezirganyan (Jr.), Dep. of Informatics and Applied Mathematics, Yerevan State University, #1, A.Manoogian St., Yerevan 375025, Armenia.

X-ray standing waves (XSW) in multilayers have been observed (see the pioneer papers [1-3]) by fluorescence measurements similar to those using natural crystals. In the grazing angle incidence x-ray dif-fraction (GID) geometry the XSW technique uses the dynamical x-ray standing wave fields formed very close to sample entrance surface by the lattice planes perpendicular or nearly perpendicular to this surface. Above the sample surface the entire wave field intensity is periodical and is modulated along this surface (e.g. see [4]).

We consider X-ray GID by a periodical multilayer with layers' interface planes normal to vacuum-multilayer entrance surface, and assume that two types of amorphous layers have enough optical contrast to give a strong diffraction. The XSW technique in the GID case makes it possible to study atomic arrangement (correlation) and interfaces of multilayers very close to entrance surface. The mathematical model corresponding to the investigated amorphous multilayer is constructed. The description of the standing wave formation is based on the method of construction of eigenvalues and eigenfunctions for this model.

P12.OE.002 OPTICAL COMPONENTS FOR POLARIZATION ANALYSIS OF SOFT X-RAY RADIATION. H. Grimmer, M. Horisberger, S. Tixier, O. Zaharko, Paul Scherrer Institute, CH-5232 Villigen PSI, Switzerland, H.-Ch. Mertins and F. Schäfers, BESSY, D-14195 Berlin, Germany.

An instrument for measuring polarization typically consists of a phase shifter and a linear polarizer. Up to 600 eV, periodic structures can be used consisting of alternating layers of two materials, one of which has an absorption edge in the photon energy region of interest [1]. The phase shift of the transmitted beam and the intensity of the reflected beam show maxima at energies just below the edge. By means of DC magnetron sputtering, phase shifters have been deposited on 100 nm thick Si_3N_4 films and linear polarizers on Si wafers. The latter were designed to work at the Brewster angle, where only s-polarized radiation is reflected. The corresponding multilayer period decreases from 8.5 nm at 100 eV to 1.4 nm at 600 eV. A reflectance of 6.8% was obtained at 512 eV for 150(V/Ni). It was shown that an Al coating reduces the oxidation of Ti/Ni multilayers.

In order to extend polarization measurements into the 1 keV region, the use of magnetic effects like magnetic circular dichroism (MCD) is being explored. This effect has been measured in 100(Fe/C) transmission multilayers close to the Fe L edge (700-750 eV). It is expected to be largest if the magnetic moments are aligned ferromagnetically and parallel or antiparallel to the beam direction, i.e. perpendicular to the layer surface. This can be realized at room temperature in periodic multilayers with 1 nm thick FeCoV layers separated by nonmagnetic layers, as shown for FeCoV/Ce by Moessbauer spectroscopy [2]. Presently, thin films of transition metal/rare earth metal alloys are being produced and investigated, in which perpendicular spin orientation at room temperature is also expected.

P12.OE.003 RAY-TRACING STUDY OF A PARALLEL-BEAM TWO-AXIS DIFFRACTOMETR FOR POWDER AND THIN-FILM DIFFRACTION. H. Toraya, H. Hibino and T. Ohnish, Ceramics Research Laboratory, Nagoya Institute of Technology, Tajimi 507-0071, Japan

A two-axis diffractometer was built for versatile uses in powder and thin-film diffraction in x-ray laboratory. Its design is based on a parallel-beam optics using flat-specimen reflection geometry and capillary-specimen transmission geometry. The diffractometer consists of two rotary tables (Huber 410 and 420) for the θ and 2θ axes and an encoder (Heidenhein, ROD 800) for reading the 2θ angle. Optical elements on the incident beam side were a parabolic multi-layer mirror, channel-cut crystal monochromators and slit systems. Horizontal parallel-slits or a flat analyzer crystal can be equipped on a detector arm together with a scintillation counter with a maximum count rate of 3M cps (Rigaku, SC300). These elements can be selectively combined in order to fit with experimental purposes, requiring narrow and strictly monochromatic beam or less parallel beam but with more flux. Ray-tracing was first conducted for analyzing the performance of each optical component. Its results were further

examined by comparing them with theoretical models, when they are available, and observed profiles. Results of the present study provide useful information for simulating instrumental alignment, interpreting the shapes of observed diffraction profiles, evaluating the precision of the diffractometer, and optimizing the optics.

P12.OE.004 HIGH ENERGY X-RAY MICROSCOPY WITH COMPOUND REFRACTIVE LENSES. I. Snigireva, M. Drakopoulos, A. Snigirev [1], B. Lengeler, C. Schroer, M. Richwin, J. Tummler, B. Benner [2], [1] ESRF, B.P. 220, 38043 Grenoble, France, [2] Physicalisches Institut, RTWH Aachen, 52062 Aachen, Germany

Recently compound refractive lenses made from low-Z materials have been proposed and already applied for focusing high energy X-rays [1-3]. In the present paper, we describe refractive lenses with a parabolic profile and rotational symmetry around the optical axis. They are genuine imaging devices, similar to glass lenses for visible light. The lenses focus in two directions. Due to their parabolic shape they show practically no spherical aberration. They can withstand the full radiation ("white beam") of an ESRF undulator source and might therefore be suited to be used together with future free electron laser sources.

Based on these lenses a high energy X-ray microscope for microdiffraction, microimaging and microfluorescence was proposed and tested at the ESRF ID22 beamline. A focal spot size in the order of micrometer was achieved in energy range from 12 keV to 40 keV. First applications for stress analysis in deformed steels and microspectroscopy (microEXAFS and microXANES) were realized and results will be presented in the paper. In the imaging mode it was demonstrated that an area 300 mm in diameter with resolution of about 0.3 microns can be imaged with 15 - 30 keV X-rays [4]. Implementation of refractive lenses with parabolic profile opens up an interesting perspective for high-resolution diffraction and imaging techniques.

P12.OE.005 A COMPARISON OF OPTICS SYSTEMS FOR MACROMOLECULAR CRYSTALLOGRAPHY, Joseph D. Ferrara, Cheng Yang, Adam Courville, Molecular Structure Corporation, The Woodlands, TX, 77380, USA.

We have done a complete and detailed evaluation of different multilayer optics systems (Osmic Cross-coupled MaxFlux Optics and Osmic Confocal MaxFlux Optics) as compared to MSC/Yale Total Reflection Mirrors. We have studied the usable flux, spectral purity, divergence, beam profile and data quality. The most striking results have been obtained using the Osmic #4 and Osmic #7 Confocal MaxFlux Optics, which were designed for 0.1 mm and 0.2 mm focal spots, respectively, in conjunction with a 0.3 mm focal spot. These optics configurations provide a 5.8-fold increase in flux and an 8.2-fold increase in flux through a 0.2 mm diameter area as compared to the MSC/Yale Mirrors. The balance of flux and divergence in the context of the single crystal x-ray diffraction experiment will be discussed in light of these results.

P12.OE.006 EVALUATION OF PARALLEL BEAM OPTICS FOR POWDER DIFFRACTOMETERS. S.T. Misture, New York State College of Ceramics at Alfred University, Alfred, NY 14802, USA

The use of multilayer and capillary optics on powder diffractometers for powder diffraction, thin film diffraction, and reflectivity will be presented. Evaluations were based on instrumental resolution, accuracy of lattice parameters, peak-to-background ratios, absolute intensities, and Rietveld results. Advantages and disadvantages of various instrumental configurations will be discussed.

Several powder specimens with a broad range of absorption coefficients were measured with internal standards, as well as several thin films and commercial thin film coatings.

Using an incident-beam graded multilayer optic for parallel beam measurements increased the absolute intensities by 3 to 6 times and increased the peak-to-background ratios by 2 to 6 times, compared to 'parallel' beam measurements using Soller collimators. In addition, the instrumental resolution and x-ray profile shape is improved significantly when the optic is used, because of the parallel nature of the incident beam.

Adding a second multilayer optic to the receiving side improves the resolution and peak-to-background further, and provides ample collimation to perform 'parallel-beam' x-ray reflectivity. Reflectivity data indicate that order-of-magnitude improvements in dynamic range may be obtained with resolution similar to that possible with parafocusing instruments.

P12.OE.007 TECHNIQUES AND LABORATORY APPLICATIONS FOR FOCUSED BEAM X-RAY DIFFRACTION. N. Loxley, D.K. Bowen, G. Fraser, M. Taylor and J. Wall, Bede Scientific Instruments Ltd, Durham, UK and L. Pina, A. Inneman, R. Hudec, Reflex sro, Prague CZ

The production and use of "microfocused" X-ray beams for materials diffraction and fluorescence was initiated in synchrotron radiation sources in the early 1980s. Recently, focused beams with high intensities have been achieved in the laboratory. The technology of these beams will be reviewed. Synchrotron radiation sources have clear advantages when sub-micron beams are required but in the range from approximately 5 μm to 1 mm, microfocus X-ray sources are highly effective. It is essential to tailor the size, divergence and intensity of these "minibeams" to the measurement, and we shall review the range of applications in relation to the available source/optics combinations. Two applications resulting from our recent X-ray optics research are discussed in more detail. The first is the in-process evaluation of semiconductor wafers by diffraction from an area no larger than a single die, typically 0.5 × 0.5 mm. This extends the application of on-line XRD in the semiconductor fabrication industry from the examination of whole wafers or "witness" samples to a much later stage in the process. The "monitor die" is masked off from the etching processes, but is exposed to all the deposition processes (epitaxial or thin film). Hence it can be used to monitor parameters such as composition and thickness of the layers even at advanced stages of the process, at a loss of only 10^{-5} of the potential yield.

The second is the identification of "library" compounds generated in the relatively new field of combinatorial chemistry. This method mimics the methods of the human immune system for selecting effective antibodies from a library of some 10^{12} antibodies. Combinatorial chemistry has been used for over a decade in drug generation and organic chemistry synthesis and is now moving into the field of materials science. In this application, hundreds or thousands of compounds are synthesized in parallel on a wafer. This is effected by deposition of combinations of thin films of source materials through a set of masks so that each cell (also typically 0.5 mm square) contains a different combination. The wafers are then reacted to form the compounds, and tested for

the desired properties. The technique has so far been very successful in identifying new magnetic materials with high GMR, high-temperature superconductors and luminescent materials. However, with previous X-ray technology, bulk samples had to be grown separately to characterize the structures. This is a slow process and, moreover, important structural characteristics of the film might be lost. The ability to take rapid, high-quality XRD data from sub-mm areas and analyze them with a search/match program that can be configured for the combinatorial problem, such as the Bede ZDS program, will provide higher and more accurate throughput in this important field.

12OF GIANT MAGNETO RESISTANCE MATERIALS

M12.OF.001 CHARGE ORDERING IN MANGANITES: IS THE Mn(III)-Mn(IV) PICTURE APPROPRIATE?. Juan Rodríguez-Carvajal, Laboratoire Léon Brillouin (CEA-CNRS), CEA/Saclay, 91191 Gif sur Yvette Cedex, FRANCE.

Charge ordering (CO) in manganites, of composition close to that of the CMR materials, is supposed to be the consequence of a spatially periodic charge localisation giving rise to well defined Mn(III) and Mn(IV) ionic species. The basic driving force is the Coulomb repulsion between electrons eventually associated with electron-lattice couplings as the Jahn-Teller effect. We discuss the results obtained from neutron diffraction experiments demonstrating that the Mn(III)-Mn(IV) picture *is not appropriate* to describe CO in Mn-perovskites. We shall compare the Mn-O distances, polyhedra distortions and valence-bond calculations on the low temperature crystal structure of the spinel $LiMn_2O_4$ [1] with those obtained for perovskites. The comparison shows that the ionic picture is well supported in the case of $LiMn_2O_4$ but not in perovskites as $R_{1/2}D_{1/2}MnO_3$ (R=La, Pr; D=Sr, Ca). The average Mn-O distances for the different crystallographic Mn-sites in $LiMn_2O_4$ are distributed in two groups consistent with the presence of Mn(III) (d=2.01 Å) and Mn(IV) (d=1.91 Å) species. In Mn-perovskites there is no evidence of such a strong difference between different Mn-sites in the published data. Recent results obtained from single crystal neutron diffraction experiments on Mn-perovskites do not provide any crystallographic evidence of well defined Mn(III)-Mn(IV) ordering. The best simple description of the CO phenomenon in perovskites should be constructed in terms of fractional orbital occupation on both Mn d-orbitals and oxygen p-orbitals.

M12.OF.002 THE CHARGE ORDERING AND MAGNETIC TRANSITIONS IN Mn^{3+}/Mn^{4+} PEROVSKITES, Z. Jirak, Institute of Physics, Prague, Czech Republic.

Recent data on the low-temperature structures and antiferromagnetic arrangements in the $Ln_{1-x}A_xMnO_3$ perovskites give new insight into the nature of charge and/or orbital ordered states and their temperature evolution. It appears that manganites in the compositional region of so-called T' (pseudotetragonally elongated) structure (0.85>x>0.75) and some compounds of the $I4_1/mcm$ parent symmetry in the T (pseudotetragonally compressed) region (0.75≥x>0.3) show an orbital ordering (polarization) with no charge order. In that case the e_g electrons are homogeneously distributed over all manganese sites. They occupy orbitals which are aligned into rows or planes and the magnetic structures are of the C and A type, respectively. On the other hand, the phases of the Pnma or Imma parent symmetry in the T region exhibit the concomitant charge and orbital ordering. To our knowledge, it occurs exclusively for ideal Mn^{3+}/Mn^{4+} ratios of 1:1, 1:2 and 1:3 (x=0.5, 0.67 and 0.75). The magnetic structures are of the CE type or analogous. A departure from the ideal Mn^{3+}/Mn^{4+} ratios results in an electronic phase separation and a phase with delocalized e_g electrons may be formed as found both for x<0.5 and x>0.5 . This second phase is distinguished by the metrics of the perovskite lattice which is rather pseudocubic and by the ferromagnetic coupling between the (antiferromagnetic) CE-like planes. It should be noted to the above mentioned charge ordered structures that, even if the valence distribution is regular, there is often certain orbital disorder on the Mn^{3+} sites known as discommensurations. The array of these discommensurations changes with decreasing temperature, supposedly by a dislocation process, and the structure tends to an ideal (commensurate) order.

M12.OF.003 EFFECT OF OXYGEN ISOTOPE SUBSTITUTION ON MAGNETIC STRUCTURE OF $(LA0.25PR0.75)0.7CA0.3MNO3$ V. Yu. Pomjakushin, A. M. Balagurov, D. V. Sheptyakov [1], P. Fischer [2], N. A. Babushkina [3]. [1] Joint Institute for Nuclear Research, 141980, Dubna, Moscow region, Russia, [2] Paul Scherrer Institute (PSI), CH-5232 Villigen PSI, Switzerland, [3] RSC ``Kurchatov Institute", Kurchatov sq.1, 123182, Moscow, Russia

The oxygen isotope effect on the magnetic structure and charge ordering in $(La_{0.25}Pr_{0.75})_{0.7}Ca_{0.3}MnO_3$ was studied by neutron powder diffraction. At first it was found that two investigated samples, one of those contained the natural mixture of isotopes (99.7% ^{16}O, metallic at T<=100K), and the other one enriched by ^{18}O in 75% (insulating in all temperature range) are structurally identical at room temperature. At the temperature lowering the sample with ^{16}O undergoes subsequent antiferromagnetic T(AFM)=150K) and ferromagnetic (T(FM)=110K) transitions, resulting in the non-collinear FM structure, while in the sample with ^{18}O the pure AFM ordering (T(AFM)=150K) is revealed. No indications of phase segregation at low temperature were found.

M12.OF.004 SPIN-CHARGE-LATTICE COUPLING IN REDUCED DIMENSIONS IN THE CMR OXIDE $La_{2-2x}Sr_{1+2x}Mn_2O_7$, x=0.3-0.5 Dimitri N. Argyriou [1], John F. Mitchell [1], Jason Gardner [2], Paolo G. Radaelli [3], David E. Cox [4], Heloisa N. Bordallo [1] and James D. Jorgensen. [1.] Argonne National Laboratory, Argonne, IL 60439, USA, [2] Los Alamos National Laboratory, Los Alamos, NM, 87545, [3] ISIS Facility, Rutherford Appleton Laboratory, Chilton. OX11 0QX, UK, [4] Brookhaven National Laboratory, Upton, NY, 11973

Spin-charge-lattice degrees of freedom in the layered CMR manganites $La_{2-2x}Sr_{1+2x}Mn_2O_7$ result in a rich structural and magnetic phase diagram over a relative small compositional range (0.3<x<0.5). We find that the electronic doping (x) plays a critical role in varying the degree and direction of the spin-charge-lattice coupling. Using neutron diffraction measurements we have measured the structural properties of these materials as a function of temperature and pressure through the coincident insulator-metal and magnetic transitions at T_{IM}. We find that charge is transferred predominately to Mn $d_{x^2-y^2}$ orbitals below T_{IM} for compositions x<0.36 and to $d_{3z^2-r^2}$ orbitals for 0.36<x<0.4. Accompanying these variations in orbital occupancy of the Mn ion, are pronounced changes in the spin arrangement below T_{IM}. For x=0.3 we find an antiferromagnetic structure along the *c*-axis that exhibits antiferromagnetic inter-bilayer coupling while the intra bilayer coupling remains ferromagnetic. For 0.32<x<0.36 we find a ferromagnetic structure with the easy axis along *c*, while for 0.36<x<0.4 the easy axis is in the *ab*-plane. For x=0.5, equal amounts of Mn^{3+} and Mn^{4+} ions order below T_{CO}~200K. Unlike similar phenomena observed in the manganite perovskites this charge ordered state is only stable between ~200-100 K.

M12.OF.005 ORBITAL ORDERING AND ANISOTROPIC BEHAVIOR IN $Nd_{1-x}Sr_xMnO_3$. H. Kawano, Solid State Division, Oak Ridge National Laboratory, Oak Ridge, Tennessee 37831, R. Kajimoto and H. Yoshizawa, Neutron Scattering Laboratory, I. S. S. P., University of Tokyo, Tokai, Ibaraki, 319-1106, Japan, H. We have performed neutron diffraction measurements on melt-grown polycrystalline samples of $Nd_{1-x}Sr_xMnO_3$ system with $0.49 < x < 0.75$[1]. As a function of x, the system shows a systematic variation of the magnetic and crystal structures. We found that this variation is accompanied by a change of the character of the Mn e_g orbitals. The MnO_6 octahedra are apically compressed in the CE-type and A-type antiferromagnetic (AFM) states due to the $d(3x^2-r^2)/d(3y^2-r^2)$ or $d(x^2-y^2)$ orbital orderings, respectively, whereas in the C-type AFM state, they are apically elongated by the rod-type $d(3z^2-r^2)$ orbital ordering. In addition, we have performed inelastic neutron scattering experiments on the spin dynamics in the Ferromagnetic [2] and the A-type AFM[3] states of $Nd_{1-x}Sr_xMnO_3$. Spin wave spectra in both states shows a distinct two-dimensional character. We will discuss that these results can be consistently interpreted from a viewpoint of the underlying orbital orderings.

P12.OF.001 THE EFFECT OF CONFORMAL ROUGHNESS ON SPIN-VALVES. J. Clarke and B.K. Tanner Department of Physics, University of Durham, South Road, Durham. DH1 3LE U.K. and C.H. Marrows, F.E. Stanley and B.J. Hickey, Department of Physics and Astronomy, University of Leeds, Leeds. LS2 9JT U.K. and R.J.T. Bunyan, Defence Evaluation and Research Agency (DERA), Electronics Sector, St. Andrews Road, Malvern, Worcestershire. WR14 3PS U.K.

Equivalent spin-valves grown on silicon oxide substrates produced either by thermal oxidation of Si (100) wafers or low pressure chemical vapour deposition of the oxide have been studied by x-ray scattering, atomic force microscopy and magnetotransport measurements. Grazing incidence x-ray scattering measurements have also been made on the bare substrates. The x-ray measurements, supported by atomic force microscopy images, show a large difference not only between the roughness of the two substrate types but also that of the spin-valves deposited on them. A high degree of conformality is observed in the roughness of the spin-valves. Magnetoresistance measurements made on the spin-valves show that the switching point of the sample grown on the low pressure chemical vapour deposited substrate is shifted away from the ideal zero point due to increased coupling and both the giant magnetoresistance and exchange field are seen to fall with increasing roughness.

P12.OF.002 PECULIARITIES OF ATOMIC AND MAGNETIC STRUCTURES OF $(La_{1-y}Pr_y)_{0.7}Ca_{0.3}MnO_3$ ($0.50 \le y \le 0.75$). D.V. Sheptyakov, A.M. Balagurov, V.Yu. Pomjakushin and V.L. Aksenov, Frank Laboratory of Neutron Physics, JINR, Dubna, Russia, and N.A. Babushkina and L.M. Belova, RRC Kurchatov Institute, Moscow, Russia, and O.Yu. Gorbenko and A.R. Kaul, Chemistry Department, Moscow State University, Moscow, Russia, and P. Fischer, M. Gutmann and L. Keller, PSI, Villigen, Switzerland.

Evolution of structural and magnetic properties of the CMR-compound $(La_{1-y}Pr_y)_{0.7}Ca_{0.3}MnO_3$ has been studied by neutron diffraction in the temperature range from 10 to 293 K for several compositions ($0.50 \le y \le 0.75$). It is shown that changes in transport and magnetic properties are directly connected with rearrangement of the atomic structure. Phase transition to the metallic state arises at the same time with ferromagnetic ordering of manganese moments. The dramatic oxygen isotope effect on the magnetic structure and charge ordering is found for $(La_{0.25}Pr_{0.75})_{0.7}Ca_{0.3}MnO_3$. At the temperature lowering the sample with ^{16}O undergoes subsequent antiferromagnetic and ferromagnetic transitions, resulting in the non-collinear FM structure, while in the sample with ^{18}O the pure AFM ordering is found. The temperature dependencies of the diffraction peak intensities associated with charge ordering are also quite different in the samples with ^{16}O and ^{18}O and correlate with the behavior of the electrical resistivity and the magnetic structure. The temperature dependencies of the unit cell parameters demonstrate several distinctive features: non-linear dependencies close to T_{CO} charge ordering temperature, sharp jump at the temperature of FM ordering, which is also well visible in $V_c(T)$ dependence.

P12.OF.003 MAGNON DAMPING BY MAGNON-PHONON COUPLING IN CMR MANGANITES N. Furukawa Department of Physics, Aoyama Gakuin University, Setagaya, Tokyo 157-8572, JAPAN

We study the magnon damping effect caused by strong magnon-phonon coupling in CMR manganites. Recent neutron scattering experiments show anomalous increase in magnon linewidth as the magnon branch crosses an longitudinal optical phonon branch. Assuming a strong magnon-phonon coupling due to Jahn-Teller interaction in manganites, we theoretically calculate the magnon linewidth as a function of magnon frequency. The result is consistent with the experiment. We also discuss some crucial tests to verify the above dumping mechanism.

12AA CELLULAR AND MOLECULAR REGULATION

M12.AA.001 ERYTHROPOIETIN RECEPTOR ACTIVATION AND SIGNALLING. I.A. Wilson, O. Livnah, and E.A. Stura, The Scripps Research Institute, Department of Molecular Biology, La Jolla, CA 92037 U.S.A., and D.L. Johnson, S.A. Middleton, and L.K. Jolliffe, R.W. Johnson Pharmaceutical Research Institute, Raritan, NJ 08869-0602 U.S.A.

A surprising development in the cytokine receptor field was the discovery of a short 20-residue peptide agonist that mimics the biological activity of the erythropoietin (EPO) natural hormone [1]. The crystal structure of the EPO receptor with an agonist peptide EMP1 showed that the peptide itself dimerizes and induces a symmetric dimerization of the receptor [2] that differs from the asymmetric dimerization of the EPO-EPOR complex [3].

Our recent work has focused on the difference between agonist and antagonist peptides and their effect on receptor dimerization and signal transduction. The antagonist peptide EMP33 can still dimerize the receptor, yet does not cause cell

proliferation [4]. Hence, the nature of the oligomeric assembly seems to play a role in the biological potency of the ligands and in subsequent intracellular phosphorylation events [1, 3, 4]. We have also undertaken x-ray structural studies of the EPO receptor in the absence of bound ligand. The unliganded receptor surprisingly forms a dimer that is substantially different from any peptide or EPO receptor complex. Our data suggest that preformed EPOR dimers occur on the cell surface and that ligand induces a conformational change in the receptor association [5]. Importantly, this model has now been tested on living cells by a protein fragment complementation assay that shows distinct dimer assemblies exist on the cell surface for unliganded and liganded EPOR [6].

M12.AA.002 STRUCTURAL BASIS OF THE ALLERGIC RESPONSE : STUDIES OF THE HUMAN HIGH AFFINTITY IGE RECEPTOR. T.S. Jardetzky & S.C. Garman, Department of Biochemistry, Molecular Biology and Cell Biology, Northwestern University, Evanston, IL 60208, and J.P. Kinet, Laboratory of Molecular Allergy and Immunology, Harvard Medical School, Boston, MA 02215

The high affinity IgE Fc-receptor (FcεRI) triggers the activation of effector cells, leading to the release of specific mediators of the immune response that initiate allergic reactions, anaphylactic shock and the killing of parasites. Human FcεRI exists in two forms, as an $\alpha\beta\gamma 2$ tetramer or an $\alpha\gamma 2$ trimer. The α subunit is involved in IgE binding and the β and γ subunits are the signal transduction modules. FcεRI belongs to a family of antibody Fc-receptors (FcRs) that play an important role in the immune response by coupling the specificity of secreted antibodies to a variety of cells of the immune system. Fc-receptors that bind IgG (FcγRI, FcγRII, and FcγRIII) mediate a variety of inflammatory reactions, regulate B-cell activation, and also trigger anti-parasitic reactions through phagocytes and potentially Natural Killer cells. Recent experiments with transgenic mice have demonstrated that the FcRs control key steps in the immune response previously thought to be carried out by the complement system.

We have solved the crystal structure of the IgE-binding domains of the FcεRI α-subunit by multiple isomorphous replacement methods [1]. A receptor α-subunit fragment expressed in insect cells yields crystals that diffract X-rays to a resolution of 2.4 Å using a high energy synchrotron source. The receptor is formed of two truncated Ig domains that fold into a bent two-domain structure that is different from other tandem Ig domain structures (figure 1). Carbohydrate moieties are observed at three of the seven N-linked attachment sites. The IgE-binding site has been identified in the second domain of the receptor and includes a prominent loop that projects from the receptor surface. The crystal structure implicates nearby residues in the first domain that may be involved in antibody binding and suggests models for the formation of a complex with the IgE-Fc region. Our structural studies provide a foundation for understanding the specificity and function of this important class of immune-system receptors.

M12.AA.003 ACTIVATION AND INHIBITION OF MAP KINASES. E. J. Goldsmith, B. Canagarajah, Z. Wang, A. Khokhlatchev and M. H. Cobb, Department of Biochemistry, UT Soutwestern Medical Center at Dallas, Dallas, TX 75235-9050.

The MAP kinases transduce of extracellular signals, and phosphorylate and activate transcription factors leading to tranformation, proliferation and other changes in the cellular program. Multiple parallel MAP kinase pathways are differentially responsive to growth factors and environmental stresses. MAP kinases are activated by phosphorylation at two sites. The structure of the active form of the MAP kinase ERK2 shows that phosphorylation forms the active site and P+1 specificity pocket. (B. Canagarajah, A. Khokhlatchev, M. H. Cobb and E. J. Goldsmith (1997). *Cell* **90**, 859-869.) Phosphorylation also promotes dimerization at a site close to the phosphorylation sites in ERK2. Dimerization leads to nuclear retention, and structurally masks a nuclear export signal. (A. V. Khokhlatchev, B. Canagarajah, J. Wilsbacher, M. Robinson, M. Atkinson, E. J. Goldsmith and M. H. Cobb (1998). *Cell* **93**, 605-615.) The dimerization also permits MAP kinases to interact with dimeric transcription factor substrates.

P38, is a MAP kinase acitvated in response to cytokines, and is the protein target of SB203580, an antiinflammitory agent synthesized by Smith Kline Beecham. P38 shares 40% sequence identity with ERK2. Crystallographic analysis of the SKB inhibitors bound to both p38 and ERK2 reveal the origin of specificity of the inhibitors for p38 to be attributable specific amino acid replacements in the active site, and differences in the size and shape of the active site derived from distal amino acid replacements. These data provide insight into how to make specific protein kinase inhibitors. (Z. Wang, B.J. Canagarajah, J. C. Boehm, S. Kassis, M. H. Cobb, P. R. Young, S. Abdel-Meguid, J. L. Adams, and E. J. Goldsmith (1998). *Structure* **6**, 1117-1128.)

M12.AA.004 RECOGNITION AND REGULATION IN TYROSINE KINASE SIGNALLING CASCADES Michael J. Eck, Department of Biological Chemistry and Molecular Pharmacology, Harvard Medical School, and the Dana-Farber Cancer Institute, 44 Binney Street, Boston MA 02115

Activation of growth factor or immune receptors on the cell surface initiates a cascade of tyrosine phosphorylation events that induces recruitment and activation of down-stream signalling proteins. Faithful execution of the appropriate signalling program requires tight control of the activity of these cytoplasmic signalling enzymes, which include non-receptor tyrosine kinases, phosphatases, and phospholipases. How are such enzymes activated in a manner that is tightly coupled to their appropriate sub-cellular localization? Crystal structures of the Src tyrosine kinase, SHP-2 phosphatase, and the adaptor protein c-Cbl will be discussed to show how modular domains such as SH2 and SH3 domains have evolved dual roles as both “recognition” and “regulatory” modules, and how they have divergently evolved to coordinate recognition with catalytic activation. The Cbl structure suggest that these signalling domains may in turn be regulated by other cellular inputs.

M12.AA.005 POWERING THE ABC TRANSPORTER: THE STRUCTURE OF THE ATP-BINDING CASSETTE, RBSA at 1.6Å RESOLUTION. Cynthia Stauffacher[1], Shelly Armstrong[1], Huide Zhang[2], Lydia Tabernero[1], and Mark Hermodson[2], [1]Department of Biological Sciences, [2]Department of Biochemistry, Purdue University, Lilly Hall, State Street, West Lafayette, IN

The structural family of ABC transporters are involved in the unidirectional transport of a wide variety of molecules across

membranes. Multiple different ABC transporters have been found in the genomes of species from bacteria and archeabacteria to mammals, and include a number of transporters involved in human disease. These molecules all contain a minimum of two copies of an integral membrane domain and two copies of an ATPase domain, called the ABC, or ATP-binding cassette. Although the sequence identity of these transporters is not high, three signature regions in the ATP-binding domain of the transporter define the class. We have undertaken the X-ray crystallographic study of the ATP-binding cassette of the ABC transporter, RbsA/C, and have solved the 1.6Å structure of the N-terminal RbsA ABC with bound MgADP. The RbsA ABC revealed is a three-layered mixed alpha/beta structure with a barrel-like domain containing the nucleotide binding site. The overall structure of the molecule bears little resemblance to other ATPases, although the nucleotide binding site does show local similarity, particularly in the region of the Walker A and B motif structures. The MgADP is bound in a relatively open pocket with a clearly defined site for the gamma phosphate, and a set of tightly bound water molecules, one of which appears to be held in a position suitable for participation in catalysis. The ABC transporter signature motif does not appear to be part of the active site of RbsA, but is located on a separate helical domain, which we propose is involved in interdomain interactions important for transport function. Homology modeling based on the RbsA ATP-binding cassette has now been used for the analysis of other members of the ABC transporter family, such as the multidrug resistance P-glycoprotein and the CFTR channel protein.

P12.AA.001 STRUCTURE OF MAMMALIAN IMPORTIN α REVEALS AUTOINHIBITION BY A PSEUDO-NUCLEAR LOCALIZATION SIGNAL. T. Teh and B. Kobe, Structural Biology Laboratory, St. Vincent's Institute of Medical Research, 41 Victoria Parade, Fitzroy, Victoria 3065, Australia.

Nuclear proteins are synthesised in the cytoplasm and need to be imported into the nucleus through the nuclear pore complexes. Such import is directed by special signals, the best characterised being the classical nuclear localisation sequence (NLS), consisting of one or two clusters of basic residues. The receptor that recognises NLSs is the importin heterodimer. Importin α contains the NLS binding site, and importin β is responsible for the actual translocation through the pore. The nuclear import is proposed to be driven by the asymmetric distribution of GDP- and GTP-bound forms of Ran. The current models predict a high-affinity form (for NLS binding) of the nuclear import receptor in the cytoplasm, and a low-affinity form in the nucleus where the receptor must release its cargo and return to the cytoplasm without it. Importin β plays a key role in the conversion between the two forms, because Ran-GTP binding to importin β in the nucleus causes its dissociation from importin α and the release of the cargo protein.

We determined the crystal structure of the full-length mouse importin α at 2.5 Å resolution (R = 18.9%, Rfree = 24.0%). The structure shows a large elongated C-terminal superhelical domain containing tandemly arranged armadillo repeats, and a less structured N-terminal importin β-binding domain containing an internal pseudo-NLS bound to the NLS-binding site. This observation provides the structural basis for the regulatory switch between the cytoplasmic, high-affinity form, and the nuclear, low-affinity form for NLS binding of the nuclear import receptor. Importin β conceivably converts the low- to high-affinity form by binding to a site overlapping the autoinhibitory sequence in a process resembling intrasteric regulation of protein kinases.

The structure also illuminates the determinants for the binding of diverse NLS sequences. The binding is achieved through a complex combination of interactions that include polar interactions orienting the NLS backbone, hydrophobic interactions with the non-polar portions of large side chains conferring the affinity, and complementary electrostatic interactions with the positively charged NLS side chains providing the specificity. The arm repeats provide a structural framework with a long shallow groove where strategically positioned side chains can sculpt the appropriate surface details. The nature of the interactions bears similarities with the similarly promiscuous but high affinity peptide recognition by MHC complexes. Analyses suggest that HEAT repeats constituting importin β may have a structure similar to armadillo repeats.

P12.AA.002 CRYSTAL STRUCTURE OF ERA: A GTPase-DEPENDENT CELL CYCLE REGULATOR CONTAINING AN RNA-BINDING MOTIF. Xinhua Ji, Xin Chen and Donald L. Court, ABL-Basic Research Program, National Cancer Institute – Frederick Cancer Research and Development Center, Frederick, Maryland 21702, USA.

ERA forms a unique family of GTPase that is widely conserved and essential in bacteria. ERA functions in cell cycle control by coupling cell division with growth rate. ERA homologues are also found in eukaryotes. We have determined the crystal structure of ERA from *Escherichia coli* at 2.4-Å resolution using a combination of MIR and MAD phasing. The structure reveals a two-domain arrangement of the molecule: an N-terminal domain that resembles p21 Ras and a C-terminal domain that is unique. Structure-based topological search of the C-domain fails to reveal any meaningful match, although sequence studies suggest that it may contain a KH-domain. KH-domains are RNA-binding motifs that usually occur in tandem repeats and exhibit low sequence similarity except for a conserved segment VIGxxGxxIK. We have identified a βααβ fold that is shared by the C-domain of ERA and the KH-domain and contains the VIGxxGxxIK sequence. We propose that the βααβ fold is the RNA-binding motif, the minimum structural requirement for RNA-binding. ERA is observed as dimers in crystal. The dimer formation involves a significantly distorted switch II region, which may shed light on how ERA protein regulates downstream events.

P12.AA.003 CONTROL OF CELL DIFFER-ENTIATION: SPO0A AND PHOSPHATE RELAY IN SPORULATING BACTERIA A.J. Wilkinson, R.J. Lewis, J.A. Brannigan [1], K. Muchova, I. Barak [2], G. Leonard [3], [1] Department of Chemistry, University of York, York, YO1 5DD, UK, [2] Institute of Molecular Biology, Slovak Academy of Sciences, Dubravska cesta 21, 842 51 Bratislava, Slavak Republic, [3] ESRF. Avenue des Martyrs, Grenoble, France

The formation of a resistant spore is the ultimate survival strategy and sporulation in B. subtilis is perhaps the simplest and best understood example of cellular differentiation. Involving as it does, the activation of numerous genes and the expenditure of a large amount of energy, sporulation is under stringent control. The master control element in the decision to sporulate is Spo0A, a gene-activator/repressor protein whose activity is regulated by phosphorylation. Spo0A-phosphate is formed via a multi-component 'phosphorelay'system fed by sensor kinases and drained by protein phosphatases. We have very recently solved the structure of the phosphoacceptor domain of Spo0A by MAD phasing of SeMet derivative data, revealing an unexpected quaternary organisation with important implications for signal transduction. Together with the structures of two other phosphorelay components, Spo0F and Spo0B [1,2], the structure provides (i) a basis for interpreting the effects of numerous '0A' mutations (ii) a framework for understanding phosphate transfer between proteins and (iii) an opportunity to understand how an extended system of proteins exerts biological control.

12BB AB INITIO AND MOLECULAR REPLACEMENT PHASING METHODS

M12.BB.001 TOWARDS AN AB INITIO METHOD FOR THE DETERMINATION OF MACROMOLECULAR CRYSTAL STRUCTURES. Peter Main, Department of Physics, University of York, York YO1 5DD,England

A method for the complete ab initio determination of macromolecular crystal structures using X-ray diffraction data from a single crystal is being developed at York. A Monte Carlo procedure is used to set up trial electron density maps consistent with the observed diffraction pattern and the predicted electron density histogram, taking into account the resolution and solvent content. Cluster analysis based on that carried out by Lunin et al.[1] is then used to provide a map, typically at about 10-15 , which shows the molecular envelope. A method to extend these low resolution phases using wavelet analysis is now under development. The problem is one of adding the right amount of detail to the right place in a map. It has been found that wavelet analysis, which effectively decomposes an image into different levels of detail, gives precise control over this (Main et al., [2]). The amount of detail is given by the statistics (histograms) of the wavelet coefficients which can be predicted for increased resolution with the positions of new features guided by the diffraction pattern. At present, 10A starting phases can be extended to about 7A with acceptable phase errors but with the addition of further information it is hoped that they can be extended to the resolution at which existing density modification tecniques can be used. The program DM ([2]), now part of the CCP4 protein crystallography program library, is normally used on MIR, MAD or molecular replacement maps, but also forms an important part in the ab initio method. DM can take an electron density map in which the tertiary structure of the molecule is resolved and increase its resolution to that of the X-ray data prior to interpretation.

M12.BB.002 STRENGTHS AND WEAKNESSES OF MOLECULAR REPLACEMENT. Dodson, E.J., Chemistry Department, University of York

Molecular replacement as a technique has come of age, and it is timely to review the class of problems it can solve. The first applications were to search for non crystallographic symmetry with the aim to improve phasing. As more related proteins were studied the emphasis moved to fitting known models into new crystal forms. This technique is now fairly straightforward; it is fair to claim that a) if the Xray data is complete, and b) if model domains have an rms deviation in CAs from the unknown structure of less than 1.0, then a solution will be obtained, even when there are several segments in the asymmetric unit of the unknown structure.

Contributions from other areas are helping. More and more macromolecular structures can be grouped into families, where there are similarities in the folds. These can be used in somewhat the same way as NMR models by analysing the structures for domains and overlapping multiple copies.

The challenge of determining NCS or cross-crystal operators before an atomic model is available has not been fully met. Averaging , both within and between crystal forms is a powerful way to improve and refine the phases of structure amplitudes, but this can only be used when there is a transformation matrix to map the molecules onto each other. Examples will be discussed where satisfactory matrices have been obtained by using uninterpretable electron density derived from poor phases as a search model.

New target functions are coming available. The traditional method has depended on Patterson overlap, which allow the exploitation of FFTs. As computors become faster, this may not be so important, and full 6 dimensional searches to other targets can be envisaged.

M12.BB.003 AB-INITIO CALCULATION OF ENVELOPES FOR MACROMOLECULES BY MAXIMISATION OF LIKELIHOOD. Petrova T.E., Lunin V.Y., IMPB RAS, 142292 Pushchino, Moscow Region, Russia and Podjarny A.D. UPR de Biologie Structurale, IGBMC, BP 163, 67404 Illkirch CEDEX CU de Strasbourg, France.

Generally, the first stage in the low-resolution phasing of proteins is obtaining the envelope. The goal of this work is to determine whether the generalised likelihood (GL) [2] can be used as a criterion for the choice of the best one from a set of possible envelopes, which either fulfill real space constraints or are calculated from proposed phase sets. For every envelope, the value of GL, which is an analogue of statistical likelihood, can be calculated by means a Monte-Carlo type computation. A great number of pseudo-atomic models are randomly generated inside the envelope. The GL value is estimated as the frequency of appearance of models with magnitude correlation greater than some fixed level.

A family of possible envelopes, which were obtained by permuting the phases of a group of strong low-resolution reflections and calculating the mask of a fixed volume for every phase set, were considered. The tests with the neutron diffraction data for the $tRNA^{Asp}$-Asp RS complex showed that ranking the envelopes according to the GL value allows the choice of a few ones, including that corresponding to the correct phase set. The phase extension procedure, which is analogous to the building of the phasing tree [1], allows the determination of the correct envelope and phase set. The results obtained were compared with the results of the choice of the best envelope from the family of spherical envelopes [3] using the same GL criterion.

M12.BB.004 USE OF THE FAST TRANSLATION SEARCH FOR LOCATION OF HEAVY ATOM SITES FOR MAD/MIR/SIR PHASING. P.D. Adams, R.W. Grosse-Kunstleve, A.T. Brunger, HHMI/Yale University, Dept. of MB&B, New Haven, Connecticut 06511, U.S.A.

The Fast Fourier Transform translation function [1] has been implemented in the program Crystallography & NMR System [2]. This CPU efficient translation function is used in two different areas of phase determination: molecular replacement, and the automatic location of heavy atom sites for MAD/MIR/SIR phasing. We have developed a new and highly automated heavy-atom search procedure which combines the fast translation function, Patterson superposition functions and Patterson-Correlation refinement. An empirical dead-end elimination procedure is used to dramatically reduce computing time. The search procedure can be applied to both native and difference Patterson maps. Differences can be anomalous, dispersive or isomorphous. The weighted average of several different Patterson

maps can be used. The procedure was successfully tested with experimental data for a number of structures at low (3.2 Angstroms) to high (1.8 Angstroms) resolution with up to 30 heavy atom sites in the asymmetric unit. Even for a large number of heavy atoms, the correct sites can be found in less than one day on a high-speed workstation, usually in a matter of minutes for cases with a good signal.

M12.BB.005 FINDING SELENIUMS WITH SnB. Charles M. Weeks[1], P. Lynne Howell[2], Ashley M. Deacon[3], Robert H. Blessing[1], G. David Smith[1,4], Russ Miller[1], Steven E. Ealick[3] and Herbert A. Hauptman[1], [1]Hauptman-Woodward Inst., 73 High St., Buffalo, NY 14203-1196, USA, [2]Structural Biol. and Biochem., Res. Inst., The Hospital for Sick Children, 555 University Ave., Toronto, M5G 1X8, Canada, [3]Dept. of Biochem., Molecular and Cell Biol., Cornell University, Ithaca, NY 14853, USA, [4]Roswell Park Cancer Inst., Elm & Carlton Sts., Buffalo, NY 14263, USA.

SnB version 2.0 [Weeks, C.M. & Miller, R. (1999), J. Appl. Cryst. 32, in press] is a computer program that implements the dual-space (Shake-and-Bake) approach to ab initio direct phase determination. It has successfully solved conventional problems involving as many as 1200 unique non-H atoms as well as large substructures such as the SeMet derivative of an epimerase which has 70 selenium sites. Substructure applications require only the 2.5-3.0Å data normally included in MAD measurements, and data sets truncated even to 5Å have led to solutions. It is important, however, to include accurate low-resolution data. So far, the best results have been obtained from consideration of single-wavelength, peak anomalous difference data alone, possibly because this approach avoids the introduction of any errors resulting from incorrect scaling between two data sets. Independent SnB analysis of data measured at different wavelengths, on the other hand, can provide valuable confirmation for questionable sites.

The key to successful use of difference data is careful data processing and computation of normalized difference magnitudes. It is essential that all erroneously large magnitudes be excluded prior to phasing. The SnB v2.0 program package accomplishes this by providing a convenient interface to the DREAR data-processing programs [Blessing, R.H. (1997) J. Appl. Cryst. 30, 421-426] which allow for fine control of the data-screening process. Default values, based on empirical study of known structures, are provided for all parameters in the main SnB phasing program. Thus, phasing can be performed automatically if desired. For further information concerning SnB, please refer to http://www.hwi.buffalo.edu/SnB/.

M12.BB.006 EXAMPLES OF MACROMOLECULAR *AB INITIO* WITH HIGH RESOLUTION DATA. I. Usón and G.M. Sheldrick, Institut für Anorganische Chemie, Universität Göttingen, Tammannstr. 4, 37077 Gööttingen, Germany

High resolution ab initio macromolecular structure solution based on real/reciprocal space iteration with the 'half-baked' method[1,2] (inspired by Shake & Bake[3], but different in detail) will be illustrated by the solution of sulphur- or chlorine containing structures which were not amenable to conventional direct methods despite exhaustive solution attempts. Ways to improve the starting random phases using the Patterson function that lead to an improved success rate of the method will be discussed. The method relies not on the solution of the Patterson to locate the sites of the heavier atoms, but rather employs a probabilistic Patterson sampling, to screen random starting phases for consistency with the Patterson function.

The method will be illustrated with some examples including hirustasin, a 55 amino acid serine protease inhibitor containing 5 disulphide bridges, which can be solved by SHELXD with either 1.2 A low temperature data, or with 1.4 A room temperature data [4].

P12.BB.001 AN ALGORITHM FOR AB INITIO ELECTRON DENSITY RECONSTRUCTION IN MACROMOLECULAR CRYSTALLOGRAPHY. J. L. van der Plas, R. P. Millane, Whistler Center for Carbohydrate, Research Computational Science and Engineering Program

A new electron density modification (EDM) algorithm has been developed and applied to ab initio phasing in macromolecular crystallography. EDM is generally used to improve experimental phases and/or extend phases to higher resolution, but we find that the new algorithm can converge to the correct electron density without any initial experimental phases when conventional EDM fails to do so. The new algorithm is based on the hybrid-input-output algorithm (HIO), which was originally developed for 2D image processing in astronomy. The new algorithm appears to be less affected by local minima than conventional EDM. Instead of simply applying constraints to the electron density, the HIO algorithm computes a driving function, that is modified at each cycle depending on how well the constraints are satisfied. Our algorithm consists of using HIO and conventional EDM in each phase extension step.

To investigate the effectiveness of the new algorithm compared to conventional EDM, both were tested on a set of synthesized structure factors calculated from a 340 A unit cell containing one Cowpea Mosaic Virus (CPMV) particle, a virus with 60-fold icosahedral symmetry, where the 5-fold axis was noncrystallographic. The synthesized diffraction data were modified by adding 10% noise and removing reflections with a resolution less than 100 A, to better represent actual experimental data. Starting with random phases, both algorithms were used to attempt to refine the phases between 100 and 20 A resolution. The phases obtained were then used to extend to 6 A resolution in five more steps. The new algorithm proved far more effective in finding the correct phases than did conventional EDM. The new algorithm therefore promises to be a useful tool for ab initio structure determination in macromolecular crystallography.

P12.BB.002 REAL-SPACE DIRECT METHODS FOR PROTEINS. M.M. Woolfson, J. Foadi, Physics Department and E. Dodson, K.S. Wilson and Yao Jia-xing, Chemistry Department, University of York, York YO10 5DD, U.K.

It has been shown to be possible to solve moderate size proteins starting with a fragment that may or may not be part of the structure under investigation. For a P1 structure the fragment, which can be as small as 1% of the structure, does not need to be

oriented or positioned but favourable orientations may be found by Patterson methods. A modified Patterson superposition map, using the sum function, has been found to be advantageous in improving the starting set of phases from the fragment.

Usual phasing procedures using phase relationships are weak and not very useful for large structures. However, the Sayre equation and non-negativity criteria apply as well to large structures as to small. Successive refinement from the starting phases is carried out in real space, firstly applying the Sayre equation (L.S. Refaat, C. Tate, & M.M. Woolfson, 1995, *Acta Cryst*. **D51**, 1036-1040) followed by density modification in the form of an improved version of low-density elimination (M. Shiono & M.M. Woolfson, 1992, *Acta Cryst.* A**48**, 451-456). The method is a multi-solution one and an effective figure of merit, based on the correlation coefficient between estimated and actual values of structure amplitudes of non-phased reflections, enables the progress of phase refinement to be followed and correct solutions to be unambiguously identified.

A P1 structure with 1 428 atoms, including 10 sulphur atoms and 286 water atoms, was solved starting with small fragments containing 10 atoms taken from another, and unrelated, structure. For the best solutions, phases found for the 16,761 reflections with |E| >1 had mean phase error (unweighted) down to 20.4°. Experiments have shown that much larger structures might also be soluble by this kind of approach, although the optimum way of obtaining the initial fragment has still to be determined.

P12.BB.003 EXPERIMENTALLY DETERMINED TRIPLET PHASES USED FOR STRUCTURE SOLUTION ON LYSOZYME. Kerstin Hölzer[a,b], Edgar Weckert[b], Klaus Schroer[a,b], and Kurt Hümmer[b], [a]Biology Department, Brookhaven National Laboratory, Upton, New York 11973, USA, [b]Institut für Kristallographie, Universität Karlsruhe (TH), D-76128 Karlsruhe, Germany

Advances in the experimental triplet phase determination using three-beam diffraction allowed the measurement of a large set of triplet phases on protein crystals [1]. For the evaluation of a structure solution based on measured triplet phases, tetragonal HEW Lysozyme was chosen as a test structure [2]. At the ESRF bending magnet BM1 (SW/NOR CRG) it was possible to determine about 100 triplet phases per day on a good-quality lysozyme crystal. From the total of 850 measured triplet phases one derive 750 structure-factor phases. The resolution of the reflections involved in the three-beam cases extends from 35 to 2.5 Å, with the maximum of the distribution at 4 Å. The mean difference of the structure-factor phases to the PDB entry 193L [3] is 16°. The quality of the resulting e-density map allows a straightforward and nearly complete interpretation, and the starting model was refined to an R-value of 17.4 %. Afterwards the influence of the experimentally phased reflections to the quality of the e-density map was investigated by applying criteria based on resolution and intensity. Thus, the number needed for an interpretable e-density map was reduced to 550 phased reflections by using the reflections with the highest intensities and a resolution > 3.6 Å.

Now the equipment necessary for the three-beam interference experiment is being installed also at the NSLS (X26C) and will be available soon as an additional tool for structure-solution methods.

P12.BB.004 OPTIMAL SELECTION OF MEASURED TRIPLET PHASES: MAXIMUM-ENTROPY AND DENSITY MODIFICATION METHODS. E. Weckert, R. Müller, Institut für Kristallographie, Universität Karlsruhe, D-76128 Karlsruhe, Germany and K. Hölzer, Biology Department, BNL, Upton, NY 11973, USA.

It has been shown that a sufficient number of triplet phases can be measured by the three-beam interference method [1,2] in order to calculate an interpretable map from the derived single phases. The difficult task of combining triplet to single phases can be accomplished by a maximum entropy based technique [3]. The aim of the presented investigation is to reduce the number of required measured triplet phases. Promising results could be obtained by the following procedure: (i) The use of Maximum Entropy and Likelihood methods to derive the most probably base-phase set from measured triplet phases and extrapolation of the phases of non-base reflections with proper weights. (ii) Further improvements of the phases by density modification techniques [4]. (iii) Application of an automatic refinement protocol [5] to this density. For the case of tetr. lysozyme a set of 850 triplet phases and a 1.5 Å intensity data set this procedure will give a map with a correlation coefficient higher than 90% compared to the F_{obs} map. The procedure is still working if the number of triplet phases is reduced to about 500. The results of these calculations as well as first applications to an unknown protein crystal structure will be presented.

P12.BB.006 A NEW CLASS OF HEME PROTEINS. STRUCTURE OF PLANT HEMOGLOBIN FROM RICE : A SIMPLE PROTEIN WITH A COMPLICATED SOLUTION. Boguslaw Stec, *Mark S. Hargrove, #Eric A. Brucker, John S. Olson, George N. Phillips Jr. Dept. of Biochemistry and Cell Biol., Rice University, 6100 Main St., Houston TX 77005, * 4128 Molecular Biology Building, Department of Biochemistry, Biophysics, and Molecular Biology, Iowa State University,Ames , IA 50010, Baxter Healthcare Corp., 2545 Central Ave., Suite FD-1, Boulder, CO 80301

We have solved and refined a representative of a new class of heme containing proteins: nonsymbiotic hemoglobin from rice (nsHb). The protein crystallized in the trigonal $P3_121$ space group. The initial attempts to solve the structure with molecular replacement failed. It was finally solved by a combination of MIR and Single Atom Anomalous Dispersion methods. The structure solution was complicated by a partial superposition of Patterson peaks and symmetry ambiguities. It was later refined in X-plor to R=21.2% with excellent stereochemistry. The final structure contains two molecules in an asymmetric unit which corresponds well with the results from solution studies which suggested a dimeric organization for this protein. The dimer present in the asymmetric unit is different from previously observed ternary arrangements seen in other hemoglobins. It seems to have a weak interface which raises some mechanistic question. The individual subunits exhibit a classical globin fold but different enough so that molecular replacement failed. Each subunit contains an unusual heme environment in which the iron atom is bonded to both proximal and distal histidine residues. A similar arrangement was previously seen in the cytochrome b family. The significant kinetic difference is that the oxygen binding kinetics are very fast, compared to the cytochromes. The structural details of this simple protein, as well as the complicated history of attempts to solve the structure will be provided in the presentation.

P12.BB.007 THE PAIR-FUNCTIONAL: A NEW DIRECT METHOD. A.D. McLachlan, MRC Laboratory of Molecular Biology, Hills Road, Cambridge, CB2 2QH, UK

The "Pair-Functional Principle" of classical statistical mechanics [1] states that there is a unique many-atom statistical ensemble which can be made to reproduce the unphased observed X-ray intensity data from any physically feasible atomic crystal structure. The ensemble has the maximum entropy consistent with the data. It is equivalent to the many-body Boltzmann distribution of N identical atoms in thermal equilibrium under a set of fictitious pairwise interaction potentials. These potentials, derived from the direct correlation function of the observed originless Patterson function, are specific and unique for any given set of observations. The paired-atom ensemble is like a dense fluid of atoms in the unit cell, with long-range periodic interactions that depend on relative distance and orientation. Each atom feels the total pairing field from all the others, and at low temperatures the fluid condenses into the correct X-ray solution. The search for the molecular structure is guided by the "Perfect Pairing Postulate": the correct solution will usually be an N-atom configuration within the ensemble that has the maximum statistical potential consistent with the observed intensities. Pairing searches have successfully solved Sheldrick's test structures of 100-200 atoms, and larger real molecules, including Anderson, Prive and Eisenberg's alpha1 helical peptide of 400 atoms. The solution method uses a temperature-dependent self- consistent field generated by the pair potentials, where each atomic peak is positioned and generated by triangulation in the combined fields of all the others in the cell. A simpler method, tested recently, is called "Pair and Square". It uses alternate cycles of best paired peak picking followed by the tangent formula.

12CC PSEUDO-SYMMETRY AND TWINNING

M12.CC.001 LOW OBLIQUITY IN PSEUDO-SYMMETRY OF LATTICES AND STRUCTURES, AND IN TWINNING BY PSEUDO-MEROHEDRY. Y. Le Page, ICPET, National Research Council of Canada, Ottawa, Canada K1A 0R6.

A new life starts for the old concept of obliquity, the angle between a lattice row and the perpendicular to a lattice plane. Lattice symmetry, space-group symmetry, as well as twinning by merohedry involve *exact perpendicularity* between lattice rows and lattice planes. In the same way, near-perpendicularity *ie low values of obliquity,* is a central concept in the prediction, analysis and interpretation of metric pseudo-symmetry of lattices, of pseudo-symmetry of structures and of twinning by pseudo-merohedry or by reticular pseudo-merohedry. So far, only passive use seems to have been made of this quantitative criterion. We show here that low obliquity can now be used actively as a means of prediction.

The problem of finding low-obliquity directions in lattices with known cell parameters boils down to finding, for each set (*hkl*) of Miller indices for lattice planes, all lattice vectors shorter than an upper limit calculable from the *d*-spacing and the maximum obliquity, and with integer indices [*uvw*] which solve the linear Diophantine equation:

$hu+kv+lw=n$ [eqn 1] , where n is a given integer.

It can be shown that the cases of pseudo-symmetry of lattices and structures, as well as the case of twinning by pseudo-merohedry do not involve values of n other than 1, 2 or 3 if the lattice is referred to a primitive reference system. If that system is Buerger-reduced, values of h, k, l, u, v, w other than 0, ± 1 or ± 2 cannot be involved in the solution. The case of twinning by reticular pseudo-merohedry involves maximum values of n and of indices which are multiplied by the twin index.

A novel straightforward solution method for the short lattice vectors which satisfy [1] for general values of h,k,l and n will be presented. Its application to detection of metric pseudo-symmetry of lattices, to detection of pseudo-symmetry of structure models and to prediction of twin laws will be explained. A corresponding software program capable of finding *all* solutions of [1] very fast within a given obliquity, for even large values (like 10^5) of h, k, l and n, and of tackling in this way the above applications, will be installed for Internet interrogation at URL http://ylp.icpet.nrc.ca/oblique/ at the time of the meeting.

M12.CC.002 TWINNING OF CRYSTALS: TWIN LAW, LATTICE RELATIONS, LIMITING CASES. Th. Hahn, Institut für Kristallographie, RWTH Aachen, D-52056 Aachen, Germany, and H. Klapper, Mineralogisches Institut, Universität Bonn, D-53115 Bonn, Germany, and V. Janovec, Institute of Physics, Academy of Sciences, CZ-18040 Prague 8, Czech Republic.

A twin is characterized by a *twin law*, which traditionally is described by a single, morphologically prominent twin operation. All twin operations relate the lattices of two twin partners in such a way that they have either a lattice row (minimal condition), or a lattice plane, or the entire lattice in common: *crystallographic orientation relation*. There exist seven types of binary (order two) twin operations for the general case.

The notion of twin law can be generalized: The *eigensymmetry H* of the crystal is extended by a twin operation to the *composite symmetry K* (supergroup of index 2). The resulting *coset* contains all twin operations which define the same orientation relation between the two twin partners (*alternative twin operations*). Hence, the full coset is a more adequate description of the twin law. A different way of expressing the twin law is the anti-symmetry symbol of the composite symmetry *K*. More complicated relations exist for multiple (*e.g*. cyclic) twins.

Special attention is devoted to the *minimal condition* of twinning, *i.e*. the limiting cases between twinning and arbitrary intergrowth. Two types of twin, both discovered already in the 19th century, belong to this category:

(i) the so-called *Kantennormalengesetz* of micas (Tschermak, 1904) in which an irrational twofold twin axis is normal to a rational lattice row common to both partners (one-dimensional coincidence);

(ii) the so-called *median law* of pseudo-hexagonal gibbsite, $Al(OH)_3$ (Brögger, 1892). It consists of an irrational twofold twin axis which relates as bisector (median) two non-equivalent but strongly pseudo-equivalent lattice rows (pseudo one-dimensional coincidence).

Both intergrowths are doubted as twins by some authors. We accept the Kantennormalengesetz as the 'minimal twin', whereas there is conflicting evidence for the median law as a twin law: only approximate coincidence of two lattice rows *vs*. frequent and reproducible occurrence of the 'twin'.

M12.CC.003 PROTEIN STRUCTURES AND TWINNING. Geoffrey B. Jameson, Institute of Fundamental Sciences, and Bryan F. Anderson, Institute of Molecular BioSciences, Massey University, Palmerston North, New Zealand.

Low symmetry crystal classes of trigonal/hexagonal (3, 6) and tetragonal systems (4) predispose protein crystals to merohedral twinning, leading to X-ray diffraction data acquiring higher symmetry (32, 6; 622; 422) than that from the underlying

true lattice. A simple and robust test for detecting twinning is the ratio $T = \langle F^2 \rangle / \langle F^2 \rangle$ examined over ~5 resolution shells. For no twinning or pseudo-centering, theoretical values of T are 0.785 (acentric) and 0.637 (centric); for perfect twinning (two equal twin components), values are 0.886 (acentric) and 0.785 (centric). Unrecognised twinning in a macro-molecular structure, where usually the data:parameter ratio is poor, may lead to misfortune in refinement. Twinning may also lead to apparently valid but overlapped solutions using molecular replacement methods. An internally consistent solution for a single twin domain may be retrieved by examination of the correlation coefficient as a function of twin fraction.[1]

SHELXL offers exceptionally convenient structure refinement, using the data as measured. Following refinement, observed data are de-twinned in order to provide observed and calculated |F| (with calculated phase angle) for calculation of Fourier maps, via an ancillary program SHELXPRO. The half-molecule R121D mutant of human lactoferrin crystallises in space group P32, but due to twinning (hkl and -h-kl perfectly overlapped; twin fraction = 0.44) data to 3.0 Å have pseudo-hexagonal symmetry and apparent space group $P6_2$. Four domains corresponding to two molecules in the asymmetric unit were located by MR, and the structure refined using SHELXL. The omitted C-terminal portion of the molecule was identified, as well as a number of differences in main-chain and side-chain conformations relative to the search molecule. Currently, R = 0.16 and $R_f = 0.20$.

M12.CC.004 WHAT THE CSD CAN TELL US ABOUT PSEUDO-SYMMETRY. Anthony L. Spek, Bijvoet Centre for Biomolecular research, Utrecht University, Utrecht 3584 CH, NL

The asymmetric part of a molecular crystal structure contains in general only one molecule. This situation is described as Z' = 1. Z' may be less than 1 when the molecule possesses a symmetry element that happens to coincide with a corresponding symmetry element in the crystal.

Molecular structures with Z' > 2 or higher are not uncommon. Steroids as an example often crystallize in pairs in space group $P2_1$ or $P2_12_12_1$. The interesting observation in such cases is that one can often discern pseudo symmetry relations between such 'dimers'. This local symmetry however doesn't appear to be (fully) compatible with the lattice symmetry.

This paper reports on our findings on this issue based on the data in the Cambridge Structural Database using the ADDSYM tool in PLATON. ADDSYM is an extended version of the powerful MISSYM algorithm (Y. Le Page) for detecting missed (real) symmetry. ADDSYM, though designed to point at 'Marshable' structure reports, turns out to be also useful as a tool to point at interesting cases of pseudo-symmetry.

The complete CSD (about 200000 entries) has been run through PLATON/ADDSYM providing a list of more than 3000 cases of missed or pseudo-symmetry. A few examples of pseudo-symmetry thus found will be discussed in some detail (e.g. a structure in $P2_1$ with Z' = 2, beta near to 90 degrees and pseudo $P2_12_12_1$).

M12.CC.005 PSEUDOSYMMETRY (OR NOT) IN STRUCTURES HAVING Z'>1. Carolyn Pratt Brock and Brian O. Patrick, Department of Chemistry, University of Kentucky, Lexington, KY 40506-0055, USA.

Many structures having Z'>1 are pseudosymmetric, but some are not. The latter group includes those crystals in which an important set of intermolecular interactions is incompatible with crystallographic symmetry. Examples of such structures include those of some monoalcohols C_nH_mOH and *vicinal*-dialcohols $C_nH_m(OH)_2$. Molecules that fill space poorly (*e.g.*, simple biphenyl derivatives) also seem to be more likely than most to crystallize with Z'>1.

Pseudosymmetric structures having Z'>1 may result from crystal cooling. Any solid-solid phase transition encountered during cooling will almost certainly reduce crystal symmetry. Such transitions are more likely if there is a large-amplitude thermal vibration at the temperature of crystal growth. The decrease in vibrational amplitudes with with decrease in temperature often leads to unfavorable intermolecular contacts that can be resolved by small, symmetry-breaking displacements. Examples of such structures include those of the linear polyphenyls.

Enantiomerically pure materials quite often pack so that two independent molecules are related by an approximate inversion center.

Other structures with Z'>1 are highly pseudosymmetric for no obvious reason. Crystals studied at room temperature may, of course, have been grown by precipitation during cooling of a hot solution. This explanation, however, does not explain all the structures in this class.

Several structures of this last type will be discussed. In some cases the structures are so pseudosymmetric that they can be refined in a higher symmetry cell with a subset of the intensity data to R < 0.10. The displacement ellipsoids resulting from such refinements then show quite clearly how the independent molecules actually differ. Possible reasons for the symmetry breaking will be discussed.

M12.CC.006 TWINNING AND POLYMORPHISM IN *o*-NITROANILINE. M.Nieuwenhuyzen, School of Chemistry, The Queen's University of Belfast, Belfast BT9 5AG, Northern Ireland.

The polymorphic nature of *o*-nitroaniline has long been known, although to date only one form has been characterised crystallographically, in 1978 Dhaneshwar *et al* determined the structure of the γ form[1]. As part of an extensive examination of amino-nitro substituted systems and their tendency to be polymorphic[2-3], this structure was re-determined as well as the structure of a second polymorph. This presentation compares and contrasts the hydrogen bonding motifs in these materials and examines the nature of the twinning in these two polymorphs. Data collected using station 9.8, a Bruker SMART system and the Siemens P4 are compared and contrasted.

M12.CC.007 CRYSTAL STRUCTURE OF $La_{0.8}MnO_{3-\delta}$ C.M.R. THIN FILM BEFORE AND AFTER ANNEALING ; X.R.D., T.E.M., X.A.N.E.S. STUDIES. H. Vincent, M. Audier, S. Pignard, G. Dezanneau, J.P. Senateur, LMGP (CNRS UMR 5628), ENS de Physique de Grenoble, BP 46, 38402 St Martin d'Heres, France.

Thin films of $La_{1-x}MnO_{3-\delta}$ composition have been deposited by a new patented process, called Injection-MOCVD [1]. Films deposited on MgO are epitaxial. For x=0.2, the as-deposited film has a semiconducting-metal and para-ferromagnetic transition at about 220 K ; after annealing under air during 3 h at 700°C, this transition temperature is about 310 K. Annealed film presents at room temperature and under low magnetic film one of the best known magnetoresistive sensitivity (30% per Tesla in [0,

1 T] range) [2]. In order to understand this performance improvement, we studied the crystal structure of this film, before and after annealing. For the first time to our knownledge, X.R. data collections have been recorded from an 1 mm^2 thin film piece, using a classical 4-Circle-diffractometer designed for single crystals. About 5000 reflections have been measured in each case from two pieces of the same film, one as deposited, the other one after annealing. Both films have apparent cubic symmetry and their cell parameter is twice the classical perovskite one. In fact, the true crystal structure is monoclinic and microdomain twinned. Space groups are nevertheless different I2/b and $P2_1/a$. Atomic positions of all the atoms have been determined using SHELXL-93 and MXD [3] refinement programs ; R and wR factors calculated on F^2 (730 independant reflections with $I / \sigma(I) \geq 2$) are about 6%. The as-deposited film is found lacunar on oxygen sites too ; annealing under air reduces the vacancy rate and increases the Mn^{4+} / Mn^{3+} ratio. XANES study confirms these results and estimates at 23% the increasing of this ratio. T.E.M. observations performed on both films agree completely with previous conclusions. Moreover they show that some MgO substrate areas close to the film are constrained and distorded after annealing ; their lattice becomes cubic F with a cell parameter twice the MgO usual one [4].

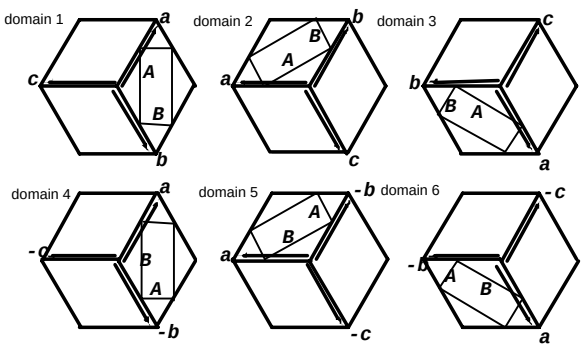
P12.CC.001 STRUCTURE REFINEMENT OF Cu_8GeS_6 II USING X-RAY DIFFRACTION DATA FROM A MULTIPLE- TWINNED CRYSTAL. M. Onoda, X.-a. Chen, K. Kato, A. Sato & H. Wada, National Institute for Researches in Inorganic Materials, Namiki 1-1, Tsukuba, Ibaraki, 305-0044, Japan.

The structure of the orthorhombic room-temperature phase Cu_8GeS_6 II has been refined on the basis of X-ray diffraction data from a 12-fold twinned crystal applying a six-dimensional twin refinement technique. For 1804 unique reflections measured using MoKα radiation, R_F was 0.083 with 77 structure parameters and 12 scale factors. The symmetry operations and the unit cell are (0,0,0; 1/2,1/2,0)+ x,y,z; y,x,z; 1/4-x,3/4-y,1/2+z; 3/4-y,1/4-x,1/2+z; a=b=9.9073(3)Å, c=9.8703(4)Å, α=β=90°, γ=90.642(4)°. The standard setting of the space group and the reduced unit cell are $Pmn2_1$; A=7.0445(3), B=6.9661(3), C=9.8699(5)Å.

Fig. 1 The major twin domains 1-6. The minor twin domains 7-12 are related to the domains 1-6 by a two-fold rotation on [111] respectively.



P12.CC.003 NON-MEROHEDRAL TWINNING AND THE CCD AREA DETECTOR Victor G. Young, Jr. [1] and Robert A. Sparks [2], [1] Department of Chemistry, University of Minnesota, Minneapolis, MN 55455, USA, [2] Bruker-AXS, Inc., 6300 Enterprise Lane, Madison, WI 53719, USA

Non-merohedral twinning is a better understood problem since the arrival of CCD area-detector diffractometers in our laboratories. These have not only increased the throughput for straightforward structure determinations, but have also provided a superior tool to assist in the unravelling of tangled reciprocal lattices brought about by non-merohedral twinning. This presentation will include discussion of strategies for indexing, data collection, integration of intensities, and least-squares refinement. Strategies for handling the partial overlap of reflections will be discussed. Examples of all common non-merohedral twinning motifs will be examined.

P12.CC.004 TURKISH ORNAMENTS ARE TWINS OF CRYSTALS. H.Necefoglu, Department of Chemistry, Faculty of Arts and Sciences, Kafkas University, Kars, TURKEY

In this report crystallographic aspects of ancient, medieval and modern Turkish ornaments are deal with. Crystallographic Patterns (CPs) are considerably different from other patterns. In the process of the construction of CPs, symmetry appears as a result of combination, but not as a means of its formation as is characteristic of other ornaments. Their symmetries are analogous with symmetries of natural objects. The atoms and molecules dispose themselves in crystals just as elements arrange themselves in CPs. In other words, CPs are constructed according to the same principle of crystal formation, i. e. the principle of tight packing.

The following are characteristic of CPs: The edge of ornament elements draw the edge of the figure; Maximal compactness of the ornament elements; Lack of background or transformation of background to ornament elements; Minimisation of the variety of ornament elements; Symmetry is not used for form creation, and it appears as a result.

The similarity (isomorphism) of crystals and ornaments enables us to describe the ornaments with structural analysis terms, and the similarity between ornaments and crystal structures can also be used in chemistry education. This will bring an aesthetical aspect to education. An invisible part of nature can be studied as ornament creation.

Each newly created CP is the structural scheme of a number of possible compounds. The familiarity with such ornaments and the ability to create them are important in solving compound structures.

12DD COMBINED POWDER DIFFRACTION, EXAFS AND DAFS

M12.DD.001 CHARACTERISING SEMICONDUCTOR NANO-PARTICLES WITH IN SITU EXAFS, XRD AND SAXS. GN Greaves* and G Sankar† *Department of Physics, University of Wales, Aberystwyth, SY23 3BZ, UK †The Royal Institution, 21 Albemarle Street, London, WX1 4BS, UK

Both EXAFS and X-ray Powder Diffraction (XRD) have been combined with Small Angle X-ray Scattering (SAXS) to characterise the nucleation of semiconductor nano-particles in cadmium exchanged sodium zeolite Y (Cd/Na:Y). X-ray experiments have been performed at the Synchrotron Radiation Source (SRS) using a specially developed miniature muffle furnace with large scattering windows. After ion exchange Cd/Na:Y was treated with sodium hydroxide, which is known to promote the precipitation of semiconductor particles. Following heating to 500(C, these were identified from cadmium EXAFS as cadmium oxide crystallites. With a size, estimated from the

cadmium shell coordination number, of 15Å+/-10Å, the nanoparticles were not evident in XRD. Instead XRD recorded the crystallography of the host through dehydration to eventual collapse to an amorphised high density phase at temperatures in excess of ~650°C. Exploring 0.0015<q<0.7Å-1, SAXS revealed a change from bulk fractal scattering to Porod scattering, identified as resulting from the semiconductor nanophase - the crossover yielding a characteristic particle size of ~20+/-5Å. Moreover the dimesionallity of the semiconductor microstructure was found to change with rising temperature, eventually becoming 3 dimensional above 450°C. In a parallel study, cadmium oxide was synthesised from a cadmium hydroxide gel utilising the same temperature schedule as for Cd/Na:Y. The kinetics of the transformation from Cd(OH)2 to CdO were determined from XRD - the linewidths pointing to particle sizes developing from 140Å to 270Å by 560°C. Interestingly, the SAXS invariant and the onset of Porod scattering were found to progress in an analogous fashion to the synthesis of cadmium oxide incarcerated in zeolite Y. In particular the development of particle volume and nanocrystalline dimensionallity point to dendritic growth, with the exception that particle sizes are significantly larger for unconstrained growth.

M12.DD.002 COMBINED XRD, XAFS AND PL FOR HIGH PRESSURE STUDIES. A.V. Sapelkin and S. Bayliss Department of Chemistry and Physics, School of Applied Sciences, De Montfort University, The Gateway, Leicester, LE1 9BH, UK

A new facility for simultaneous EXAFS, XRD and Photoluminescence (PL) measurements under high pressures is being developed for use on station 9.3 at Daresbury Laboratory. The rig includes translational and rotational stages for positioning the sample mounted inside a diamond anvil high pressure cell. Translations are necessary to align the sample in the x-ray beam and rotations are required to minimize influence of diamond glitches in the EXAFS spectrum. PL spectroscopy is carried out using a He-Cd (325 nm and 442 nm wavelengths) laser and spectrometer. Data acquisition facilitates motor control and a video camera and monitor is used for remote sample alignment. Pressure calibration is carried out with the above optical system using the fluorescence from ruby chips mounted with the sample inside the diamond anvil cell. The idea of the development of the high pressure facility (code named HI-PREXX) is to enable users to make multi-technique high pressure experiments at any suitable station at a synchrotron source. Furthermore full remote operation of the rig allows simultaneous collection of optical and structural data whilst varying the pressure. The set-up is very flexible and can be tailored for a particular experiment, such as time or temperature-dependent measurements. The Hi-PREXX system will be described, and results presented from initial experiments conducted on the 1-BM-A beamline at the APS and on Station 9.3 at Daresbury Laboratory. Analysis of data from high pressure experiments on amorphous and crystalline GaSb and crystalline and nanocrystalline GaN will be given. Particular attention will be paid to comparing the use of Energy Dispersive EXAFS (EDE) and Quick Scanning EXAFS (QUEXAFS) techniques under pressure in conjunction with XRD. Finally, points associated with the equipment development and beamline properties for future experiments will be discussed.

M12.DD.003 MEASURING XRD/XAFS FROM HIGH TEMPERATURE OXIDES AND LIQUIDS. C. Landron, Centre de Recherches sur les Materiaux a Haute Temperature, CNRS, 45071 Orleans cedex 2, France.

In-situ characterisation has been performed on various oxides at very high temperature by using a laser heating system and aerodynamic levitation. A containerless investigation by synchrotron radiation has been used on the basis of the combination of X-ray Absorption Spectrometry in fluorescence mode and X-ray Diffraction on millimetre sized spheres of refractory oxides. For this, an analysis cell, operating under various gas conditions from room temperature up to 2800°C, has been developed.

Experiments have been carried out at LURE (Orsay, France), at ESRF [1] (Grenoble, France) and at SRS (Daresbury, UK) [2]. We have studied the long-range order and the local structure in YAG, zirconia, iron oxides and rare-earth oxides. We have shown that the X-ray absorption and X-ray diffraction data, calculated from in-situ synchrotron radiation experiments, contain valuable information on the different types of disorder in solid oxides. This technique proposes also an opportunity to gain a complete insight into the local structure in liquids. The information is directly derived from the temperature dependence of the spectra with the characteristic parameters of the structure described by the pair correlation function. The synchrotron radiation data obtained by this contactless technique present implications for the understanding of the solidification process in liquid oxides by crystallisation or vitrification.

M12.DD.004 COMBINED EXAFS-XRD APPLIED TO ORGANIC SOLID STATE REACTIONS. M. Epple. Institute of Inorganic and Applied Chemistry, University of Hamburg, Martin-Luther-King-Platz 6, D-20146 Hamburg, Germany

X-ray absorption spectroscopy (EXAFS) and X-ray diffraction (XRD) represent complementary methods for the study of solid compounds. While diffraction techniques yield specific information on the long-range order, EXAFS gives information on the Ångstrom scale around specific elements. Contrary to diffraction, EXAFS does not require long-range order, therefore liquid and amorphous phases can be detected as well. The combination of both techniques is especially powerful if they are applied in-situ, i.e. during a solid-state reaction. Detection of both short- and long-range order can uncover intermediate phases and identify final products. Quantitative evaluation of both methods is possible, and the reaction extent can be computed for all phases present.

Reactions involving molecular crystals ("organic solid state reactions") are of importance, e.g., in materials science and in pharmaceutical technology. Unfortunately, the most common elements in organic compounds (hydrogen, carbon, oxygen, nitrogen) are not available for EXAFS analysis, therefore heavier elements (like, Cl, Br) must be present if the method is to be applied. Examples for successful applications of the combined EXAFS-XRD technique that gave through insight into solid-state reaction mechanisms will be reported.

M12.DD.005 RECENT DEVELOPMENTS IN D.A.F.S. J.L. Hodeau, H. Renevier, S. Bos, V. Favre-Nicolin, P. Wolfers, Laboratoire de Cristallographie - CNRS, BP 166, 38042 Grenoble 9, France

The Diffraction Anomalous Fine Structure (DAFS) spectroscopy provides in the same experiment information regarding the local atomic environment through X-ray absorption processes and long-range order information through diffraction processes. Anomalous scattering and DAFS can provide site selective and chemical selective structural information.

After an introduction to the DAFS spectroscopy, we will show the experimental requirements for such studies. Efforts are being made at different Synchrotron Radiation Facilities to

develop the data acquisition with different experimental set-up: a) the energy-scanned one which uses classical monochromatic optics (J.O. Cross et al. J. Synchrotron Rad. 5, 911 (1998)) and b) the Dispersive Diffraction one that uses dispersive optics and a 2D position sensitive detector (N. Sugioka et al. J. Synchrotron Rad. 5, 908 (1998), V. Favre-Nicolin et al. J. Appl. Cryst submitted). We will briefly present these two set-ups and discuss their strengths and limitations. We will also present the analysis of the EDAFS oscillations (Extended DAFS) and point out the interest of using the DAFS spectra to recover quantitative information about the crystallographic structure and particularly the positions and Debye Waller factors of the anomalous atoms.

At last we will report different applications of the DAFS spectroscopy: (i) the study of strained III-V semiconductor thin films by using both a single first shell analysis and a multishell analysis; (ii) the use of DAFS site selectivity in superlattices to obtain information about their interfaces; (iii) DAFS site specification to separate overlapping X-ray absorption edges;

(iv) the use of DAFS spatial selectivity in powdered catalytic samples containing diluted particles; (v) valence difference studies on manganese oxide powders; (vi) DAFS on superlattice or forbidden reflections in oxides to extract the precise positions of the anomalous atoms.

12EE PEROVSKITE AND RELATED MATERIALS

M12.EE.001 LOW TEMPERATURE CRYSTALLOGRAPHIC STUDY OF THE $HgBa_2CuO_{4+\delta}$ HIGH Tc SUPERCONDUCTOR. Pierre Bordet and Fabienne Duc, Laboratoire de Cristallographie CNRS, BP166, 38042, Grenoble Cedex 9, France

Recent theoretical as well as experimental works have focused on the importance of the charge inhomogeneities in the CuO_2 planes for the mechanism of superconductivity in the High-Tc cuprates. For most of these compounds, such weak effects are in competition with lattice distortions due to bond mismatch, which can lead to strong structural changes with temperature (phase transitions, superstructures). The High-Tc mercury cuprates are free of such bond mismatch, because of the quasi-absence of in-plane bonds in the reservoir layers. Hg-1201 is the best candidate for precise structural studies, due to its simplicity, and the absence of stacking faults.

In order to investigate the existence of structural distortions in the Hg-1201 compound, we have undertaken a detailed low temperature structural study by means of single crystal x-ray and synchrotron diffraction, powder neutron diffraction and EXAFS.

Static disorder in the HgO_δ layers reveals the tendency toward formation of weak Hg-O bonds in the presence of extra oxygens. The observation of diffuse scattering could be related to short range ordering of such bonds or to charge inhomogeneities in the CuO_2 planes. Strong anharmonic displacements of the cations as well as anisotropy of the thermal parameters indicate a marked difference between the average and local structures. This is confirmed by coupled EXAFS and neutron data which reveal an anomalous behavior of the Cu-O and Cu-Ba displacement correlations above Tc.

M12.EE.002 COMPUTER MODELING, GROUP THEORETICAL ANALYSIS AND STRUCTURE PREDICTION OF DISTORTED PEROVSKITES P.M. Woodward, P.N. Santhosh [1], H.T. Stokes [2] and J.L. Fiallega [3]: [1] Department of Chemistry, Ohio State University, Columbus, OH 43210-1185, [2] Department of Physics and Astronomy, Brigham Young University, Provo, UT 84602-4675, [3] FDP Corporation, 2140 S. Dixie Highway, Miami, FL 33133

Perovksite and perovskite related materials make up one of the most prevalent and important structure families in all of materials science. The aristotype perovskite structure is very simple. However, the vast majority of perovskite materials are distorted from the ideal structure. We have examined the structural features which result when octahedral tilting distortions are combined with (a) 1:1 cation ordering in $A_2MM'X_6$ compounds, (b) 2:1 cation ordering in $A_3M_2M'X_9$ compounds, (c) layered cation ordering in $AA'M_2X_6$ and $AA'MM'X_6$ compounds and (d) Jahn-Teller distortions of the MX_6 octahedra. Using the principles of group theory and symmetry, complete crystallographic descriptions (space groups, lattice parameters, atomic positions) of the structures, which result from the combined action of octahedral tilting and (a) – (d) above, have been determined.

Analyzing the combined effect of octahedral tilting with cation ordering and/or Jahn-Teller distortions on the A-site coordination sphere, allows us to identify those combinations which lead to the most stable structures. The stability of $A_2MM'X_6$ structures, where M' is a Jahn-Teller ion (i.e. Mn^{3+}) and M has regular octahedral coordination (i.e. Mn^{4+}), has implications for structural studies involving charge ordering in the $Ln_{1-x}A_xMnO_3$ perovskites.

As a result of this work the software program SPuDS has been developed to calculate crystal structures of distorted perovskites using only the composition as input. The accuracy, availability and potential uses associated with this software package will be discussed.

M12.EE.003 CHARGE SEGREGATION IN $RNiO_3$ PEROVSKITES: SIMULTANEOUS METAL-INSULATOR AND STRUCTURAL TRANSITION. M.T. Fernández-Díaz, Institut Laue-Langevin, B.P. 156X, F-38042 Grenoble Cedex, France, J.A. Alonso, M.J. Martínez-Lope, M.T. Casais, Instituto de Ciencia de Materiales de Madrid, C.S.I.C., Cantoblanco, E-28049 Madrid, Spain, J.L. García-Muñoz, Institut de Ciència de Materials de Barcelona, C.S.I.C., Campus UAB, Bellaterra, E-08193 Barcelona, Spain and M.A.G. Aranda, Departamento de Química Inorgánica, Cristalografía y Mineralogía, Facultad de Ciencias, Universidad de Málaga, E-29071 Málaga, Spain.

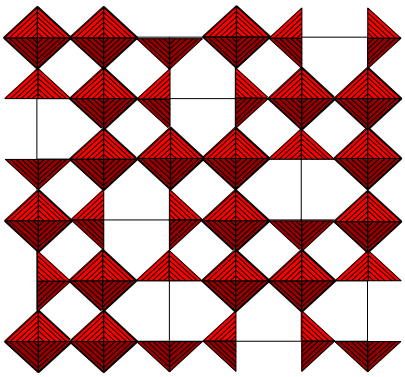
$RNiO_3$ perovskites (R = 4f rare earth) are one of the few families of undoped oxides showing a metal to insulator transition as a function of temperature. The origin this first-order transition has been one of the long-standing questions associated with these compounds.

Our neutron and synchrotron diffraction data of small-rare-earth members of the series provide the first observation of changes in the crystal symmetry at the metal-insulator (MI) transition in $RNiO_3$ perovskites. At high temperatures, $RNiO_3$ are orthorhombic and metallic and below T_{MI} they change to a monoclinic insulator. This fact unambiguously shows the tight electron-lattice coupling. The structural reorganization at T_{MI} gives rise to two crystallographically independent Ni positions and the insulating phase consist of alternating expanded ($Ni1O_6$) and contracted ($Ni2O_6$) octahedra along the three directions of the crystal cell. This finding indicates a mutual self-doping process occurs, in which there is an accumulation of extra charge at Ni1 sites at expenses of inducing charge defects at the adjacent Ni2 sites. This charge modulation phenomenon of wave vector $\mathbf{k}_{cubic}$ = (1/2,1/2,1/2) in the pseudocubic basis is the driving force for the orthorhombic to monoclinic transition concurrent with the metal to insulator transition.

From the magnetic point of view, the antiferromagnetic structure of the Ni sublattice is the same to the one previously reported for less distorted $RNiO_3$ compounds, with a magnetic propagation vector $\mathbf{k}_{mag}$ = (1/2,0,1/2).

M12.EE.004 OXYGEN VACANCY STRUCTURES: A NEW ROUTE TO METASTABLE CMR RUDDLESDEN-POPPER PHASES J. F. Mitchell, J.E. Millburn, M. Medarde, A. Berger, D.N. Argyriou, Materials Science Division, Argonne National Laboratory, Argonne, IL 60439 USA

By use of intermediates containing large numbers of oxygen vacancies, we have extended the phase diagram of the Ruddlesden-Popper (R-P) series $La_{1-2x}Sr_{1+2x}Mn_2O_7$ beyond the normally accessible range $0.3 \leq x \leq 0.5$ and into the Mn^{4+}-rich regime. Colossal magnetoresistive (CMR) manganites display a fantastic range of structural, magnetic, and electronic phases as a function of hole concentration, temperature, magnetic field, etc. Although the bulk of research has concentrated on the 3-D perovskite manganites, the ability to study anisotropic magnetic and electronic interactions made available in reduced dimensions has prompted growing interest in the R-P phases of the manganite class. By using high temperature techniques to synthesize oxygen deficient inter-mediates, we have succeeded in making metastable phases with $0.5 \leq x \leq 1.0$. The intermediate compounds are unusual among oxygen vacancy structures in the R-P class, as the vacancies lie in the nominally MnO_2 conduction planes rather than between them. We will describe the synthesis, crystal and magnetic structure, and properties of these phases and explore the broader picture of the electronic and magnetic phase diagrams of these layered materials. We will also discuss the existence of ordered oxygen vacancy structures and highlight the extreme sensitivity of these structures to cation stoichiometry.



M12.EE.005 ORDER DISORDER IN $LnBaMn_2O_{6-x}$ PEROVSKITES. V. Caignaert, F. Millange, B. Domenges and B. Raveau, CRISMAT-ISMRa, Bd du M[al] Juin, F-14050 Caen, and E. Suard, Institut Laue Langevin, Av. des Martyrs, F-38042 Grenoble

Cation ordering in perovskite structures may induce physical properties that differ from those of disordered allotypes. Only few studies evidence this phenomenon owing to the difficulty to obtain the disordered and ordered forms. The disordered cubic perovskites $LnBaMn_2O_6$ (*Ln= La*, *Pr*, *Nd*) have been synthesized by solid state reaction and compared to the ordered perovskites, obtained by topotactic oxidation of $LnBaMn_2O_5$ oxygen-deficient perovskites.

The $LnBaMn_2O_5$ compounds (*Ln= La-Ho*, *Y*), synthesized under inert atmosphere, crystallized with the tetragonal space group P4/nmm ($a \approx \sqrt{2}a_p$, $c \approx 2a_p$ where a_p is the cell parameter of the cubic perovskite). The structure, allotype of $YBaCuFeO_5$, is described with an alternate stacking of rare earth and barium layers along the *c* axis. In addition the Mn^{+2} and Mn^{+3} cations adopt a rock-salt arrangement. The two magnetic sublattices are connected by an antiferromagnetic interaction, which lead to a ferrimagnetic behavior. The sign and the intensity of superexchange interaction in the (ab) plane are related to the value of the Mn^{+2}-O-Mn^{+3} angle.

The structure and the magnetic properties of the ordered $LnBaMn_2O_6$ depend of the rare-earth ionic radius. The Lanthanum compound is tetragonal (space group: P4/mmm; $a \approx a_p$, $c \approx 2a_p$) and ferromagnetic (F) while the Neodymium is orthorhombic (space group: Cmma; $a \approx b \approx c \approx 2a_p$) and antiferromagnetic (AF). Two magnetic transitions are observed in $PrBaMn_2O_6$. The comparison between the ordered and disordered compounds reveals strong differences in the physical properties.

By topotactic reduction of $LnBaMn_2O_6$, new oxygen-deficient perovskites $LnBaMn_2O_{5.5}$ (*Ln= La-Ho*, *Y*), are synthesized (space group: Ammm; $a \approx a_p$, $b \approx 2a_p$, $c \approx 4a_p$).

P12.EE.001 IN-SITU NEUTRON DIFFRACTION STUDY OF MIXED CONDUCTIVITY $SrFeCo_{0.5}O_Y$ MATERIAL, B.J. Mitchell and J.W. Richardson Jr., IPNS, Argonne National Laboratory, 60439, IL, USA, B. Ma and U. Balachandran, ET, Argonne National Laboratory, J.P. Hodges and J.D. Jorgensen, MSD, Argonne National Laboratory.

$SrFe_{1-x}Co_xO_y$ mixed ionic and electronic conductors possessing high oxygen permeability have created considerable interest for use as oxygen separation membranes. $SrFeCo_{0.5}O_y$ (SFC2) was shown to have the best properties in this series [1]. SFC2 is actually a complex assembly of phases; the composition and weight fractions dependent upon temperature and oxygen partial pressure. In-situ and ex-situ diffraction studies have identified $SrFe_{1.5-a}Co_aO_y$ (236), $SrFe_{1-b}Co_bO_{3-\delta}$ (perovskite), $(Co_{1-c}Fe_c)_3O_3$ (rocksalt) and $(Co_{1-c}Fe_c)_3O_4$ (spinel) to be present under certain conditions. We shall demonstrate that the 236 perovskite-rocksalt intergrowth crystal structure as described in the literature [2] is incorrect, and describe the variable nature of the cobalt and oxygen contents of individual phases under synthesis conditions and at oxygen partial pressures believed to be present across operational ceramic membranes.

B. Ma, U. Balachandran, B.J. Mitchell, J.W. Richardson Jr., J.P. Hodges, J.D. Jorgensen, "Oxygen Transport in the $Sr_2Fe_{3-x}Co_xO_y$ System", MRS Fall Meeting Boston, December 1998.

P12.EE.002 SUPERCONDUCTING CUPRATES: FROM LAYERS THROUGH LADDERS TO CHAINS. T.I. Ivanova, O.V. Frank-Kamenetskaya and I.V. Rozhdestvenskaya, Department of Crystallography, Saint-Petersburg State University, 199034 Saint-Petersburg, Russia.

In the past few years the attention was being gradually shifted towards the degradation of dimensionality of the Cu-O modules in the structures of the superconducting (SC) cuprates seeking for the one which is intrinsically related to the appearance of SC state. It turned from *two-dimensional* infinite CuO_2-planes in various perovskite-like phases through *quasi-one-dimensional* Cu_2O_3-planes containing two-legged ladders in $(Sr,Ca)_{14}Cu_{24}O_{41+y}$ (T_c = 12-9 K at a pressure of 3-4.5 GPa) [1] to *one-dimensional* infinite CuO_2-chains in the ladder compound and in the newly synthesised $Ba_2Cu_{3-x}O_{6-y}$ crystals (T_c = 5-13 K) [2]. All the modules consist of similar CuO_4-squares but have different mode of their linkage. The squares share either corners to form CuO_2-planes or edges to form CuO_2-chains. Ladders represent the case where corner- and edge-sharing squares alternate. The coincidence of the temperatures of SC transitions in $Ba_2Cu_{3-x}O_{6-y}$ and in the ladder compound with the temperature (10 K) of the sharp magnetic transition in another infinite-chain compound $Sr_{0.73}CuO_2$ [3] seems to be intriguing.

Reported is the $Ba_2Cu_{2.89}O_{6-y}$ crystal structure (sp.gr. ***Pccm***, ***a*** = 13.065, ***b*** = 20.654 and ***c*** = 11.431 Å [4]). It contains parallel CuO_2-chains assembled into sheets which are separated by the layers of Ba atoms. The primary difference between the structures of all known infinite-chain compounds appears to be in the mode of stacking of Cu-O sheets along *c*-axis. They are shifted in [100] direction by ½ of Cu-Cu distance in $Sr_{0.73}CuO_2$ and in the CuO_2-substructure of ladder compound but are rotated by 115.4° in $Ba_2Cu_{2.89}O_{6-y}$. This defines the differences in the symmetry of their crystal structures but suggests the similarity of the translations normal to the layers.

The work was supported by INTAS and by Russian Council of Ministers.

P12.EE.003 CRYSTAL STRUCTURE DETERMINATION AND RIETVELD REFINEMENT OF NB-DOPED $PB(ZR_{0.97}TI_{0.03})O_3$ CERAMIC MATERIAL. Hongchao Liu and Hideo Toraya, Ceramics Research Laboratory, Nagoya Institute of Technology, Asahigaoka, Tajimi 507-0071, Japan

ab initio crystal structure analysis and Rietveld refinement were employed to investigate the crystal structures of $Pb(Zr_{1-x}Ti_x)O_3$ [PZT (1-x/x)] series ceramic materials. In this work, the crystal structure of a orthorhombic phase of Nb-doped $Pb(Zr_{0.97}Ti_{0.03})O_3$ ceramic material was reported. For complex distortion in the crystal structure, the powder diffraction data were collected with high-resolution synchrotron radiation source. The orthorhombic symmetry was confirmed by the indexing procedure. However, the Rietveld refinement showed that the diffraction pattern of this ceramic material could not be fitted well with published structural models of space group Pbam and Pba2. The whole pattern profile fitting and crystal structural analysis based on the powder diffraction data showed the most appropriate space group for this material is Pnnm, rather than the widely accepted Pbam or Pba2. The structure was then solved with space group Pnnm by the direct methods. The obtained structural parameters confirm that Zr atoms participate in the displacement along *z-axis*. They also support that local disorder appears in the oxygen substructure as observed by Glazer et al [1] in single crystal study, since the obtained amount of oxygen atoms is larger than the chemical formula shows. The origin of disorder was attributed to the existence of micro-domain smaller than x-ray coherence length in the studied ceramic material.

P12.EE.005 IN-SITU SYNCHROTRON DIFFRACTION STUDY OF THE HP-HT SYNTHESIS OF HIGH Tc MERCURY CUPRATES. P.Bordet, S. LeFloch, A. Prat, Laboratoire de Cristallographie CNRS, BP166, 38042, Grenoble Cedex 9, France, M. Mezouar, ESRF, BP220, 38043 Grenoble France

High-pressure high temperature synthesis techniques have been extensively used in the past few years for the discovery of new oxide materials, particularly high Tc superconducting oxides. However, the complexity in tuning the many synthesis parameters (starting material composition and oxidation state, pressure, temperature, gradients, etc.), as well as the impossibility to control the reaction mechanisms (but only by analysing the reaction products), has hindered the development of this powerful synthesis technique. This was particularly true in the case of the $HgBa_2Ca_{n-1}Cu_nO_{2n+2+\delta}$ series of high Tc cuprates, where the member obtained depends on precise oxidation state of the precursor material, and temperature range chosen. In order to get better insight into the reaction mechanism of these materials and to optimise their synthesis conditions, we have undertaken an in-situ synchrotron diffraction study at the ID30 beamline of the ESRF, using the Paris-Edinburgh large volume pressure cell. The combination of a high energy of 77 keV and fast 2D detector allowed us to obtained good quality diffraction spectra on the time scale of a minute up to ≈ 1200°C and 4GPa. The synthesis conditions used in the laboratory belt type apparatus for the synthesis of the Hg-1201 and Hg-1223 mercury cuprates were carefully reproduced (gold capsule, starting compositions, pressure and temperature). We could then determine the pressure and temperature stability ranges of the various phases involved in the reaction process, as well as the kinetics of reactions. For example, in the case of the Hg-1223 compound synthesis at 3GPa, the mixture of HgO and prereacted oxide precursor first form the $CaHgO_2$ compound which partly transforms on heating into a new $Ca_4Hg_6O_{10}$ high-pressure phase. These phases react at higher temperatures to form mercury cuprates of increasing n value at increasing temperature. Single phase Hg-1223 is then obtained at T=1000°C.

P12.EE.006 CRYSTAL STRUCTURE OF A FERROMAGNETIC SUPERCONDUCTOR. A. C. McLaughlin and J. P. Attfield, Department of Chemistry and IRC in Superconductivity, University of Cambridge, Cambridge CB2 1EW, UK, and A. N. Fitch, ESRF, BP 220, F-38420 Grenoble, France, and J. L. Tallon, Industrial Research Ltd., P.O. Box 13130, Lower Hutt, New Zealand.

A remarkable new ruthenocuprate has been prepared in which ferromagnetism and superconductivity co-exist at low temperatures [1]. The structure of this material has been refined using highly-resolved powder X-ray diffraction data collected on ESRF instrument BM16. Room temperature and 4 K data have been analysed, giving information about the twists and tilts of the metal oxide polyhedra within this layered structure.

P12.EE.007 SYNTHESIS OF FUNCTIONAL PEROVSKITE OXIDES WITH LANTHANUM IN A-SITE FROM AQUEOUS SOLUTIONS. T. Yao, Y. Uchimoto, T. Sugiyama and Y. Nagai, Department of Fundamental Energy Science, Graduate School of Energy Science, Kyoto University, Yoshida, Sakyo-ku, Kyoto, 606-8501, JAPAN

Functional perovskite oxides with lanthanum in A-site: $LaMeO_3$ (Me=Cr, Mn, Fe, Co or Ga) have interesting properties and now are paid a great attention as candidates for electrode, cathode, anode or interconnecting materials for solid oxide fuel cells and high-temperature steam electrolyzers. Thin films, either dense or porous, are desirable because of the high surface area, the reduction of both the ion-diffusion path length and electrical resistance, light and compact system construction and so on. Chemical vapor deposition, sputtering and sol-gel methods are used for preparing thin films, however, these methods have some disadvantages in actual use. For chemical vapor deposition and sputtering, expensive vacuum equipment is required and the film area is restricted. For sol-gel method, the film geometry is limited, and moreover, heat-treatment, which is injurious because of the possibility of a change in the shape and/or size of the film and crack formation, is inevitable to form crystalline states. A method for forming films from an aqueous solution is expected to be advantageous because no vacuum, no high temperature and no expensive apparatus will be required and substrates even with wide areas and/or complicated shapes are available. For the above reason, we have been studying about the synthesis of functional ceramic materials from aqueous solutions and we have presented the methods for synthesizing ZrO_2 and $LaCrO_3$, $LaMnO_3$, $LaFeO_3$ and $LaCoO_3$ from aqueous solutions[1,2,3], previously. Recently, we have developed the method and have made it possible to synthesize $LaGaO_3$ from aqueous solution.

Powder of $LaMeO_3$ perovskite was dissolved in hydrofluoric acid and a solution of fluoro-complex ions was obtained. Boric acid was added to the solution, the fluoride ions were consumed by the formation of BF_4-, and then the fluoro-complex ions were hydrolyzed to $LaMeO_3$ in order to increase the

amount of fluoride ions. X-ray diffraction peaks attributed to the respective perovskite oxides were observed on the soaked substrates. The peaks were sharp and strong enough to confirm the high crystallinity. A number of synthesized particles of $LaMeO_3$ were observed on the substrates in scanning electron microscope images.

P12.EE.008 ANOMALOUS MANGANESE-OXYGEN BOND COMPRESSIBILITY IN LAYERED MANGANITES. K. V. Kamenev, M. R. Lees, G. Balakrishnan and D. M^{c}K. Paul, Department of Physics, University of Warwick, Coventry CV4 7AL, UK.

We present the results of neutron diffraction study of $(La_{0.6}Nd_{0.4})_{1.2}Sr_{1.8}Mn_2O_7$ oxide by time-of-flight technique under pressures of up to 18 kbar. This material belongs to the class of double-layer manganites which became a subject of intense interest after a large magnetoresistance effect was found in $La_{1.2}Sr_{1.8}Mn_2O_7$ [1].

In the layered $(La_{0.6}Nd_{0.4})_{1.2}Sr_{1.8}Mn_2O_7$ the tetragonal lattice is composed of double MnO_2 sheets separated by $[(La_{0.6}Nd_{0.4})_{0.4}Sr_{0.6}]_2O_2$ NaCl-type block layers. Each manganese ion participates in three types of interatomic links: i) within the MnO_2 sheet; ii) between the adjacent MnO_2 sheets forming a double-layer; and iii) between the adjacent double-layers. We have found that in paramagnetic phase the manganese-oxygen covalent bond involved in the inter-double-layer link expands under applied pressure, while the other two types of bonds contract. We explain such an anomalous extension of the apical manganese-oxygen bond under pressure in terms of the electronegativity equalization principle.

The results of neutron diffraction are combined with high-pressure resistivity and magnetic ac susceptibility data to discuss the effect of structural changes on transport and magnetic properties of the layered manganites.

12FF TEACHING CRYSTALLOGRA|HY

M12.FF.001 EXPERIENCES IN TEACHING NEW TECHNIQUES TO THE CRYSTALLOGRAPHIC COMMUNITY. Bi-Cheng Wang, Department of Biochemistry and Molecular Biology, University of Georgia, Athens, GA 30602 U.S.A

In the last decade, we have witnessed a revolution in crystallographic methodology and the expansion of crystallography into many new scientific disciplines.

To provide students with necessary crystallographic knowledge to meet todayís challenges, we at the University of Georgia (UGA) have emphasized both the basics of crystallography and the application of the latest crystallographic techniques. Students at UGA are offered a number of crystallography courses including: a one-semester graduate course in crystallography as well as numerous lectures on crystallography in several other graduate and undergraduate courses.

Since 1997, UGA has hosted the American Crystallographic Association (ACA) Summer Course in Crystallography. This is an intensive 12-day course with lectures in mornings and evenings, and hands-on laboratory sessions in afternoons. The first eight days of the Course are devoted to fundamental crystallography as applied to small molecule crystallography. The last four days of the Course are on the application of crystallography to macromolecular structures. For 1999 Summer Course information see www.uga.edu/~biocryst/ACA99.html.

The data collection facilities on the UGA campus, include Nonius and Bruker single crystal diffractometers, Rigaku and MarResearch image plate detectors and a Bruker CCD detector as well as Silicon Graphics workstations in the UGAís Molecular Graphics Laboratory have been used in lectures, hands-on experiments, and demonstration in the Summer Course.

In the past two years, UGA has also hosted the Bruker and R-Axis Users Group Meetings. These meetings provide the crystallographic community an opportunity to learn from experienced users about data collection hardware and techniques, data processing programs, structure determination packages, and the use of second and third generation synchrotron sources.

Aspects of the ACA Summer Course and the Bruker and R-Axis Users Meetings will be discussed.

M12.FF.002 TEACHING CRYSTALLOGRAPHY ON THE INTERNET. David S Moss, Clare E Sansom, Jeremy K Cockcroft, Ian J Tickle and Huub P C Driessen. Department of Crystallography, Birkbeck College, Malet St., London WC1E 7HX, UK.

The Department of Crystallography at Birkbeck College has been a pioneer in delivering formal courses at advanced University level using the medium of the Internet. Our Advanced Certificate Courses in Principles of Protein Structure (PPS) and Protein Crystallography (PX) are accredited, one-year, part-time courses that lead to the award of an Advanced Certificate from London University. Principles of Protein Structure has run as an accredited course every year since 1996, and over 150 students have completed it. The protein crystallography course was offered for the first time in the 1997-8 academic year. Four PPS graduates have taken, or are currently taking, this course. Many students on both courses work in the pharmaceutical industry. Others take one of our courses as part of their graduate studies programme; some of these come from emerging economic areas. Forty students from central and eastern Europe have taken the PPS course with bursaries from the Open Society Institute.

Course material is distributed via the World Wide Web, with a new section released every few weeks. The material is developed in-house but makes extensive use of many excellent Internet resources for structural biology: pre-eminently, of course, the Protein Data Bank. Interaction between students and tutors takes place via email discussion lists and tutorials using the “BioMOO” virtual reality conference system. In these tutorials, students can question their tutors about any aspect of the course in “real time”. Formal assessment consists of an examination, for which students need to attend in person at one of a number of local centres, and project work. A new course, the Advanced Certificate in Powder Diffraction, will be starting in October 1999 and we hope to be able to offer Internet-based M.Sc. degrees in structural biology from 2000.

M12.FF.003 CRYSTALLOGRAPHY FOR MATERIALS SCIENTISTS - THE MATTER SOFTWARE CONSORTIUM. Peter J Goodhew, Ann Fretwell, Andrew Green, MATTER Project, Materials Science & Engineering, University of Liverpool, L69 3GH, UK

The MATTER project is supported by a consortium of 19 Universities and its aim is to produce and support software for use in the teaching of materials science. 20 modules have been produced so far, covering a large range of subject matter. Protocols have been developed for the production and evaluation of each module and this typically involves collaboration between one or two academics and members of the development team.

Undergraduate crystallography teaching is supported by a new software module in the MATTER series. This is described

here as an illustration of the approach. The module exploits the interactive and graphical capabilities of the computer in presenting concepts which are of key importance to students of materials science. These include symmetry operations, point and space groups, indexing of planes and directions and the building of common structures using space-filling spherical atoms.

The approach adopted in the module is to start from two dimensional lattices, which provide a less extensive set of rules and examples which are easier for the student to master. Three dimensional lattices are then developed in a fairly conventional way. The use of interactive exercises ensures that understanding is developed as the student proceeds. Graphical interactions are used where they are most effective. First-year classes have been taught using this module and assessed using a companion software package. Student and staff response has been very positive, particularly to the computer-based assessment.

A further module on introductory diffraction follows a similar style. Extracts from both modules will be used to illustrate the presentation. Further details of these and other modules produced by the MATTER team can be found at www.liv.ac.uk/~matter/home.html.

M12.FF.004 TEACHING POWDER DIFFRACTION FOR MATERIALS SCIENCE. Karimat El-Sayed, Physics Department, Ain Shams University, Cairo, Egypt

The plan of the topics was designed according to the need of other courses given to the M.Sc materials science students. The contents of the powder diffraction course were perfectly selected from lectures given by International lecturers (experts in powder diffraction) at schools held in Egypt. Their lectures as well as their practical sessions and lectures materials were the sources of the development of the powder diffraction course presented in this paper. In the I U Cr XVII Congress (1996) at Seattle, USA, a short talk was given about teaching crystallography in general for physics students in Egypt in which we mentioned that powder diffraction and electron microscopy techniques are the main contents of the M.Sc post graduate course. In this paper an overview will be given on the main contents of the powder diffraction course.

The course contents are: Powder diffraction instrumentation - Data collection strategies and Cautions - Amorphous and polycrystalline diffraction patterns - Indexing of powder diffraction patterns - Analytical functions used in powder diffraction line profile - Profile fitting procedures - Phase identifications using the powder diffraction file - Phase diagrams and phase transformations - Structural characterization and crystal structure refinements (using Rietveld and the two stage methods) - Solid/solid reaction - Lattice strain and stress analysis - Microstructural analysis for materials having either intrinsic or extrinsic properties - Quantitative analysis of phases - Degree of disordering in disordered materials - Lattice and super lattice detection - Preferred orientation and expitaxial growth.

M12.FF.005 TEACHING DIFFRACTION WITH THE AID OF COMPUTER SIMULATIONS R.B. Neder, Institut für Mineralogie, Am Hubland, 97074 Würzburg, Germany and Th. Proffen, Department of Physics and Astronomy, Michigan State University, East Lansing, MI 48824-1116, USA

Computer simulations are a versatile tool to enhance teaching diffraction physics and related crystallographic questions. Students attain a very high degree of motivation and very effective learning is achieved. Computer simulations allow students to visualize a crystal structure and its Fourier transform. No physical limitations apply to the structure and a systematic approach can be taught by simulation individual atoms, small clusters of molecules, and any extended structure. These simulations can be used to enhance standard illustrations. The most efficient use is made, though, if the students perform their own computer experiments. They will rapidly acquire a rich experience on the correlation between structure and diffraction pattern by modifying given simulations and ultimately by experimenting with own simulations.

In this talk we present a course that guides students from the diffraction by a single atom to diffraction by complex disordered materials. The material includes simulations of: diffraction by individual atoms and small clusters, the geometry of real versus reciprocal space, the effect of structural modifications on the Fourier transform, the crystallographic phase problem, inverse- and difference-Fourier transforms, anomalous scattering, powder diffraction, and diffuse scattering.

A separate section deals with examples related to structure solution via direct methods. These examples illustrate intensity statistics, determination of origin, and phase relationships.

Neder, R.B. & Proffen, Th.: J. Appl. Cryst. **29** (1996) 727.

P12.FF.003 THE STORY ABOUT ONE CRYSTALLOGRAPHIC COLLECTION. T.K.Ivanova Earth Science Museum at Lovonosov Moscow State University, University,Square,1, 119899 Moscow, Russia, and G.I.Dorokhova ,Department of Geology, Mocow State University, Sguare,1, 119899, Moscow, Russia, and E.N. Belova, Institution of Cristallography of the Russian Academy Science, Moscow, Russia

The invaluable contribution to the study of mineral, working out their crystal chemical systematization (that of silicates,in particular) have been made by the founder of the British and Russian crystal chemical school-the father and son W.G.Bragg and W.L.Bragg and the academician N.V.Belov. In 1970 the morld scientific community celebrated the 80-th birthday of William Laurance Bragg-the patriarch of crystallography, author of the first definitions of crystall structures based on the usage of X-ray structural analysis.In connection with the anniversary date the International symposium had been held in London; there were invited the scientists from Russia -the academicians N.V.Belov and B.K.Vainshtein (the director of the Institute of Crystallography of the USSR Academy of Sciences).

The Russian crystallographers wanted to express their special respect to the outstanding scientist. Within the precincts of the Institute of Crystallography the splendid idea had arised: as the present for W.L.Bragg, to create the collection of structure models of minerals using the polyhedra method of structure depiction, which had been developed by Linus Pauling, the american scientist and Nobel prize laureate twice, and improved by N.V.Belov. Yrii Semakin, the expect modeller from the Institute of Crystallography, the two similar collection were made One collection was solemnly given as present to the hero of the anniversary W.L.Bragg, the other -left in the Institute of Crystallography for the memory of that non-ordinary event.

Howdays the main part of the “Bragg‘s” collection is kept in Shubnikov Institute of Crystallography of the the Russian Academy of Sciences-N.V.Belov’s Museum.(Moscow). In 1989 Belov’s daughter Elena Belova made the present -she gave some of the models to the Earth Science Museum at Lomonosov Moscow State University for the text illustration of the poster-memorial “Structural Mineralogy of N.V.Belov”.

P12.FF.005 INNOVATIVE TECHNOLOGIES FOR BI-LINGUAL EDUCATIONAL DICTIONARY AND KNOW-LEDGE BASE FOR CRYSTALLOGRAPHY. A.Y. Boyko[2], B.N. Kodess[1,2], Z. Sidikov [2], [1]VNIIMS, Moscow, 119361, Russia, [2] ICS&E, Aurora, CO 80015, USA

Understanding of new approaches to application of materials gained its reflection in the system of integrated

education. Material science and crystallography education in the US, Great Britain, Russia as well as at the centers of materials science in many countries of Europe and Japan, is based on the integration of knowledge about various properties of crystals and methods of their growing**.** Methodology and a product of efforts in compilation of the new Russian-English-Russian dictionary and knowledge base for purposes of education, translation and support of complete and current databases are described.

Elements of artificial intelligence are used for the purposes of the information retrieval, classification and presentation. Generic and crystallography-related knowledge and expertise are presented in form of an expert system, constructed from factual, procedural and other types of knowledge. The system exploits such methods of knowledge manipulation as backward and forward chaining, fuzzy logic and neural nets. Among other uses, this approach provides capability of computer-assisted context analysis for translation of text in the area of materials science and crystallography. Content of the knowledge base itself reflects a shift in the system of key concepts and terms of crystallography towards the field of dynamic systems and modeling at various levels of the concept of open systems.

The implemented approach embraces development of the content of basic concepts in materials science, which are new as well as traditional to the field. The concepts are product of research of new phenomenon in materials, advances in applications of materials, and introduction of new technologies.

The concise version of the dictionary is for reference, standardization and educational purposes mostly. It contains about 9000 terms related to the crystallography and other general concept of physics and chemistry of materials science. Extended version of the dictionary includes a hierarchical system of related words originating from intersecting thesauruses. For example, 60 terms related to defects in the thematic index of the concise version are extended into a system of more than 2500 related words etc. The polysemy of words and the introduction of more than 30000 interrelated words and collocations support the interdisciplinary nature of the content. Another basic principle of compiling this dictionary version was to provide a reader the ability to read any abstracts from publications such as Physics Abstracts (Solid State section), "Metadex"(Metals Abstracts), "Ceramical Abstract" and corresponding "VINITI " abstract etc, without addressing any other technical dictionary.

P12.FF.006 ON THE ROCKS... CRYSTAL GROWTH FOR HIGH SCHOOLS. C. Teixeira, Centro de Química Estrutural, Instituto Superior Técnico, Av. Rovisco Pais 1049-001 Lisboa, Portugal

In spite of all the importance crystals have in our daily life and modern technology, the subject of crystal growth is either completely absent, or reduced to a trivial purification technique, in most part of General Chemistry textbooks. The magnificent beauty of single large crystals has not yet been exploited for teaching purposes. This beauty can be largely enhanced, if giant crystals of well known inorganic compounds are allowed to grow from supersaturated aqueous solutions on rough surfaces like those of rocks and shells. With a right choice of the substances, using non expensive glassware at schools, universities, or even at home, one can easily obtain a large collection of spectacular samples, covering the chemistry of most common elements of the Periodic Table and their compounds. Some examples of this rich diversity are: isomorphous metallic salts, like alums and schönites, forming solid solutions with a large variety of colours; occlusion of dyes into the crystals of transparent substances; habit modifiers purposely added to the solutions, or contained in the rock or shell composition; reactions between the solutes and the components of the rocks and shells, etc. Since 1994, 180 high school teachers were trained by our research group in this field, sponsored by Ministry of Education (FOCO Program) and Ministry of Science and Technology, (Ciência Viva Program). Many of these teachers were able to perform these experiments with their students, included in their regular laboratory programs of Chemistry, Physics, Geology, Arts or at their "Science Clubs" in schools.

13OA HOT MACROMOLECULAR STRUCTURES (I)

M13.OA.001 AN ORIGINAL SYSTEM OF IRON ACQUISITION FROM HEME: STRUCTURAL STUDY OF THE EXTRACELLULAR COMPONENT. P. Arnoux , M. Czjzek [1], R. Haser [2], N. Izadi, A. Lecroisey [3], C. Wandersman [4], [1] AFMB, IBSM, CNRS, 13402 Marseille, France, [2] IBCP, CNRS, 69367 Lyon , France, [3] Laboratoire de RMN, Institut Pasteur, 75724 Paris,France, [4] Laboratoire de Physiologie Cellulaire, Institut Pasteur, 75724 Paris, France

Iron is involved in many essential reactions such as photosynthesis, respiration and nitrogen fixation showing its importance in biological processes. Bacteria have different way to use the extracellular available iron. A major change occurs during the host infection where bacteria have to face drastic iron limitation. They have developed various ways in using the host's iron from iron containing proteins. Serratia marcescens can use the iron from hemoglobin through the secretion of a hemophore called HasA (1) which takes up the heme from hemoglobin and shuttles it to the outer membrane receptor HasR, which in turn, releases heme into the bacterium. The mechanism by which HasA is secreted in the extracellular medium appeals to an ABC transport system.

We have determined the crystal structure of the heme/HasA complex at 1.9Å. The architecture and topology of the complex reveals a new type of fold. The 178 residues are structured in a highly curved six stranded β-sheet again which are packed, on one side, the four α-helices. The fourteen last residues, which were known to be important in the secretion mechanism, are present but are not seen in the e/density. This argues in favor of an unstructured sequence which places the four last hydrophobic residues accessible to the solvent and potentially interacting with the membrane and/or membrane proteins. The heme is located at the interface between the a and b part of the molecule and is held by two exposed loops containing the two iron ligands His32 and Tyr75. This type of iron coordination, together with the high surface complementarity between the heme and the protein, lead to a low dissociative constant since it is less than 10nM (2). The -550mV redox potential of the heme can be explained by the coordination type and the high solvent exposure of the heme. The heme binding site structure showed that the His83 Nd is hydrogen bonded to the Tyr75 OH ligand. This novel arrangement of the residues around the heme group suggests a mechanism for the processes involved in both heme uptake and release.

M13.OA.002 THE CRYSTAL STRUCTURE OF C-TERMINAL MEROZOITE SURFACE PROTEIN 1, A HIGHLY PROTECTIVE MALARIA VACCINE CANDIDATE. Graham A. Bentley, Véronique Chitarra and Inge Holm, Unité d'Immunologie Structurale, Institut Pasteur, 25 rue du Dr. Roux, 75724 Paris, France; Stephane Pêtres, Laboratoire de Technologie Cellulaire, Institut Pasteur, Paris France; Shirley Longacre, Unité de Parasitologie Expérimentale, Institut Pasteur, Paris, France.

The GPI-bound surface protein MSP1 from the Plasmodium merozoite is synthesised as a precursor ranging from 180 to 250 kDa, which matures to the final C-terminal product of 90 - 100 resides, depending on species. Correct maturation of MSP1 is essential for successful erythrocyte invasion by the parasite since antibodies specific for the protein, or the addition of protease inhibitors which prevent cleavage of the polypeptide, can block this process. Nonetheless, the precise role of MSP1 has not been characterised. We have determined the crystal structure of a soluble baculovirus recombinant form of C-terminal MSP1 from P. cynomolgi at 1.8 Å resolution by isomorphous replacement. The structure comprises two EGF-like domains, and sequence comparisons strongly suggest that the same conformation is present in all species of Plasmodium, including P. falciparum and P. vivax which are pathogenic in man. In particular, conserved inter-domain contacts between the two EGF modules should preserve the unusually compact form of the molecule in all species. Recombinant C-terminal MSP1 is a promising malaria vaccine candidate since it confers excellent protective efficacy in primate vaccination trials. Antisera obtained from vaccinated monkeys, or from animals with natural immunity acquired through infection by the parasite, recognise the recombinant protein in its native form but not in the disulphide-reduced state, showing that the epitopes are conformational. Expression systems or refolding protocols for recombinant C-terminal MSP1 that are capable of reproducing the native pairing of cystine links are therefore an essential requirement for vaccine production. A model of C-terminal MSP1 from P. falciparum based on the P. cynomolgi crystal structure shows that the dimorphic residues in this species are sufficiently spaced to form non-overlapping B-cell epitopes. The heterogeneity of the antibody response should therefore be insensitive to dimorphic permutations, and consequently two recombinant constructs carrying, respectively, the alternate residues at these sites should suffice to induce antiserum responding to all common polymorphs of C-terminal MSP1.

M13.OA.003 PROTEIN PROSTHETICS: X-RAY STRUCTURE OF THE *E. COLI* FIMC-FIMH CHAPERONE-ADHESIN COMPLEX. Stefan Knight and Devapriya Choudhury, Department of Molecular Biology, Uppsala Biomedical Center, Swedish University of Agricultural Sciences, Box 590, S-753 24 Uppsala, Sweden., Andrew Thompson, EMBL Grenoble Outstation, C/o Avenue des Martyrs, BP 156X, 38042 Grenoble, France, Vivian Stojanoff, ESRF, Avenue des Martyrs, 38400 Grenoble, France, Solomon Langermann, MedImmune, Inc., Gaithersburg, Maryland 20878, Jerome Pinkner and Scott J. Hultgren, Department of Molecular Microbiology, Washington University School of Medicine, St Louis, Missouri 63110, U.S.A.

The X-ray structure of the bacterial adhesin that mediates colonization of uropathogenic *E. coli* to the bladder epithelium, FimH, in a complex with its chaperone, FimC, was solved to 2.5 Å resolution. FimH consists of an NH_2-terminal mannose-binding domain and a COOH-terminal pilin domain used for incorporation of the adhesin into the pilus. The pilin domain of FimH has the same immunoglobulin-like topology as the NH_2-terminal domain of PapD-like chaperones, except that the seventh strand is missing. This creates a deep scar on the surface of the domain, leaving part of the hydrophobic core exposed. A donor strand complementation mechanism was revealed in which the chaperone donates a strand to the pilin domain. We propose that an extension at the NH_2-terminus of pilins participate in a donor strand exchange mechanism in pilus assembly. The donor strand complementation mechanism provides the first example of a class of proteins for which the primary sequence does not contain all of the steric information needed for correct folding.

M13.OA.004 STRUCTURE OF A HETEROPHILIC ADHESION COMPLEX BETWEEN HUMAN CD2 AND CD58 (LFA-3). Jia-huai Wang [1], Alex Smolyar [1], Kemin Tan [1], Jin-huan Liu [1], Mikyung Kim [1], Zhen-yu J. Sun[2], Gerhard Wagner[2],Ellis Reinherz[1], [1] Immunobiology Division, Dana-Farber Cancer Institute, Harvard Medical School, Boston, MA. 02115, USA, [2] Department of Biological Chemistry and Molecular Parmacology, Harvard Medical School, Boston, MA. 02115, USA.

Interaction between CD2 and its counter-receptor, CD58 (LFA-3), on opposing cells optimizes immune recognition, facilitating contacts between helper T lymphocytes and antigen presenting cells as well as between cytolytic effectors and target cells. Here we report the crystal structure of the heterophilic adhesion complex between the amino terminal domains of human CD2 and CD58. A strikingly asymmetric, orthogonal, face-to-face interaction involving the major b-sheets of respective immunoglobulin (Ig)-like domains with poor shape complementarity is revealed. In the virtual absence of hydrophobic forces, interdigitating charged amino acid side chains form hydrogen bond and salt link network at the interface. These charged interactions not only ensure high specificity, but also provide binding energy for this low affinity adhesion. These features explain CD2-CD58 dynamic binding, which is best suited to permit the T cell to broadly sample the surface of an opposing cell in search of the correct antigenic pepetide/MHC complex and co-stimulatory ligands. We have also inferred from sequence comparison that there is a subfamily within the Ig superfamily (IgSF) that utilizes the same interaction mode for cell adhesion, but the physico-chemical character of the subset of residues involved in interface determines the relative binding affinity to meet the different biological requirement.

M13.OA.005 THE CRYSTAL STRUCTURE OF LEECH ANTI-PLATELET PROTEIN, AN INHIBITOR OF HAEMOSTASIS. E.G. Huizinga[1,2], A. Schouten[1], T.M. Connolly[3], J. Kroon[1], J.J. Sixma[2] & P. Gros[1]. (1) Department of Crystal and Structural Chemistry, Bijvoet Center for Biomolecular Research, Utrecht University. (2) Department of Haematology, University Hospital Utrecht. (3) Department of Biological Chemistry, Merck Sharp & Dohme Research Laboratories, West Point, Pennsylvania.

Leech anti-platelet protein (LAPP) is a collagen binding protein from the leech *Haementeria officinalis*. It interferes with the adhesion of blood platelets to collagen by blocking the binding of von Willebrand factor and integrin $\alpha_2\beta_1$ We have determined the crystal structure of recombinant LAPP using single isomorphous replacement with anomalous scattering combined with solvent flattening and three-fold molecular averaging. The model of LAPP has been refined at 2.2 Å resolution (R-factor 21.5%; Rfree 23.7%). LAPP contains two distinct domains. The 89 residue C-terminal domain consists of a 6-stranded anti-parallel β-sheet. On one side the β-sheet is flanked by an α-helix, on the other side by two extended loops. Despite the absence of detectable sequence homology the fold of LAPP resembles closely that of the N-domain of hepatocyte growth-factor. The r.m.s. fit for 69 aligned Cα positions is 2.0 Å . The best conserved part with an r.m.s fit of 1.4 Å for 36 aligned Cα positions is the central β-sheet and the α-helix that packs against it. The central β-sheet in LAPP contains one additional strand contributed by the N-terminal region of the domain. The conserved features also include two disulfide bonds that link the α-helix to the core of the protein, indicating that these bonds may form an important stabilizing element in this type of fold. The 36-residue N-terminal domain of LAPP is rich in glycines, lacks hydrophobic residues and is not visible in the electron density map. Although LAPP has been shown to exist as a monomer in solution at neutral pH, the crystal packing suggested that LAPP may form tightly interacting

dimers. Dynamic light scattering experiments confirm that LAPP undergoes dimerization at pH 4.5, the pH used for crystallization.

M13.OA.006 CRYSTAL STRUCTURE OF ALLERGENIC DOMAIN OF THE MAJOR GRASS POLLEN ALLERGEN, PHL P5B. K.R. Rajashankar[1], A. Bufe[2], W. Weber[1] and Ch. Betzel[1], [1]Institute of Physiological Chemistry, UKE, c/o DESY, Building 22a, Notkestrasse 85, 22603 Hamburg, Germany; [2]Forschungzentrum Borstel, Klinische Allergology, Parkallee 22, 23845 Borstel, Germany.

Phl p 5b is a major allergen from timothy grass pollen which induces allergic rhinitis and bronchial asthma in millions of allergic patients world-wide. Until today there are no structural reports on this group of allergens. As an important step towards understanding the interactions between pollen allergen and components of the human immune system, we have determined the three-dimensional structure of the allergenic domain of Phl p 5b.

The protein adopts a compact four-helical bundle structure which dimerises by involvement of one intermolecular disulphide bridge. A repeating sequence motif observed in this protein seems to be typical for all group V and VI grass pollen allergens and this motif assumes helix-turn-helix topology. It is not clear whether the nuclease activity found for this protein is essentially connected to the allergenic property.

Native X-ray intensity data up to 1.98 Å were collected at 120 K using synchrotron radiation at the beam line BW6 (HASYLAB, DESY, Hamburg). Crystals belong to space group $C222_1$ with unit cell parameters a = 38.97, b = 50.36, c = 107.80Å and Z=4. Derivative (Mercury) data up to 3.0Å were collected using Cu K_α radiation. The CCP4 suite of programs were used for most of the phasing calculations. Application of anomalous data complemented the phasing procedure. Backbone of the protein model was traced using a density modified SIRAS map calculated with the phases from a six site heavy atom model. Phase extension and phase combination methods were used to build the complete model. The model was refined using the torsion-angle molecular dynamics slow-cooling refinement protocol of X-PLOR. The final model has 102 amino acid residues and 97 solvent molecules with agreement factors of R = 19.7% and R-free = 24.1%. The structural features of this pharmaceutically important protein, Phl P5b, will be discussed with clinical and biological implications.

P13.OA.001 THE CRYSTAL STRUCTURE OF AN INVERTEBRATE PENTRAXIN-LECTIN WITH A NOVEL MOLECULAR ASSEMBLY. Annette K. Shrive, Jamie R. Cartwright, Alison M. Metcalfe and Trevor J. Greenhough, School of Life Sciences, Keele University, Staffs ST5 5BG, UK.

C-reactive protein (CRP) and serum amyloid P component (SAP) are members of the pentraxin family of oligomeric serum proteins which has been conserved through evolution, although an invertebrate SAP-like pentraxin has not previously been identified and it has been postulated that CRP and SAP are products of gene duplication within vertebrate, even mammalian evolution. The known pentraxin structures human CRP [1], human SAP [2] and rat CRP [3] are all mammalian and all exhibit cyclic pentameric symmetry.

We have isolated SAP from the haemolymph of the phylogenetically ancient invertebrate horseshoe crab *Limulus polyphemus* and determined the three dimensional structure by x-ray crystallography. The structure of the previously undiscovered *Limulus* SAP, the first invertebrate lectin structure to be determined, reveals the pentraxin fold and a novel doubly-stacked octameric ring. Pairs of protomers, one from each octameric ring, form continuous, twisted β-sheet structures across the hexadecamer. Comparison of known *Limulus* pentraxin sequences with the human and *Limulus* SAP structures, particularly in the region of the ligand-binding site, provides convincing evidence that the observed pentraxin sequence heterogeneity in *Limulus* may be due to the presence of multiple CRP-like pentraxins with distinct ligand-binding properties. A complex and diverse pattern of competitive ligand binding, involving not only PC and PE but also carbohydrate moieties, may be a general feature of *Limulus* pentraxins. The crystal structure and the discovery of both prototypic pentraxins in *Limulus* raise the possibility that both were present in the common ancestors of arthropods and chordates over 500 million years ago.

P13.OA.002 YEAST RNA POLYMERASE II STRUCTURE AT 5 Å RESOLUTION. J. Fu, P. David, D. Bushnell, A. Gnatt and R. Kornberg. Department of Structural Biology, Stanford University School of Medicine, Stanford, CA 94305, USA.

RNA polymerase II (pol II) forms the core of the giant eukaryotic transcription machine responsible for all mRNA synthesis. Pol II assembles with general transcription factors onto a promoter, forming a pre-initiation complex. It then initiates mRNA synthesis and clears the promoter to enter a phase of highly processive RNA chain elongation. The formation of the pre-initiation complex, promoter clearance and transcription elongation are all under intricate regulation in response to developmental needs and environmental changes. Knowledge of the three-dimensional structure of pol II is required in order to fully understand the regulatory mechanisms and functional roles of the many protein-protein and protein-nucleic acid interactions involved in transcription.

Pol II presents a formidable challenge to the method of heavy-atom isomorphous replacement, due to its enormous size. Pol II is composed of 15 polypeptides of 12 different types, with a total mass of 550 kDa. We have grown yeast pol II crystals diffracting to 3.1 Å resolution, obtained multiple isomorphous derivatives with heavy-metal clusters and resolved the phases to 5 Å. The resulting MIRAS map shows well connected density features, many of them rod-shaped and indicative of α-helices. The molecular outline in the current X-ray map agrees well with the molecular envelope previously determined at 16 Å by electron crystallography [1], validating the current phase solution. In one region, a small domain, packed against the majority of the molecule in the electron-microscope (EM) structure, pivots away from the majority of the molecule by nearly 40°. As a result of this conformational change, a narrow channel previously noted in the EM structure is transformed into a groove which runs into the presumed DNA binding channel [1,2]. The key to success in phasing the pol II diffraction lay in the modeling of the scattering factor for an 18-tungsten cluster bound to pol II at a single site. Techniques and procedures used in the crystallization screen, flash-freezing and treatment of the heavy-metal cluster data will be discussed.

P13.OA.003 A NOVEL PROTEIN RADICAL SITE IN THE CRYSTAL STRUCTURE OF AN ANAEROBIC RIBONUCLEOTIDE REDUCTASE. Derek T. Logan[1], Jessica Andersson[2], Britt-Mare Sjöberg[2] & Pär Nordlund[1], Depts. Of Biochemistry[1] and Molecular Biology[2], Stockholm University, S-106 91 Stockholm, Sweden.

Ribonucleotide reductases (RNRs) occupy a pivotal role in the life of cells, as they are the only enzymes to catalyse the first dedicated step of DNA synthesis, i.e. the reduction of

ribonucleotides to deoxyribonucleotides. Despite the apparent simplicity of the reaction, free radical chemistry must be employed. RNRs can be divided into three classes based on the mechanisms they employ for radical generation, which are amazingly varied.

We have solved the crystal structure of a class III RNR [1]. This type of RNR is expressed by facultative or obligate anaerobes under anaerobic conditions. They generate a stable glycyl radical, in contrast to the structurally characterised class I enzymes, which use tyrosyl radicals. Our work provides the first structural evidence that the three classes of RNR have a common evolutionary ancestor, in spite of statistically insignificant sequence homology. In addition, it reveals the structure of a novel protein glycyl radical site. This lies in close proximity to the active site, again in contrast to class I, where the radical is probably transferred over a long hydrogen-bonded path before being made available for catalysis. However, the structure shows that one of three conserved cysteine residues in the active site, essential in class I and II RNRs, is not conserved in class III, which obliges us to reconsider the proposed reaction mechanism.

The class III RNR structure suggests that a growing family of anaerobic glycyl radical enzymes, including pyruvate formate lyase, may also be structurally related to RNRs and provides an appealing evolutionary scenario where enzymes involved in primary metabolism became the first to be able to catalyse the difficult reduction of ribonucleotides. Preliminary data on the structural basis for allosteric regulation of class III RNRs will also be presented.

P13.OA.004 COLICIN E3 AND ITS IMMUNITY PROTEIN: AN ENZYMATIC CYTOTOXIN AND ITS INHIBITOR. M. Shoham, S. Soelaiman and C. Li, Case Western Reserve University, School of Medicine, Department of Biochemistry, 10900 Euclid Ave, Cleveland, Ohio 44106-4935, USA. E-mail: shoham@biochemistry.cwru.edu

Colicin E3 is a multifunctional elongated protein cytotoxin that kills cells by inactivation of their ribosomes. The 68kDa *E. coli* protein is composed of three domains responsible for receptor binding on the outer membrane, translocation across the plasma membrane and killing the infected cell inside the cytoplasm, respectively. The C-terminal domain acts as an RNase that nicks 16S rRNA at a specific site, thereby blocking protein biosynthesis in the ribosomes. The immunity protein acts as a specific inhibitor of this RNase function by forming a specific 1:1 complex with colicin E3. Interactions between colicins and immunity proteins are extremely tight with subfemtomolar affinity.

The crystal structure of free immunity protein has been determined to a resolution of 1.8Å by MIR phasing. The secondary structure consists of a four-stranded antiparallel β-sheet flanked by three α-helices, all located on one side of the sheet. The two molecules in the asymmetric unit are covalently linked by a putative zinc ion that is coordinated to the single cysteine of each subunit.

Cocrystals of colicin E3 and the immunity protein diffract to 2.8Å resolution. They belong to the monoclinic space group $P2_1$ with unit cell dimensions a =66.6, b = 193.6, c = 84.3Å and β = 113.2°. There are four binary complex molecules per asymmetric unit. Several suitable heavy-atom derivatives have been found, and the structure determination is in progress by MIR phasing and non-crystallographic symmetry averaging.

P13.OA.006 THE STRUCTURE OF E. COLI ADP RIBOSE HYDROLASE: A PARADIGM FOR NUDIX HYDROLASES? S.B. Gabelli[1], M.A. Bianchet [1], M.J. Bessman [2], L.M. Amzel[1], [1]Department of Biophysics and Biophysical Chemistry.School of Medicine. Johns Hopkins University. [2]Department of Biology. Johns Hopkins University.

Nudix hydrolases1, previously known as MutT proteins catalyze the hydrolysis of diverse nucleoside diphosphates . The family is characterized by the consensus sequence GX5EX7REAXEEX2L. This sequence appears to be a versatile nucleoside and catalytic site present in more than two hundred enzymes found throughout nature from archae and prokaryotes to eukaryotes. The common feature of the substrates of nudix enzymes is the diphosphate linkage which is hydrolyzed by the enzymes. We have determined the first crystal structure of a nudix hydrolase: the ADP ribose hydrolase, product of the ORF209 E.Coli gene. It hydrolases ADP-ribose to AMP and ribose 5-P. Crystals were grown by vapor diffusion at 18o C using polyethylene glycol as precipitant. Crystals belong to space group $P2_12_12_1$, cell constants a=66.9 , b=67.9 , c=98Å. , and diffract to 1.9Å using a synchrotron source. The Crystal contains two molecules in the asymmetric unit related by a local two fold axis. The structure was solved by MIRAS techniques using the program SOLVE2. Initial phases were further improved and extended by density modification and histogram matching using the program DM3. The refinement of the structure is in progress.

P13.OA.007 THE CRYSTAL STRUCTURE OF FOLYLPOLY-GLUTAMATE SYNTHETASE TO 2.4Å RESOLUTION. C.A. Smith, X. Sun and E.N. Baker, School of Biological Sciences, University of Auckland, Auckland, New Zealand and A.L. Bognar, Department of Medical Genetics and Microbiology, University of Toronto, Toronto ON Canada M5S 1A8

Folylpolyglutamate synthetase (FPGS), responsible for the addition of a polyglutamate tail to folate and folate derivatives, is an ATP-dependent enzyme isolated from eukaryotic and bacterial sources. The enzyme plays a key role in the metabolism of dietary folates and the retention the intracellular folate pool [1]. The enzyme is also able to polyglutamylate a range of antifolate anticancer drugs, making these compounds better substrates for their target enzymes. We have determined the 2.4Å resolution crystal structure of the MgATP complex of the enzyme from *Lactobacillus casei* [2]. The structural analysis reveals that FPGS is a modular protein consisting of two domains, one with a typical mononucleotide-binding fold, and the other strikingly similar to the folate-binding enzyme dihydrofolate reductase. We have located the active site of the enzyme in a large interdomain cleft, adjacent to an ATP-binding P-loop motif. Opposite this site, in the C-domain, a cavity likely to be the folate binding site has been identified and inspection of this cavity and the surrounding protein structure suggests that the glutamate tail of the substrate may project into the active site. A further feature of the structure is a well-defined Ω-loop which contributes both to the active site and to interdomain interactions. The determination of the structure of this enzyme represents the first step toward the elucidation of the molecular mechanism of polyglutamylation of folates and antifolates.

P13.OA.008 CRYSTAL STRUCTURE DETERMINATION OF THE SMALL GTPASE SAR1, A REGULATOR FOR ENDOPLASMIC RETICULUM (ER) BUDDING. Mingdong Huang, Cheng-Qian Wang, William E. Balch, Ian A. Wilson Departments of Molecular Biology and Cell Biology The Scripps Research Institute 10550 N. Torrey Pines Rd. La Jolla, CA 92037

Movement of protein from the endoplasmic reticulum (ER) to the Golgi involves vesicle carriers that bud from specific sites on the ER membrane. Cargo exiting the ER includes both endogenous transport components that must be recycled from post-ER compartments, and newly synthesized proteins that are delivered to downstream subcellular destinations and the cell surface. Cargo is sorted from resident ER proteins and selected for export by interacting with COPII coat components. Sar1 is the pivotal GTPase that regulates cargo selection and vesicle formation, and is essential for cell growth and development. Sar1 function is unrelated to other GTPases belonging to the Ras superfamily of GTPases such as ARF1 involved in budding from the Golgi and Rab proteins involved in vesicle fusion. We have successfully crystallized the Sar1 protein and its selenomethionine derivative in PEG conditions using a sitting drop setup, and collected a native data set to 2.5Å. The current data set is 98.8% complete with an Rmerge of 17.8%. The crystal belongs to $P2_1$ space group with cell parameters of a=53.4Å, b=61.7Å, c=71.1Å, ß=107.5°. There are two Sar1 molecules in the asymmetric unit as estimated from Matthews coefficient. The structure determination and refinement is currently underway.

13OB TIME-RESOLVED DIFFRACTION AND PROTEIN DYNAMICS

M13.OB.001 INTRODUCTION TO THE MICROSYMPOSIUM. Ilme Schlichting, Max Planck Institute for Molecular Physiology, Dortmund, Germany;

In the general excitement of a time when new protein structures are published every week, it is often forgotten that a structure in itself does not tell one how the molecule works. For that, one needs to know a great deal about mechanism, intermediates and dynamics; a structure is only a beginning, although an important one. Due to the large gap between the time scales of protein motions or enzymatic reactions on the one hand and the crystallization and data aquisition on the other hand crystallographic determination of structures of reaction intermediates is usually not straightforward. It can be made feasable by either slowing or trapping the reaction (e.g. by cooling, or/and using poor substrates, suboptimal pH, and slow mutants) or by decreasing the data acquisition time (e.g by using the Weissenberg or Laue geometry). Both approaches require that the intermediate of interest can be generated fast and efficiently in the crystal. In addition, physico-chemical analysis methods need to be established to follow the reaction as it proceeds in the crystal. Reactions can be triggered by changes in thermodynamic parameters such as temperature or pressure, by concentration changes, by light or other radiation.

The tools for doing time-resolved crystallographic studies have developed rapidly; only a couple of years have passed since the first application of the Laue method to solve a protein structure [1] or to follow an enzymatic reaction after photolysis of a caged substrate [2]. Recently, studies with nanosecond time-resolution of reversible light-triggered reactions have become feasable at third generation synchrotrons [3].

M13.OB.002 KINETIC CRYSTALLOGRAPHY OF PHOSPHORYL TRANSFER CATALYZED BY GLUTATHIONE SYNTHETASE. Hiroaki Kato*, Masaharu Endo*, Amane Aoyagi*, Dominique Bourgeois†, Ilme Schlichting¶, Soichi Wakatsuki†, Toru Nakatsu*, Jun Hiratake* & Jun'ichi Oda*§. *Institute for Chemical Research, Kyoto University, Uji, Kyoto 611-0011, Japan; ¶Max Planck Institut für Molekulare Physiologie, Abteilung Physikalische Biochemie, Rheinlanddamm 201, 44139 Dortmund, Germany; †ESRF, BP-220, Grenoble, Cedex, France; §Fukui Prefectural University, 4-1-1 Kenjojima, Matsuoka, Fukui 910-1195, Japan.

Glutathione synthetase (GSHase) catalyzes the synthesis of gluta-thione from MgATP, γ-L-glutamyl-L-cysteine (γ-Glu-Cys) and glycine. The reaction is thought to proceed through the formation of an acyl-phosphate intermediate, γ-Glu-Cys phosphate, followed by nucleophilic attack of glycine to yield glutathione. In the light of the proposed reaction mechanism, we synthesized a transition state analogue (TSA), in which the C-terminal carboxyl group is replaced with a tetrahedral phosphinyl group with 2-carboxyethyl moiety mimicking the incoming glycine[1]. The compound is slowly- and tightly- bound (K_i = 21nM) to GSHase in the presence of MgATP. X-Ray diffraction analysis has shown that the tight-binding species is a phosphorylated TSA produced in the enzyme active site. The slow catalytic rate (the half life is 4 min in the crystalline state) renders the system suitable for analysis by kinetic crystallography. To start the reaction synchronously, we thus crystallized the enzyme complexed with TSA and caged ATP. This system makes it possible to release ATP upon photolysis to initiate the phosphorylation of TSA within the enzyme active site. Flash photolysis was achieved with a Xe flash lamp developed by Gert Rapp, EMBL, Hamburg. Photolytic efficiency was determined by HPLC from the contents of the caged and released nucleotides in the crystals. After reaction initiation several snapshots of the reaction were obtained at intervals of several seconds with millisecond time resolution using the Laue technique. A high-resolution structure at the beginning of the reaction was also captured by rapid freezing technique with liquid nitrogen. Beamline ID9 at the ESRF has been used for the data collection of Laue diffraction, and ID14/EH3 for that of monochromatic one. The methods used, and the structures obtained will be described.

M13.OB.003 TIME-RESOLVED ENZYME CRYSTALLOGRAPHY. Gregory A. Petsko, Departments of Biochemistry and Chemistry and Rosenstiel Basic Medical Sciences Research Center, Brandeis University, Waltham, MA 02254

The structures of enzymes determined by X-ray crystallography are a dual average over the time required to collect the diffraction data and all of the unit cells in the crystal lattice. Since most enzymatic reactions are finished in less than a second, the temporal averaging process makes it impossible to visualize an enzyme-substrate directly by X-ray crystallography under normal conditions. The spatial averaging also imposes the requirement that every molecule in the lattice be at the same stage of the reaction during data collection. It is clearly important to be able to look at productive complexes, but it is also very difficult to do so for most crystalline enzymes. The advent of Laue diffraction techniques (Amoros et al., 1975) using synchrotron radiation has made it possible to collect protein crystal data sets on a

millisecond time-scale (Hajdu and Johnson, 1990). To carry out time-resolved studies of enzyme reactions at atomic resolution, the most significant problem is the problem of synchronization: it is necessary that all of the molecules in the crystal be at the same stage of the reaction at the same time (Ringe et al., 1992). Four techniques have been developed to achieve this, and some success has been obtained with each one. Photo- activation has the widest applicability, and has been used to obtain time- resolved structures of the human oncogene protein H-ras p21 in both its active (GTP-bound) and inactive (GDP-bound) states (Schlichting et al.,1990). Although these results are encouraging, several serious problems remain: First, the requirement of the Laue technique for a very well-ordered crystal is a major obstacle to many studies. Efforts to ease this problem are needed. Second, the fundamental issues in time-resolved crystallography are now chemical rather than crystallographic. Methods for the rapid initiation of other reactions must be developed (for a clever approach, see Stoddard et al., 1991). Third, it is imperative that the kinetics of the process in question be studied in the crystal before any diffraction experiments are done. We need better ways to make those solid state kinetic measurements. Fourth, we should make use of combined methods, such as cryoenzymology plus Laue diffraction or site-directed mutagenesis plus Laue diffraction, to bring many processes into the time regime in which we currently can work. Fifth, we have to be able to deconvolute diffraction data that come from a mixture of two or three discrete species. Sixth, we need better methods of obtaining good electron density maps from partial data sets (Campbell et al., 1990). Finally, it seems to me that some of the most important events in any enzymatic reaction are not going to be accessible: consider the formation and decomposition of a transition state as an example. I will close my talk by discussing the role of computational biochemistry in filling in those frames of our enzymatic movie that we cannot observe directly by time-resolved X-ray crystallography.

M13.OB.004 DYNAMICAL MODELS OF PEANUT LECTIN DISACCHARIDE COMPLEXES G M Bradbrook[1,2], J V Pratap[1], J Raftery[2], B P Reddy[1], A Surolia[1], M Vijayan[1] and J R Helliwell[2], [1] Molecular Biophysics Unit, Indian Institute of Science, Bangalore, India, [2] Department of Chemistry, Univeristy of Manchester, Manchester, M13 9PL, UK.

Peanut lectin, a 110 kD tetrameric lectin, from Aracheas Hypogea, is specific to galactose and has a high affinity for the T-antigenic disaccharide, Gal(1-3) GalNac. From calorimetric data, T-antigen has a 20 fold higher affinity than lactose (Gal (1-4) Glc). Nanosecond MD simulations have been performed at different temperatures for both the complexes. The free sugars in an unbound, hydrated state were also subjected to nanosecond MD simulations.

The dynamical models of the protein-saccharide interactions derived from this study have been used to estimate the difference in binding enthalpy between the two complexes. A reasonable agreement between the dynamical models and calorimetric data was obtained. Similarly, the H-bonding patterns observed in the dynamical models are in agreement with those seen in the crystal structure.

Further, the models indicate some alternate binding motifs also for the protein-disaccharide complexes, offering some explanations for the mutant studies done on this protein. These rare and energetically less favourable states could play an important role in preventing dissociation of the complex and thereby yielding a higher association constant. From this, it is suggested that approaches to ligand design may include the promotion of a series of bound states.

M13.OB.005 TIME-RESOLVED MACROMOLECULAR CRYSTALLOGRAPHY AND PROTEIN MOLECULAR DYNAMICS . J R Helliwell, Department of Chemistry, University of Manchester, Manchester, M13 9PL, UK.

High intensity sources have opened up time-resolved monochromatic and Laue diffraction structural studies via reactions initiated in protein crystals. SR source, detector (CCDs) and Laue data processing software have radically improved in the last few years. Ultrafast (sub-nanosecond) reversible 'pump probe' experiments have become possible at ESRF. Irreversible processes pose a variation of the data acquisition challenge for which pixel detectors look promising. Cryo-crystallography opens up freeze trapping approaches, guided by spectral signals and/or Laue data and electron density map time slices. Cryo-protection of the protein crystal sample also allows ultra-high resolution data collection ie with high X-ray data to parameter ratio in model refinement; anisotropic displacement parameters (ADPs) then indicate directional dynamics and/or disorder effects. Protein molecular dynamics trajectories yield another estimate of atomic movements, larger than from ADPs, but this might be reconciled with the crystallographic model refinement since X-ray diffraction patterns often show diffuse scattering in addition to the Bragg scattering. In another aspect neutron Laue diffraction has opened up a wider range of protein structure studies with neutrons than hitherto, which makes feasible larger unit cells and/or smaller protein crystals for H/D exchange structural information and placement of bound water deuterium atom positions. The integration of this broad range of static and time-resolved dynamics information offers then a considerable insight into macromolecular structure and interactions. Examples will be given from studies on hydroxymethylbilane synthase (HMBS) and concanavalin A (without and with saccharides).

Acknowledgements: I am very grateful to all the persons listed in these publications for many happy collaborations. This work is based on protein crystallographic data measured over many years at the Daresbury SRS, ESRF and Cornell synchrotron X-ray sources and more recently at the Institut Laue Langevin neutron source. The intensive crystallographic and molecular dynamics computations that these studies involved were done on the Manchester Structural Chemistry SG Workstations and SG Challenge. I am also very grateful for research grant support over the years from The Wellcome Trust, SERC, EPSRC, BBSRC, EU and The British Council.

P13.OB.001 STRUCTURE AND FUNCTION STUDIES OF HYDROXYMETHYLBILANE SYNTHASE. J.R. Helliwell, J.Raftery, J.Habash, P Faulder (1), F.Schotte, M.Wulff (2), A.Haedener (3), (1) Department of Chemistry, University of Manchester, (2) ESRF, Grenoble (3) Department of Chemistry, University of Basle

Hydroxymethylbilane synthase (EC 4.3.1.8, HMBS), also known as porphobilinogen deaminase, is the third enzyme in the biosynthetic pathway of the tetrapyrroles which include haem, chlorophyll, vitamin B12 and similar pigments. HMBS catalyses the polymerisation of four molecules of porphobilinogen to form hydroxymethylbilane. A dipyrromethane cofactor is present in the HMBS holoenzyme and is covalently attached to a cysteine side-chain (Cys242). There are four covalent enzyme-substrate

intermediate complexes existing in the catalytic pathway, i.e. ES1, ES2, ES3, ES4. Previously, a reduced, active selenomethionine form of the holoenzyme has been solved to 2.4A using the MAD method principally at SRS station 9.5 and subsequently also at ESRF BM14 [1]. Time-resolved Laue diffraction has since been employed at ESRF to study the enzyme structure (K59Q mutant) during catalysis [2,3]. The experimental Laue difference maps revealed an elongated peak near the active site, most prominent at 2 hours, commencing at the position of ring 2 of the oxidised cofactor (the putative binding site for substrate) and directly above the critical Asp84 carboxyl side chain implicated in the first ring coupling step. The density then extended past residues that are known from protein engineering to affect later stages of the catalysis, and out into open solvent. In order to improve the 'static' protein structure, and to establish freeze trapping conditions, since the time-evolution of this irreversible (i.e. in terms of the colourless to red colour change) reaction in the crystal has now been established from the Laue diffraction, cryo temperature data has been collected on the reduced, active wild-type HMBS holoenzyme to 1.65A at ESRF (ID09). Moreover two other cryo data sets were measured for the wild type HMBS crystals on ID09 involving freezing after two hours soaking of a crystal in substrate solution and also an inhibitor soaked crystal. Difference Fourier map evaluation and model refinement is underway. The missing loop of residues 49 to 57 in all current HMBS structures undertaken at ambient temperature is of keen interest in these cryo studies. Progress with the structural studies will be reported.

P13.OB.002 LAUE-DIFFRACTION AT ID09: TIME-RESOLVED STUDIES ON PHOTOACTIVE PROTEIN CRYSTALS AT PHYSIOLOGICAL TEMPERATURES. R. Kort [1], F. Schotte [1], K.J. Hellingwerf [2], E.M. Landau [3], K. Moffat [4] and M. Wulff [1]. [1] European Synchrotron Radiation Facility, Grenoble, France, [2] Laboratory for Microbiology, University of Amsterdam, The Netherlands, [3] Biozentrum, University of Basel, Switzerland and [4] Department of Biochemistry and Molecular Biology, University of Chicago, USA.

The beamline for structural kinetics at the ESRF is the white beam station ID09. The time structure of synchrotron radiation in single-bunch or hybrid mode in combination with a 900 Hz chopper allow the isolation of 100-ps X-ray pulses. After reaction initiation by a laser pulse, these polychromatic X-ray pulses can probe crystal structures, with a delay chosen by the user, ranging from the sub-nanosecond to millisecond time scale (Wulff *et al*., 1997). The use of protein crystals that display a reversible reaction triggered by light, enables stroboscopic data collection for the accumulation of sufficient intensity for a Laue diffraction experiment. Crystallizable proteins with intrinsic photoactivity, inducing physiologically relevant conformational changes in a cyclic chain of reactions, are excellent model systems for the type of experiment discussed here: X-rays at IDO9 probed an early intermediate of the bacterial photosensor photoactive yellow protein at 1 nanosecond after reaction initiation, showing how this protein (i) accommodates rapid chromophore isomerization without collisions and (ii) can store energy by this restricted movement for larger structural changes required for signal transduction (Perman *et al*., 1998). In addition, the use of this technique on crystals of the retinal-containing proton pump bacteriorhodopsin (BR) may catch essential structural changes for the pumping mechanism. Future plans will be revealed.

P13.OB.003 ELECTRON DIFFRACTION OF TRAPPED BACTERIORHODOPSIN INTERMEDIATES. Richard Henderson and Sriram Subramaniam, MRC Laboratory of Molecular Biology

We have studied the photocycle of the light-driven proton pump bacteriorhodopsin, using time-resolved plunge-freezing of naturally occurring two-dimensional crystals to trap particular intermediate states, followed by electron diffraction structure analysis to determine their atomic structure. We have investigated specific intermediates that occur in the later stages of the wild type bacteriorhodopsin photocycle as well as a variety of mutant proteins with kinetic defects in the photocycle. The timescale of the flash and trap experiments range from 0.5 milliseconds to several seconds.

Our experiments demonstrate that in wild-type bacteriorhodopsin, a large conformational change occurs within 1 msec after illumination. This large structural change occurs in the M intermediate and with only small differences also in the N and O intermediates. However, a considerably larger variation in structure is observed when the same intermediates are trapped in different mutants. In one spectacularly clear case, the D96G/F171C/F219L triple mutant, the full extent of the conformational change is already present in the dark with minimal additional light-induced changes. Our observations thus support a simplified view of the wild type photocycle in which the structures of the initial state and the early intermediates are (K, L and M1) well-described by one protein conformation while the structure of the later intermediates (M2, N and O) are well-approximated by the other protein conformation. In wild type bacteriorhodopsin and most mutants, this conformational change between the M1 and M2 states is likely to be a major factor in efficiently switching accessibility of the retinal Shiff base from one side of the membrane to the other.

13OC APERIODIC AND INCOMMENSURATE STRUCTRES (II)

M13.OC.001 RANDOM TILING MODELS OF QUASICRYSTALS AND INCOMMENSURATE PHASES. Michael Widom, Department of Physics, Carnegie Mellon University, Pittsburgh PA, 15213, USA.

Aperiodic tilings of space model incommensurate and quasicrystalline materials. While certain tilings may *force* a quasiperiodic structure, similar structure arises spontaneously in *random* tilings. Random tilings may be appropriate models for entropically stabilised quasicrystals that are thermodynamically stable equilibrium states at high temperatures only. Successes of the theory of random tilings include exact solutions, prediction of crystal-incommensurate and incommensurate-quasicrystal phase transitions, and the prediction of phason elasticity which implies specific observable patterns of diffuse scattering. The outlook for

the future includes the derivation of random tiling models from atomistic models of quasicrystals via ab-initio total energy calculations, and modelling defect structures such as grain boundaries and dislocations and their interactions.

M13.OC.002 COLOR SYMMETRY IN QUASI-PERIODIC STRUCTURES. Ron Lifshitz Condensed Matter Physics, California Institute of Technology, Pasadena, CA 91125, U.S.A.

Color symmetry groups are powerful abstract tools which can be used for the classification of properties such as alloy ordering and magnetic phases in solids. The development of a theory of color symmetry for quasiperiodic crystals [1] is therefore a natural step in the evolution of modern crystallography.

I shall give an outline of this theory, starting from a brief introduction (for the non specialist) of the notion of symmetry in quasicrystals, which will then be generalized to the case of colored quasicrystals. I shall describe the color space group classification scheme which emerges, and give applications, ranging from colored quasiperiodic tilings to the super-lattice ordering observed in certain decagonal and icosahedral quasicrystals.

M13.OC.003 IN SITU STUDY OF THE SUPERLATTICE ORDERING OF THE ICOSAHEDRAL ALPDMN PHASE. M. de Boissieu (1), A. Letoublon (1), T. Ishimasa (2), M. Boudard (1), M. Audier (3), 1 LTPCM, INPG, UMR CNRS 5614, BP 75 38402 St Martin d'Heres Cedex (France), 2 Department of Nuclear Engineering, School of Engineering, Nagoya University, Nagoya 464-01 Japan, 3 LMGP, UMR CNRS 5628, St Martin d'Heres, France.

The reversible transition between the i-AlPdMn phase and the F2M phase has been studied by in-situ X-ray and neutron diffraction and transmission electron microscopy. The transition takes place around 720°C, the i-phase being stable only at high temperature. The F2M low temperature phase is multidomains, with crystallographic orientational relationship between domains imparting an overall icosahedral symmetry. Each domain presents a diffraction pattern with a cubic symmetry and S1 superstructure reflections. The mechanism of the phase transition was followed by in situ-X-ray diffraction. In the initial stage of the transformation streaks of diffuse scattering appear, which then condense into superstructure reflections. There is a correlation between the intensity of the diffuse scattering and the phason component of the wavevector, which indicates that the transition is phason driven. The F2 phase, previously identified by T. Ishimasa, is a transient state towards the F2M phase.

M13.OC.004 NON-PERIODIC POINT SETS AND THEIR GENERALIZED SYMMETRIES Michael Baake [1] and Dieter Joseph [2], [1] Institut fuer Theoretische Physik, Universitaet Tuebingen,Auf der Morgenstelle 14, D-72076 Tuebingen, Germany, [2] Max Planck Institute for Physics of Complex Systems, Noethnitzer Str. 38, D-01187 Dresden, Germany

While the symmetries of crystals are well understood, this is not so for the hierarchy of ordered states between crystalline and amorphous, of which quasicrystals form only one example. In particular, classification attempts based upon direct or upon reciprocal space techniques will lead to different results -- quite in contrast to the crystallographic situation. This talk introduces appropriate direct space equivalence concepts such as local indistinguishability or local equivalence and discusses their relation with standard concepts.

M13.OC.005 MATHEMATICAL QUASICRYSTALS WITH TORIC INTERNAL SPACES AND DIFFRACTION. Jean-Louis Verger-Gaugry, Institut Fourier, UJF Grenoble, Mathematics Department - BP 74 - Domaine Universitaire, 38402 - Saint Martin d'Hères, France.

Aperiodic Crystals viewed as Delaunay sets of points, $\Lambda \subset IR$, on the real line, having an average lattice, are studied in the context of mathematical quasicrystals with toric internal space and cut-and-congruence schemes. The windows exhibit variable Hausdorff dimensions and the fractal rates of occupancy, at infinity, of the lattices associated with the Delaunay sets are shown to be simply related to the scaling exponents of the Fourier transform of the autocorrelation of Λ in the diffraction process, with Hausdorff 0-dimensional windows. We show that scaling exponents of the intensity can be defined without limit for the autocorrelation, allowing the study of the singular continuous component of the spectral measure. The case of the Meyer set formed by the Thue-Morse sequence is explicitly developed to exemplify and justify this approach.

P13.OC.001 STRUCTURAL STATE OF BETA(CSCL)-SOLID SOLUTION IN QUENCHED QUASICRYSTAL-FORMING ALLOYS ALCUFE. E.V.Shalaeva [1], A.F.Prekul [2], [1] Institute of Solid State of Chemistry, Ural Div., Russ. Academy of Sci., Ekaterinburg 620219, Russia, [2] Institute of Metall Physics, Ural Div., Russ. Academy of Sci., Ekaterinburg 620219, Russia

With the discovery of stable quasi-crystalline (i-) phases, the components of which are elements with good metallic properties, a tide of interest has been at its height in studying the structural transformations that are accompanied with stabilization of the system due to the gain in electron energy. Of particular interest is the experimental investigation of structural state of cubic phases that undergo transformation into i-phase, in looking for signs of instability in the crystal lattice with regard to such phase transformation that is theoretically described as a reconstructive transition of displacement type.

With the goal of searching for such signs, the structural characteristics were studied for the quenched beta(CsCl)-solid solution in the system of AlCuFe. Within the composition range of Cu-Fe between 26-12 and 28-14 at.%, a biphasic state (i+beta-solution) is observed that is characterized with a great content of beta-solution which can be heat treated into a nearly uniform i-phase.

The electron microscopy revealed that in the quenched quasicrystal-forming alloys $Al_{62.5-x}Cu_{25-y}Fe_{12.5-z}$, near the concentration region of the ordered tau-phases the structure of beta-solution is characterized with a combined short-range order, showing both the concentration and atomic displacement wave features. The displacement-type order is of the nature of the incommensurable waves of displacement that are typical for the disordered state of alloys with a bcc-lattice that show instability in terms of the bcc --> omega-phase transition. Possible sequences were analyzed for the phase transition of beta (CsCl) solid solution into i-phase with the involvement of the short-range order of omega-type displacement.

P13.OC.003 APPROXIMATE SYMMETRY OF THE QUASICRYSTALS. I.N.Mochtchenko, A.I.Aizenberg, I.K.Mochtchenko, North Caucasus Scientific Center, Pushkinskaia 140, Rostov-on-Don, 344006, Russia.

Using the theory of the almost periodicity function we showed that the quasicrystals is characterised by the approximate symmetry. The elements of such symmetry are the elements of the group of the motion of the Euclidean space, which transform quasicrystal into itself with some error. The group of approximate

symmetry is generated by the subgroup of the exact point symmetry and the subgroup of the almost periods. Such group determines all symmetry and quasiperiodicity properties of the quasicrystal. The condition of the equality of approximate symmetry for several objects is obtained: the moduluses induced by the spectrums of the objects must be equal. The models having real approximate symmetry, but sample structures are presented. For example, the model of decagonal quasicrystals is the quasilattice, which consist from fife periodic lattices formed by the 5-fold axis from one. Such models allow to investigate symmetry and many macroscopic physical properties such as selected rule, the topology of the phase diagrams etc.

The theory of the representations of approximate groups is developed. Such representations are the homomorphic matrix groups of approximate symmetry. They connect with the representations of superspace group, but do not equal them and distinguish by the translation elements and the core of homomorphism. The last is isomorphic to some approximate subgroup. The condition of this is next: the modulus induced by the real spectrum must be included to modulus induced by the spectrum of the core of homomorphism. It is also obtained that the invariants of the representations of the superspace groups are the almost invariants of the approximate groups. The obtained results allow to investigate the quasicrystals using the method elaborated for crystals (Landau theory of phase transitions etc.)

P13.OC.004 DIFFRACTION PATTERNS OF DD-Ta-Te QUASICRYSTALS WITH FRACTAL OCCUPATION DOMAINS. Akiji Yamamoto Nat. Inst. Res. Inorg. Mat. Namiki 1, Tsukuba, 305 Japan.

A recently found Ta-Te quasicrystal is the first stable phase with dodecagonal (DD) symmetry.[1] It shows square-triangle tiling of 20Å atom clusters similar to the Stampfli tiling [2] but the latter includes many skinny rhombus. There are two clusters with the 6-hold rotation symmetry but with different orientations. One is related to the other by [$\bar{1}$2]. In order to remove the skinny rhombus, we need to use fractal occupation domains. This leads to 5-dimensional cluster models with fractal occupation domains for realistic models of the DD phase.

Recently two 5-dimensional models of the DD Ta-Te quasicrystals with 'pinwheel-shaped' occupation domains are proposed.[3] They have the 5D space group $P[\bar{1}2]m2(12^5mm)$ and both lead to an existing tetragonal approximant structures with a = 37.58, c = 20.66 Å by the introduction of a linear phason strain. These two models have same in the cluster arrangement but different in their orientation. In this paper, the detectability of the fractal occupation domains by diffraction experiments is examined.

The diffraction patterns of the two models indicate that the both models show characteristic intensity distribution in the DD Ta-Te but they are indistinguishable from each other in practice or from the third model with random cluster orientations because of a small difference in diffraction intensity. This suggests that we can not prove whether a quasicrystal has fractal occupation domains or not by means of usual X-ray experiments.

13OD STRUCTURE SOLUTION FROM POWDERS USING ELECTRON AND POWDER DIFFRACTION TECHNIQUES

M13.OD.001 SOLVING STRUCTURES OF MICROCRYSTALS BY HIGH RESOLUTION ELECTRON MICROSCOPY AND CRYSTALLOGRAPHIC IMAGE PROCESSING. X.D. Zou, Structural Chemistry, Stockholm University, S-106 91 Stockholm, Sweden

High resolution electron microscopy (HREM) can be used for structure determination of micro/nano-crystals too small for single crystal X-ray diffraction [1]. One of the most important advantages of using HREM is that the crystallographic structure factor phase information is present in the images. The phases, as well as the amplitudes, can be extracted from the Fourier transform of the HREM images by crystallographic image processing.

HREM images are very sensitive to the electron optical conditions of the microscope, such as electron beam tilt, spherical aberration, defocus and astigmatism of the objective lens. They are also distorted by crystal misalignment. Furthermore, the strong interaction between the crystal and electrons gives rise to dynamic effects which makes the relation between HREM images and the structure complicated. In general, phases extracted directly from the HREM images are not exactly the same as the crystallographic structure factor phases.

Most of these distortions can be compensated by crystallographic image processing. The effects of dynamic scattering are difficult to compensate for before we know something about the crystal structure. However, in most cases it is possible to find so thin crystals (< 10nm) that most scattered electrons are kinematical. Here we will demonstrate how the amplitudes and phases extracted from the image are related to the structure factors of the crystal and how a crystal structure is solved from HREM images. The accuracy of atomic positions obtained from images is usually better than 0.2Å. The structure model can be further refined against electron or X-ray powder diffraction data. This method will be demonstrated on several compounds including oxides, metal-rich clusters and silicate minerals.

M13.OD.002 STRUCTURAL STUDY OF ZEOLITE RELATED MATERIALS BY ELECTRON CRYSTALLOGRAPHY. O. Terasaki, A. Carlsson, M. Kaneda, Y. Sakamoto, T. Ohsuna, S. Ritsch, K. Hiraga [1], P. Wagner [2], [1] Department of Physics, CREST-JST and Institute for Materials Research, Tohoku University, Sendai, Japan, [2] Division of Chemistry & Chemical Engineering, CALTEC, Pasadena, USA.

Micro- and mesoporous materials are of importance for making containers of quantum confined materials as well as for catalysts in chemical industries. More than a hundred different materials have been reported and new interesting materials are frequently synthesised. Knowledge of the structure of these materials is the key for understanding their properties. They are synthesised in micrometer size that is too small for single crystal X-ray analysis and they sometime contain faults, and therefore it is rather difficult to solve new structures from powder X-ray diffraction profile without having some structural clues. Electron crystallography is a very powerful method for solving/characterising the structures of these materials. Since the density of the materials is low, it is expected that dynamical scattering effect will be less serious than for other inorganic materials. The framework connectivity and the wall geometry are the most essential point to know for the structures of microporous and mesoporous materials, respectively. There are two methods for phase recovery among various reflections, from HREM images and by the direct method which has been developed for X-ray analysis. The amplitudes for the reflections are obtained either from the image or from electron diffraction patterns. The resolution is, of course, higher for the latter. We have succeeded

in characterising mesoporous material by the former and in solving a new structure of microporous material by the latter.

M13.OD.003 ELECTRON DIFFRACTION STRUCTURE ANALYSIS – AN OPTION WHEN THE POWDER METHOD FAILS TO SOLVE THE STRUCTURE. Thomas E. Weirich, Darmstadt University of Technology, Materials Science - Div. Structural Research, Petersenstrasse 23, 64287 Darmstadt, Germany

Exploiting X-ray powder data for structure determination consists of three parts (a) the determination of the correct unit cell parameters and space group (b) finding a rough structure model close enough to the true structure (c) completing and refining the structure model. While the latter is nearly routine work utilising the Rietveld technique, it turns out in practice that the first two steps are often extremely difficult to overcome. The indexing of powder patterns is often ambiguous due to the accidental or systematic overlap of diffraction peaks and the subsequent extraction of reliable intensities - which is an indispensable precondition for solving the structure - is still a non-trivial problem.

Electron diffraction structure analysis of micro-crystallites is an option to by-pass many obstacles in the early stages of a structure determination from powder data. The electron diffraction (ED) patterns from small single crystals consist of well separated spots which enable straightforward indexing and a readily determined unit cell. Structural modulations can easily be recognised. Systematic absences for space group determination are much more reliably obtained from ED than from X-ray powder data. In the case of polyphasic samples, ED is superior since it allows the separate investigation and characterisation of the different crystallites. Recent it was shown that crystal structures can be solved by direct methods using ED data from crystallites containing only non-light elements.

The combination of structure analysis by ED and X-ray powder diffraction is a powerful tool for structure investigations on many materials which are beyond the capabilities of the powder method. In particular, many structural problems which suffer from pronounced preferred orientation of the crystallites or by poor crystallinity of the sample can be tackled with the proposed approach.

M13.OD.004 POWDER XRD AND ELECTRON MICROSCOPY APPLIED TO THE LOW TEMPERATURE OXIDATION OF ANOSOVITE TO ANATASE. I.E. Grey, CSIRO Minerals, Clayton, Australia 3168, L.M.D. Cranswick, CLRC Daresbury Laboratory, Warrington, WA4 4AD, UK, R. Stranger, Dept. of Chemistry, ANU, Canberra, ACT 0200, Australia and T.J. White, Nanyang Technological Institute, Singapore 639798.

Decreasing peak resolution of powder X-ray diffraction patterns (PXRD), for example due to line broadening or peak overlap, results in increasing ambiguity in the structural model used to fit the data. Poorly resolved patterns can be equally well fitted by a number of different structure models. In these situations, other techniques are needed in combination with the powder diffraction analysis to reduce the ambiguity. A particularly suitable complementary technique is transmission electron microscopy. The electron diffraction (ED) patterns can be used to establish correct unit cell parameters and possible space groups, and orientation relationships between coexisting phases, while high resolution TEM images can provide starting models of atomic arrangements for the powder refinements, as well as providing information on local ordering in disordered structures.

We have used TEM methods to assist in the PXRD refinements of the structures of phases formed during the low temperature oxidation of trivalent titanium in anosovite, (Mg, Mn, Fe, Ti)$(Ti^{3+}, Ti^{4+}, Al)_2O_5$. When finely ground anosovite is heated for extended periods at ~100°C, it transforms to a new C-centred monoclinic phase having $a_m \sim a_{anos}$=9.9Å, $b_m \sim b_{anos}$=3.75Å, $c_m \sim 2xc_{anos}$=21.1Å, β=93.1°. Further heating at a higher temperature of ~400°C results in a transformation to a disordered form of anatase. ED patterns show that the anatase crystallites are oriented relative to the anosovite such that $(101)_{anat}$ // $(001)_{anos}$ and $[010]_{anat}$ // $[010]_{anos}$. The application of the TEM/ED data to generating models of the intermediate monoclinic superstructure phase for PXRD refinement will be described.

M13.OD.005 STRUCTURE DETERMINATION OF ϕ-$Bi_8Pb_5O_{17}$ BY ELECTRON AND POWDER X-RAY DIFFRACTION. M. Gemmi, INFM, Università di Bologna, Viale Berti Pichat 6, 40127 Bologna, Italy; A.Migliori, CNR-LAMEL, Area della Ricerca di Bologna, Via Gobetti 101, 40129 Bologna, Italy; D. Belletti, G. Calestani, L. Righi, Dip. di Chimica Generale ed Inorganica and CNR-CSSD, Università di Parma, Viale delle Scienze, 43100 Parma, Italy; M. Santarosa, M. Bettinelli, A. Speghini, Dip. Scientifico e Tecnologico, Università di Verona, Ca' Vignal, Strada Le Grazie, 37134 Verona, Italy.

By heating tetragonal β_2-$Bi_8Pb_5O_{17}$ above 450°C, a new fast ionic conducting material (ϕ), that transforms above 590°C in the cubic β phase, is obtained [1]. Attempts to determine the ϕ structure by XRD failed in the past, because of the impossibility to grow single crystals and of the extreme complexity of the powder diffraction spectra. The structure has now been determined by sinergic use of electron and X-ray powder crystallography. 33 ED patterns were recorded in SAED mode using a Slow Scan CCD camera in 22 different zone axes. The QED package [2] was used for cell determination, 3-D indexing and intensity extraction. ϕ-$Bi_8Pb_5O_{17}$ is triclinic, s.g. P-1, a=7.4550(2), b=14.1677(3), c=7.2053(1)Å, α=97.185(1), β=118.464(1), γ=80.684(2)° and the cell contains 19 independent atoms. The rough position of the eight heavy atoms was found by direct methods (SIR97) [3] on merged 3-D ED data and the model was refined by Rietveld technique (GSAS) [4] on powder XRD data by fixing the stoichiometric Bi and Pb occupancy on each site. The oxygen atoms were located in successive steps in ΔF maps obtained with electron and XRD data by using the previously Rietveld refined model. Final residuals were R_{wp}=7.32% R_p=5.12%.

P13.OD.001 TEREPTHALATE SALTS. SALTS OF MONOPOSITIVE CATIONS. James A. Kaduk, BP Amoco PLC, Naperville IL 60566

The crystal structures of dilithium, disodium, and diammonium terephthalate have been solved *ab initio* using Monte Carlo simulated annealing techniques, and refined using synchrotron powder data. The use of synchrotron data was critical to obtaining the correct unit cells. Both reciprocal space and real space minimizations were necessary in the structure solutions. The structure of dipotassium terephthalate has been refined using standard single crystal techniques. Although over 8×10^9 pounds of terephthalic acid is produced each year, very little is known about the nature of terephthalate complexes.

$Li_2C_8H_4O_4$ crystallizes in the monoclinic space group $P2_1/c$, with a = 8.35921(5), b = 5.13208(2), c = 8.48490(5) Å, β = 93.1552(4)°, V = 363.451(3) Å^3, and Z = 2. The Li are tetrahedrally-coordinated, and the packing of the terephthalate anions is reminiscent of the γ packing of aromatic hydrocarbons.

$Na_2C_8H_4O_4$ crystallizes in the orthorhombic space group $Pbc2_1$, with a = 3.54804(5), b = 10.81604(16), c = 18.99430(20) Å, V = 728.92(2) Å^3, and Z = 4. The coordination of the two independent Na is trigonal prismatic, and the TA packing resembles the β packing of hydrocarbons. Each carboxylate group of the TA is chelated to one Na, and is bonded to four other Na above and below the ring plane. The carboxylates are rotated approximately 20° out of the ring plane. $(NH_4)_2C_8H_4O_4$ also crystallizes in $Pbc2_1$, with a = 4.0053(5), b = 11.8136(21), c = 20.1857(24) Å, V = 955.1(2) Å^3, and Z = 4. The cations and planar anions are linked by hydrogen bonds, and the TA packing is a looser version of the β packing. $K_2C_8H_4O_2$ crystallizes in $P2_1/c$, with a = 10.561(4), b = 3.9440(12), c = 11.535(5) Å, β = 113.08(3)°, V = 442.0(3) Å^3, and Z = 2. The K is trigonal prismatic, and the TA packing is also β. These structures form enough of a data base to begin to understand the energetics of the packing of terephthalate anions, and to use this information in determining the solid state structures of process-related terephthalate salts.

P13.OD.002 ELECTRON CRYSTALLOGRAPHY ON NLO-ACTIVE COMPOUNDS. U. Kolb , A. Yakimanski and I.G. Voigt-Martin Institut für Physikalische Chemie, Johannes Gutenberg-Universität Mainz, Welder Weg 11, 55099 Mainz

Microcrystalline compounds can be investigated by selected area electron diffraction, giving structural information which cannot be gained by x-ray methods. In addition structures can be visualised in real space directly using high resolution technique (HRTEM). In diffraction mode three dimensional data sets can be measured by tilting the sample around suitable axes (max. tilt angle ±60°). Determination of the unit cell and the space group is usually possible with enough projections and can be refined using a combination of x-ray powder diffraction and packing energy calculations. From the NLO-active compounds 4-nitrophenyl-hexyl-urethan (NPHU) and 3-para nitrophenyl-propan-1-ol (NPP), with a non-linear optical activity up to 80 times urea, ≈100-200 Å thick crystals were grown from ethanol. For structure analysis using simulation methods [1] cell dimensions, space group, an initial model of the molecule obtained from semiempirical, quantum mechanical calculations [2] and structure factor amplitudes were used. Packing energy minimisation and simulation of diffraction patterns are performed alternatingly gaining a good R-factor. Based on the obtained atomic coordinates, hyperpolarizability tensors were calculated using quantum mechanical methods and related to the crystal by appropriate co-ordinate transformation [3]. Separately, a 3D-data set was buildt up and statistical ab initio methods such as "Maximum Entropy" [4] were used.

P13.OD.003 CRYSTAL STRUCTURE DETERMINATION OF ζ-AgZn. A. Olsen, P. E. Runde and O. B. Karlsen, Centre for Materials Science, University of Oslo, Gaustadalléen 21, 0371 Oslo, Norway.

The crystal structure of Ag_2Ga was recently [1] determined by single crystal X-ray diffraction to be hexagonal (space group $P\bar{6}2m$), and not trigonal ($P\bar{3}$) as earlier reported. This leaves the low temperature ζ phase, sometimes referred to as the ζ' phase, in the silver-zinc system as the only phase in the literature to have the trigonal AgZn-type of structure. ζ-AgZn was determined by Edmunds and Qurashi by X-ray powder diffraction data, [2]. It was reported to have trigonal symmetry with space group $P\bar{3}$, nine atoms in the unit cell and cell dimensions a = *0.76360 nm* and c = *0.28197 nm*. Because of the new structure determination of Ag_2Ga and the fact that it was reported to be isostructural to ζ-AgZn, we have reinvestigated the structure of the ζ phase using transmission electron microscopy (TEM) and X-ray powder diffraction.

Results from selected area electron diffraction (SAED) suggested the hexagonal Bravais lattice and cell dimensions as above. No general or special reflection conditions were found. Convergent beam electron diffraction (CBED) experiments show symmetry consistent with the $P\bar{6}2m$ space group and not with $P\bar{3}$. Rietveld refinement of X-ray data based on the trigonal model [2] did not result in convergence. A starting model for Rietveld refinement based on space group $P\bar{6}2m$ and the Ag_2Ga structure with complete disorder was then tried. The refinement converged with R_p = 0.063 and cell dimensions a = *0.76379 nm*, c = *0.28188 nm*. The Zn atoms fully occupy *1a* and *2d* positions. The remaining zinc and all Ag atoms share the *3f* and *3g* positions.

P13.OD.005 TRICE - A PROGRAM FOR RECONSTRUCTING 3D RECIPROCAL SPACE AND DETERMINING UNIT CELL PARAMETERS X.D. Zou, Structural Chemistry, Stockholm University, S-106 91 Stockholm, Sweden and A. Hovmöller, Rudbeck School, S-192 51, Sollentuna, Sweden

Determination of crystal unit cell is the first and an important step of *ab initio* structure determination. This is often a very difficult step of structure determination by X-ray powder diffraction, especially when the sample contains several different phases. It is possible to obtain electron diffraction patterns of individual micro/nano sized crystals in transmission electron microscopes. Due to the very short electron wavelength (~ 0.02 Å), an electron diffraction pattern is an undistorted representation of a two dimensional section of the three dimensional reciprocal lattice. The 3D reciprocal lattice can be obtained by tilting the crystal in the microscope and collecting a series of diffraction patterns from the same crystal.

In practice, it is not easy to reconstruct the 3D reciprocal lattice and determine the unit cell dimensions manually from the diffraction pattern series. We have developed a program system - Trice for this purpose. Electron diffraction patterns are digitised into a PC. The position and intensity of each diffraction spot from each diffraction pattern in the tilt series are determined and refined by the program system ELD [1]. These data plus the direction of the tilt axis and angle of tilt are used as input for Trice.

Trice combines the electron diffraction patterns of different orientations and reconstructs a part of the 3D reciprocal lattice. The 3D reciprocal lattice can be rotated and visualised from any direction. The unit cell parameters are determined directly by Trice. Normally diffraction patterns from three different orientations are enough for determining the unit cell. The lattice type and symmetry can be also determined from the 3D reciprocal lattice. Trice runs under Windows95, 98 and NT. The unit cell parameters can be further refined against X-ray powder diffraction data to higher accuracy.

13OE ABSORPTION CORRECTIONS

M13.OE.001 COMPARISON OF ABSORPTION CORRECTIONS FOR CRYSTALS IN THE INTERMEDIATE ABSORPTION RANGE. Larry R. Falvello, University of Zaragoza-C.S.I.C., Department of Inorganic Chemistry, Plaza San Francisco s/n, E-50009 Zaragoza, Spain.

Comparisons are made between the results of single crystal structure determinations in which different absorption correction techniques have been used, for samples with linear absorption coefficients μ in the range of 10 – 50 mm^{-1} (near and beyond the upper end of the range typically found, for example, for organometallic complexes of the third series of transition metals). Measured absorption corrections using traditional ψ-scans, three-dimensional ψ-scans, and Laue-equivalent data are considered, along with *a posteriori* calculated corrections. Uncorrected data are also included in the comparisons. The effects on both the structural results, including anisotropic displacement parameters and the data themselves will be described.

M13.OE.002 EMPIRICAL CORRECTION FOR ANISOTROPIC ABSORPTION AND "ABSORPTION-LIKE" EFFECTS. Robert H. Blessing, Hauptman-Woodward Medical Research Institute, 73 High Street, Buffalo, New York 14203, USA. blessing@hwi.buffalo.edu

An absorption anisotropy (or anisotropic scaling) correction calculated from differences among multiply measured data equivalent by symmetry and/or azimuth rotation is implemented in the program SORTAV (Blessing, 1995). The principles, practice, and calibration of the correction calculation will be reviewed, and recent improvements in the program implementation will be described. Among the improvements are down-weighting or rejection of outlier measurements (Blessing, 1997) and use of the eigenvalue filtering technique (Watkin, 1994) in the least-squares fit of correction parameters that might be effectively perfectly correlated or indeterminate from the available data in an unfiltered fit.

Research support from USDHHS PHS NIH grant no. GM46733 is gratefully acknowledged

M13.OE.003 SADABS: A PROGRAM FOR EXPLOITING THE REDUNDANCY OF AREA-DETECTOR X-RAY DATA. Ludger Häming[1] George M. Sheldrick[2], [1]Bruker Analytical X-ray Systems GmbH, Karlsruhe, Germany, [2]Institut für Anorganische Chemie, University of Göttingen, Germany

The use of area-detectors with nearly or literally no readout time, like CCD detectors or multi-wire proportional counters, opened the possibility of a much improved data collection strategy. Instead of restricting the experiment just onto the asymmetric part of reciprocal space these detectors are able to scan the complete reciprocal sphere. The standard data collection protocol for the SMART system will already give redundant data. Depending on the Laue-group symmetry of the sample and the expected absorption effects, a small modification of such a strategy will lead to sufficient redundancy. These redundant intensity measurements do not only contain symmetry related reflections but also multiple observations of Bragg reflections under slightly different geometrically conditions.

SADABS exploits this data redundancy to reduce various systematic errors in the measured intensities and puts the esds on a more absolute scale. For instance effects like crystal or beam decay can be treated by a smoothed scale factor for each X-ray diffraction frame. This treatment does also correct against effects which are due to changes in the sample volume irradiated (e.g. needle shaped crystals). X-ray absorption appears not only within the crystal but also within its support. SADABS uses spherical harmonic functions to model the overall absorption effects of the experimental setup. The individual measured Bragg intensities are fitted to the mean of their equivalent observations. In addition a correction for the lamba/2 contribution can be applied.

M13.OE.004 DIFABS REVISITED. D.J.Watkin, Chemical Crystallography Laboratory, 9 Parks Road, OXFORD, OX1 3PD, UK. & A.N. Chernega, Institute of Organic Chemistry, National Academy of Sciences of Ukraine, Ul. Murmanskaya, 5, Kiev-94, 253600, UKRAINE.

Since its appearance in 1983, DIFABS and DIFABS-like programs have divided the crystallographic community more deeply than almost any other controversy. The pro- and anti-DIFABS lobbies are drawn up like opposing armies. This is a fruitless confrontation, since a useful compromise almost certainly exists. The original implementation of DIFABS was an excellent first attempt at utilising a concept, but it suffered from various problems which have clouded the differentiation between concept and implementation. Amongst the problems are:

1 The name. The process actually adjusts the model (or data) for *any* systematic residual between Fo and Fc as a function of diffraction geometry.

2 In the original code, Fo was modified (*as with most other absorption corrections*). There is no reason why corresponding changes cannot be made to Fc as part of the modelling process.

3 In 1983, most data were collected on serial (conventional) diffractometers, giving little redundancy in the data. The use of DIFABS with area detector data is closely related to a constrained multi-scan correction.

The value of DIFABS cannot easily be assessed unless a broad body of experience is available. The growing use of crystallography as a first-line analytical method, the growing use of area detector diffractometers for routine data collection, and the growing use of the oil-drop crystal mounting technique means it is time to look closely at DIFABS once again.

M13.OE.005 CRYSTAL SHAPE MEASUREMENT FOR ABSORPTION CORRECTION BY USE OF CCD CAMERA. Akihito Yamano, Katsunari Sasaki, Tsuneyuki Higashi, X-ray Research Laboratory, Rigaku Corporation, 3-9-12, Matsubara-cho, Akishima-shi, Tokyo 196-8666, Japan

It is well known that the absorption correction based on the crystal shape is the most precise and reliable among various correction methods. Accordingly, the Notes for Authors of Acta Crystallographica Section C says that analytical or numerical corrections are strongly recommended when the absorption effect of a sample crystal is judged to be significant. The traditional method of obtaining the crystal shape is to use a four-circle or kappa goniometer and a telescope, bit it requires certain knowledge of crystallography and some experiences.We have developed an easy method to obtain the crystal shape by the use of a CCD camera. The procedure of the method is as follows. Photographs of a crystal are taken at various goniometer settings. Crystal boundary in each photography is manually defined on a

screen using graphical tools. The boundaries are then analyzed to make a set of Cartesian planes. We have also written a Gaussian absorption correction program which accepts Cartesian planes as a crystal shape. All the programs written in C run currently on an SGI and are being transported to a PC on Windows95/98 OS. A next step is to add a function identifying a crystal boundary in a semi-automatic manner.

13OF STRONG CLOSED SHELL INTERACTIONS IN CRYSTALS

M13.OF.001 WEAK INTERACTIONS IN CRYSTALS OF GOLD(I) COMPOUNDS. L.G. Kuz'mina, Institute of General and Inorganic Chemistry, Russian Academy of Sciences, Leninskii pr. 31, Moscow 117907, Russia, and A.A. Bagatur'yants, Photochemistry Center, Russian Academy of Sciences, ul. Novatorov 7a, Moscow 117421, Russia, J.A.K. Howard, Chemistry Department, University of Durham, Durham DH1 3LE, UK.

Unusual structures of mono and polynuclear (including small clusters) Au(I) compounds are considered. These structures are characterized by a manifestation of strong closed-shell Au...Au aurophilic interactions and Au...heteroatom and Au...π–system secondary bonding. The pronounced tendency to form closed-shell aurophilic bonds often gives unpredictable results when weak organic acids undergo simple auration with $[O(AuPPh_3)_3]BF_4$. Either small clusters or dimeric compounds rather than mononuclear gold(I) complexes form in this case (via Au...Au interaction). An example when simple auration results in the cleavage of a C-N bond is also known. Structural nonrigidity of some Au(I) compounds is discussed within the concept of secondary bonds and suggested as a way of modeling some dynamic processes. Differences in structural manifestations of formally isolobal AuL^+, HgR^+, and H^+ are discussed.

We thank the Russian Foundation for Basic Research for funding this work (projects 98-03-33142 and 99-03-33180).

M13.OF.002 THEORETICAL STUDIES OF CLOSED-SHELL INTERACTIONS. N. Runeberg, Department of Chemistry, University of Helsinki, POB 55, 00014 Helsinki, Finland.

The attraction between systems with fully occupied shells has recently gained a lot of attention in inorganic chemistry, covering both its experimental and theoretical aspects (for a review see ref.[1]). One common type of closed-shell attractions is the *metallophilic* attraction, typically found between d^{10} coinage-metal centers. The attraction between closed-shell cationic gold(I) centers represents the strongest, and most thoroughly studied class of this metallophilic interaction. Although the strength of this interaction is comparable with strong hydrogen bonds or weak covalent bonds, it cannot be satisfactorily explained by classical theory, such as hybridization. Theoretical studies indicate that the aurophilic attraction is an electron-correlation effect, strengthened by relativity. Extensive ab initio studies shows that the attraction at large distances is dominated by a dispersion contribution, described as interactions between instantaneous dipoles. When approaching equilibrium distances the dispersion contribution is accompanied by a newly identified ionic contribution, represented by instantaneous charge-transfers between the gold-centers.[2]

M13.OF.003 ELECTRON-DENSITY VIEW ON THE CLOSED-SHELL INTERACTIONS. V. G. Tsirelson, Quantum Chemistry Division, D.I. Mendeleev University of Chemical Technology, Moscow 125047, Russia.

This presentation considers the closed-shell atomic and molecular interactions in crystals from the electron-density view. These interactions are characterised within Bader's topological theory by the negative value of Laplacian of the electron density (ED) in the (3,-1) critical point on the interaction line. The value of the ED at this point deviates from 0.01 e·E in compounds of the inert gases till 0.3 e·E in the perovskites. Corresponding-ly, the strength of the closed-shell interactions is different. The deformation ED and Laplacian of the ED as well as a full pattern of the critical points in the ED was determined in the inert gas compounds, rock- salt and molecular crystals, perovskites and silicates. The analytical models were used in order to reconstruct the accurate quasi-static parameters of the electron density (ED) from both experimental and Hartree-Fock X-ray structure amplitudes determined with accuracy of 1-2%. Electrostatic potential (EP) also reflecting the nature of the interatomic interactions was considered additionally. It was found that interrelated analysis of the topological features of the ED and EP allows to better understand the limits of the close-packing concept of crystals as well as a nature of distortion of the ideal atomic close-packing. An origin of the one-dimensional EP maximum on the anion-anion line in rock-salt type crystals was investigated and connected with mutual sizes of cations and anions. The important role of regions of the electron deconcentration in the atomic valence shells in the formation of the closed-shell interactions is stressed.

The support of this study by the Russian Foundation for Basic Researches (grants 96-03-00071G and 98-03-32654) and the Deutsche Forschungs-gemeinschaft (grant 435 RUS 113/128/0) is gratefully acknowledged.

M13.OF.004 CATION AGGREGATES IN IONIC SOLIDS: THEIR RELATION TO THE PARENT METALS. A. Vegas. Instituto de Química Física "Rocasolano", CSIC, Serrano 119, E-28006 Madrid, Spain.

An inspection to the cation arrays of ionic solids reveals [1,2 and references therein] that cations are not the "isolated entities" predicted by the ionic model. In many ionic compounds, cations are forming aggregates which reproduce both, topology and distances of the parent metals structures, as if some kind of interaction would exist between them. Thus, the (100) planes of the Ti-subarray in the rutile (TiO_2) structure are identical to the (100) planes of *hcp*-Ti, the Mg atoms in olivine (Mg_2SiO_4) form aggregates which are fragments of the structure of *hcp*-Mg, in the bixbyite-type structure of In_2O_3, the In atoms form a structure which is a distortion of the lattice of elemental In, and in spinel ($MgAl_2O_4$), the Al-subarray is just one half of the *fcc* structure of Al metal. Although we give here only some significant examples, a systematic study of all the crystal structures contained in ICSD reveals that, for a given metal, the distribution of the cation-cation distances is not uniform but present maxima which coincide with the values of the shortest M-M distances in the pure metals. In some cases, maxima coincident with the second-nearest neighbours are also present.

These features occur not only with cations which adopt a noble gas configuration (Mg^{2+}, Al^{3+}, Sc^{3+}, Ti^{4+}) but also with atoms which have not a closed-shell, as they are the cations of the Rare Earths [2]. They are difficult to justify with the ionic model and it could be explained if we assume an inclomplete redox process between cations and anions and that part of the non-transfered electrons could be used in the formation of M-M interactions.

The impression is that metallic nets do not need necessarily to be broken down in atoms to form a compound. They are only transformed, modified or broken in fragments by the inclusion of the anions, but maintaining the topology and distances of the parent metals.

M13.OF.005 CLOSED-SHELL BONDING IN IONIC CRYSTALS FROM THE PERSPECTIVE OF THE ATOMS IN MOLECULES THEORY. V. Luaña, A. Martín Pendás, A. Costales, P. Mori-Sánchez, and M. A. Blanco Departamento de Química Física y Analítica, Universidad de Oviedo, 33007-Oviedo, Spain.

The quantum mechanical laws of motion are, in general, not applicable to arbitrary regions within a molecular or crystalline system. It is only when regions are bounded by surfaces with zero flux of the gradient of the electron density ($[(\nabla)\vec{\rho}\cdot[(n)\vec{\rho}] = 0$) that all quantum mechanical laws hold and all observables are locally well defined. Upon this single requirement a rigorous, well defined, and unique theory of chemical bonding has been developed: the Atoms in Molecules (AIM) theory of R. F. W. Bader and collaborators [1].

We have used the AIM theory to analyze the electron density in a large variety of compounds and several crystalline families [2,3,4,5]. Some of the main results emerging from our work will be presented in this talk. Of particular importance is the coherence of the bonding properties in crystals and molecules once the interatomic distance is properly accounted for. Many ionic crystals have been found to exhibit secondary bonding, i.e. bonding between second and further neighbors, this behavior being mainly controlled by the particular crystalline structure and ionic size.

P13.OF.001 RECOGNIZING FRAGMENTS OF THE NOBLE GASES STRUCTURES IN THEIR COMPOUNDS. A. Vegas. Instituto de Química Física "Rocasolano", CSIC, Serrano 119, E-28006 Madrid, Spain.

The compounds of the Noble Gases, in the solid state, tend to reproduce part of the elemental crystal structures of the gases. This feature, which has been found to be a general trend in metal oxides [1], is also observed in the noble gases compounds, indicating that elements, in spite of being coordinated by other atoms, tend to preserve their structure when forming compounds.

In the tetragonal structure of KrF_2, the molecules are parallel to the (002) planes, producing an slight expansion of the elemental *fcc* structure of Kr in the *ab* plane but maintaining the **c** axis (5.83 Å) almost identical to the **a** parameter of elemental Kr (5.72 Å). However, in XeF_2, the linear molecules are parallel to the **c** axis of the tetragonal net, and the exfoliation takes place along the **c** axis, but maintaining almost unaltered the (002) planes of *fcc*-Xe (Xe-Xe distances of 4.31 and 4.38 Å, respectively). In the monoclinic phase of XeF_4, the distortion is greater, The Xe atoms, at (0,0,0) and (1/2, 1/2, 1/2) form an I monoclinic net which is a distortion of the tetragonal I cell contained in *fcc*-Xe, but where the **c** axis (6.20 Å) correspond almost to the **b** axis in the monoclinic cell (5.92 Å) and where the shortest Xe-Xe distances are only 0.2 Å longer than in the element. In the mixed crystal $XeF_2 \bullet XeF_4$, the Xe atoms form linear chains, separated at 4.50 Å (4.38 Å in the element).

The most striking structure is XeF_6. Although the Xe atoms are coordinated by six F atoms, they form tetrahedral and octahedral clusters in which the Xe-Xe distances (4.22 and 4.40 Å respectively) are close to the value in elemental Xe. Thus, the structure can be regarded as the elemental structure of Xe, broken in fragments (octahedra and tetrahedra), by the inclusion of the F atoms. It is also surprising that Xe atoms of different tetrahedra form squares (l = 6.24 Å) which are identical to the (100) faces of elemental Xe (a = 6.20 Å), This makes that *fcc*-Xe could also be reconstructed by forming unit cells with an octahedron and two parallel squares.

13AA HOT MACROMOLECULAR STRUCTURES (II)

M13.AA.001 CRYSTAL STRUCTURE OF THE ATP-BINDING SUBUNIT OF AN ABC TRANSPORTER. L.-W. Hung, E.O. Lawrence Berkeley National Laboratory, I. X. Wang, K. Nikaido, P.-Q. Liu and G. F.-L. Ames, Department of Molecular and Cell Biology, University of California, Berkeley, and S.-H. Kim, E.O. Lawrence Berkeley National Laboratory and Department of Chemistry, University of California, Berkeley, Berkeley CA 94720

We report the crystal structure at 1.5 Å resolution of HisP, the ATP-binding subunit of the histidine permease, an ABC transporter from *Salmonella typhimurium*. Members of the ABC transporter superfamily are widely found in prokaryotes and eukaryotes. Among the eukaryotic members, several are medically important proteins, such as the cystic fibrosis transmembrane conductance regulator (CFTR), the P-glycoprotein (MDR: muti-drug resistance protein), and the transporter associated with antigen processing (Tap1/Tap2). ABC transporters have two highly conserved ATP-binding domains and two transmembrane domains. We correlate the crystal structure of HisP with the biochemical, genetic, and biophysical properties of the wild type and of numerous mutant HisP proteins as well as with the properties of mutant CFTR and MDR proteins.

The overall shape of the crystal structure of the HisP monomer is that of an "L" with two thick arms; the ATP-binding pocket is near the end of one of the arms. A six-stranded β-sheet spans both arms of the "L" with a domain of α + β type on one side and a domain of mostly α-helices on the other side of the sheet. The overall fold of the structure is different from that of any known protein. However, the topology of the ATP binding pocket is close to that of RecA and of the α- and β-subunits of bovine F1 ATPase. In agreement with the notion that HisP forms a dimer in vivo, a dimer consisting of two monomers related by a two-fold axis is also found in the crystal structure of HisP. All available biochemical data about HisP in the HisQMP2 complex are compatible with the characteristics of HisP in the crystal structure. The structure of HisP provides a basis for understanding properties of ABC transporters and those of defective CFTR proteins.

M13.AA.002 CRYSTALLOGRAPHIC STUDIES OF THE MIP PROTEIN FROM LEGIONELLA PNEUMOPHILA. A. Riboldi-Tunnicliffe, R. Hilgenfeld. IMB, Department of Structural Biology and Crystallography, Beutenberg Str 11, Jena D-07745, Germany

Macrophage infectivity potentiator protein (MIP) is located on the outer membrane of L.pneumophila, the causative agent of Legionnaires' disease. This protein has been shown to be one of the major virulence factors of this organism (Fischer et al., 1992). MIP belongs to the protein class of peptidyl prolyl cis/trans isomerases (PPIases) which catalyse the cis/trans isomerisation of the peptide bond at the N-terminal side of the amino acid proline. MIP belongs to the family of FK506 binding proteins; these bind and are inhibited by the macrolides FK506 and rapamycin, both are important as suppressors of T-cell activation (Hacker et al., 1993). Sequence analysis suggested the presence of 2 domains (Ludwig et al., 1994). Initial attempts to solve the structure by molecular replacement using human FKBP12 as a model proved impossible with little or no density extending beyond the model. However, this model did reveal the presence of a tightly bound zinc ion within the structure. With this information we were able to perform a MAD experiment on the zinc edge, and solve the structure to 2.4A. The structure of the MIP dimer is highly unusual. the N-terminal domain is a small helical dimerisation module which we belive to be a novel fold, comprising residues 10-50. This is followed by a very long isolated alpha-helix the C-terminal of which carries the FKBP domain. The two FKBP domains of the dimer are approx. 21A apart. This unusual structure suggests modes of interaction with a receptor and new ideas for the design of drugs directed against Legionella and Chlamydiae.

M13.AA.003 THREE-DIMENSIONAL STRUCTURE OF A NOVEL ADENYLYLTRANSFERASE IN THE CO-ENZYME A BIOSYNTHETIC PATHWAY. Tina Izard & Arie Geerlof, Department of Biochemistry, University of Leicester, LE1 7RH, UK

Coenzyme A (CoA), the principal acyl carrier in all living cells, is required for numerous synthetic and degradative reactions and is also involved in the control of intermediary metabolism. It is invariably synthesised from pantothenate (vitamin B5), cysteine and ATP in five steps.

Phosphopantetheine adenylyltransferase (PPAT) is an essential enzyme in bacteria that catalyses a rate limiting step in coenzyme A (CoA) biosynthesis, by transferring an adenylyl group from ATP to 4'-phosphopantetheine, yielding dephospho-CoA (dPCoA). Its structure is of interest in gaining a new knowledge base that broadens our understanding of the metabolic origins of an important co-factor for human metabolism.

PPAT from Escherichia coli has been overexpressed, purified and crystallised. The PPAT-dPCoA co-crystals belong to the space group I23 with unit cell dimensions a = 135 Å. Here we present the three-dimensional structure of PPAT and some insights into its mechanism of reaction.

M13.AA.004 TRANSCRIPTIONAL REGULATION OF PURINE BIOSYNTHESIS IN *B. SUBTILIS*. S.Sinha[1], B.S.Shin[2], S.Lange[1], P.Rappu[3], J.M.Krahn[1], D.R.Tomchick, P. Mäntsälä[3], H.Zalkin[2] and J.L.Smith[1]. [1]Dept. of Biological Sciences and [2]Dept. of Biochemistry, Purdue University, West Lafayette, IN 47907,USA; [3]Dept. of Biochemistry and Food Chemistry, Turku University, Turku, Finland.

Proteins encoded by the *purR* operon in *B. subtilis* are responsible for transcriptional regulation of genes of *de novo* purine biosynthesis from the precursor PRPP. Two translationally coupled genes from the *purR* operon, *purR* and *orf2*, encode a 285-residue, transcription initiation repressor, PurR, and a 125-residue protein, Orf2, respectively[1]. A PurR homodimer binds to unknown specificity elements in a long segment of control-site DNA of the *pur*, *purA* and *purR* operons[2]. PRPP induces these operons by inhibiting DNA binding of PurR. Orf2 modulates PurR function *in vivo* by an unknown mechanism. Structures of the two proteins have provided information important to elucidating their functions.

Structures of both proteins have been solved using MAD techniques; PurR to 2.3Å by SeMet MAD (space group *P*1, a=65.4 Å, b=72.5 Å, c=83.4 Å, α=84.7°, β=84.6°, γ=67.5°, z=4 monomers) and Orf2 to 1.7 Å by Hg MAD (space group $P6_5$, a=b=53.5 Å, c=204.9 Å, z=18 monomers).

PurR belongs to the Type I phosphoribosyltransferase (PRTase) structural family. Unlike the catalytic PRTases, PurR uses the PRTase fold to bind PRPP as an effector molecule. A highly basic N-terminal helix-turn-helix (HTH) domain may be responsible for DNA binding. However, the mode of DNA binding may differ in PurR and other dimeric HTH DNA binding proteins, as an extensive hydrophobic interface between the PurR HTH domains appears to fix the DNA recognition helices in an unusual orientation.

Orf2 is the first structural representative of a widely distributed protein family of unknown function. The extensive subunit interface of Orf2 indicates that it is a biological trimer. Its electrostatic surface potential suggests Orf2 and DNA do not interact directly. Residues conserved in various Orf2 homologs map to a single, solvent-accessible pocket, suggestive of a ligand or substrate binding site.

M13.AA.005 CRYSTAL STRUCTURE OF HUMAN HMG-COA REDUCTASE. Eva S. Istvan[1], Maya Palnitkar[2], and Johann Deisenhofer[1,2]. [1]Dep. of Biochemistry, University of Texas Southwestern Medical Center, Dallas, TX, USA. [2]Howard Hughes Medical Institute, Dallas, TX, USA.

3-hydroxy-3-methylglutaryl-coenzyme A (HMG-CoA) reductase catalyzes the committed step in the biosynthesis of sterols such as cholesterol and isoprenoid compounds such as farnesyl-PP. Although cholesterol is required for eukaryotic membrane structure, and protein farnesylation is essential for cell growth, overaccumulation of products of the mevalonate pathway can be toxic and lead to hypercholesterolemia. Inhibitors of HMG-CoA reductase are widely used in therapy as cholesterol-lowering drugs.

We solved the structure of the 50kDa catalytic domain of human HMG-CoA reductase in the presence of substrate at 2.6 Å resolution. The protein crystallizes in space group $P2_1$ as a dimer of dimers with four molecules in the asymmetric unit. Human HMG-CoA reductase shares 20% sequence identity with *Pseudomonas mevalonii* reductase, which has been solved at 3.0Å[1]. Although the overall fold is similar, the structure of the human enzyme is significantly different from the *P.mevalonii* structure, and Patterson searches with the structure of the bacterial enzyme failed. Multiple isomorphous replacement techniques were also unsuccessful because of severe non-isomorphicity problems. The structure was finally solved by MAD using the seleno-methionine variant. 42 of the 68 seleno-methionines present in the asymmetric unit could be located by direct methods using the package *Shake-and-Bake* (v2.0)[2]. Additional 16 sites were identified using anomalous difference fourier techniques. The structure refinement to 2.1Å is now in progress.

M13.AA.006 THE STRUCTURE OF A REGULATORY COMPLEX CONTAINING A UNIQUE RNA BINDING PROTEIN FROM THE AMIDASE OPERON OF *PSEUDOMONAS AERUGINOSA*. B.P. O'Hara, R. Norman, T. Barrett, S.M. Roe, P.T.C. Wan, R. Drew and L.H. Pearl. Dept. of Biochemistry and Molecular Biology, University College London, Gower Street, London WC1E 6BT, UK.

Pseudomonas aeruginosa is an opportunistic Gram-negative bacterium responsible for chronic lung infections in cystic fibrosis and immunologically suppressed conditions. Signal transduction in bacteria occurs via two component regulatory systems, with a histidine protein kinase sensor and a response regulator. In effect, a molecular switch regulated by a phosphorylation cycle. However, expression of the amidase operon of *Pseudomonas aeruginosa* is regulated by a novel signal transduction pathway, which, while using a two component system, is controlled by a steric hindrance mechanism.

In this system AmiC is the ligand sensor and AmiR the response regulator, a transcription anti-termination factor. Under inducing (acetamide) growth conditions AmiR binds to the operon RNA leader transcript to prevent formation of transcription terminator and allow operon expression. In the presence of the co-repressor butyramide, AmiC and AmiR form a non-active complex. Acetamide causes dissociation of the regulatory complex and represents a unique molecular switch, regulating operon expression.

We have isolated, purified and crystallised a stable soluble AmiC/AmiR complex in the presence of the non-inducing ligand butyramide. The crystals, which diffracted to 2.2Å, belong to the monoclinic spacegroup C2, with two molecules of AmiR and two molecules of AmiC in the asymmetric unit. AmiR is a dimer, with each monomer interacting with one AmiC molecule. The AmiR N-terminal domain is structurally similar to the classic response regulator receiver domain (CheY-fold). The C-terminal domain consists of a long helix with a final helix-turn-helix, which, from mutational studies, contains the sequence specific RNA binding motif.

13BB THE MAD METHOD

M13.BB.001 SOLVE - AUTOMATED MIR AND MAD STRUCTURE DETERMINATION. Thomas C. Terwilliger, Joel Berendzen, Structural Biology Group, Los Alamos National Laboratory, Los Alamos, NM 87545 Biophysics Group, Los Alamos National Laboratory, Los Alamos, NM 87545.

We have developed a fully automated procedure for determination of heavy atom sites and calculation of native phases in a MAD experiment or in all derivatives in an MIR experiment. The only input required consists of the space group and cell constants, resolution limits, the type of heavy atoms present, and the scaled data. The output consists of ranked sets of refined heavy atom parameters and native electron density maps. The most important new feature of the procedure is the scoring of potential solutions. Four criteria are used in scoring. The first corresponds to peak heights at expected positions in the Patterson function. The second is peak heights at heavy atom positions in "omit" heavy atom difference Fouriers. The third is the figure of merit of the phasing obtained. The fourth is the non-randomness of the native Fourier obtained. Each of these criteria are evaluated based on the Z-score obtained from a comparison of the solution being tested and the mean over many solutions. The procedure uses a Patterson search procedure (a modified version of HASSP) to obtain plausible starting solutions. The solutions are scored and ranked. One at a time, solutions are considered as test starting solutions for generation of new solutions by addition or deletion of individual sites. After calculation of native phases from a test solution, difference Fourier maps (and cross-difference Fourier maps for the MIR case) are used to identify possible additional sites. New solutions are scored and included in the ranked list of solutions. The procedure is iterated until no additions or deletions to existing highly-ranked solutions yield an improvement in score. SOLVE is now installed at several synchrotron sources (including the ESRF, NSLS beamlines X-4A, X-8c, and X-12C; SSRL beamlines 7-1 and 9-1, CHESS, the ALS, and the APS) so that crystallographers can solve structures immediately after data is collected. MAD structures with as many as 52 selenium sites in the asymmetric unit have been solved with our procedure, and a number of structures have been solved within hours of data collection. We are now exploring the application of density analysis and modification techniques to the maps output by SOLVE. The presence of distinct regions of protein and solvent in macromolecular crystals has been widely used to improve crystallographic phases through solvent flattening techniques. The same characteristics can be used to evaluate phase quality in direct methods and to rank heavy-atom solutions in the MAD and MIR approaches. The presence of solvent and protein regions can be evaluated either in real-space and in reciprocal-space. The reciprocal-space calculations can be formulated in a series in which only a small number of terms need to be evaluated. Possible applications of measures of macromolecular map quality will be discussed

M13.BB.002 CRYSTAL STRUCTURES OF THE SYNAPTIC FUSION MACHINERY SOLVED BY MAD PHASING. Axel T. Brunger, R. Bryan Sutton, C. Ostermeier, L. M. Rice, and R. Yu, Howard Hughes Medical Institute and Department of Molecular Biophysics and Biochemistry, Yale University, New Haven, CT 06518

Our primary focus is to understand the molecular mechanism of synaptic neurotransmission, and how this process is controlled and regulated by a set of dynamically interacting proteins. Vesicle fusion occurs in several stages: tethering, docking, priming, and Ca2+-dependent fusion. We are investigating the proteins involved at each of these stages by X-ray crystallography, nuclear magnetic resonance, and other spectroscopic methods. We have recently solved the structures of a core of the synaptic fusion complex, the D2 domain of the SNARE complex dissociating chaperon NSF, and the Rab3A-rabphilin-3A complex by MAD phasing. Structure solution of the synaptic fusion used a combinatorial labeling strategy. Each component of the complex was labeled individually or in combination with other components. MAD experiments were carried out on each of the labeled complexes. Phase combination of the resulting probability distributions produced more accurate phases than could be obtained from any of the individual MAD experiments. In addition, solution of the heavy atom site positions was simplified for the MAD experiments involving subsets of the total number of methionines in the complex. This multi-MAD technique was essential for structure solution of this complex and other vesicle-fusion related structures since the crystals were highly mosaic, diffracted weakly, and were highly variable.

M13.BB.003 PROTEIN PROSTHETICS: X-RAY STRUCTURE OF THE *E. COLI* FIMC-FIMH CHAPERONE-ADHESIN COMPLEX. Stefan Knight and Devapriya Choudhury, Department of Molecular Biology, Uppsala Biomedical Center, Swedish University of Agricultural Sciences, Box 590, S-753 24 Uppsala, Sweden., Andrew Thompson, EMBL Grenoble Outstation, C/o Avenue des Martyrs, BP 156X, 38042 Grenoble, France, Vivian Stojanoff, ESRF, Avenue des Martyrs, 38400 Grenoble, France, Solomon Langermann, MedImmune, Inc., Gaithersburg, Maryland 20878, Jerome Pinkner and Scott J. Hultgren ,Department of Molecular Microbiology, Washington University School of Medicine, St Louis, Missouri 63110, U.S.A.

The X-ray structure of the bacterial adhesin that mediates colonization of uropathogenic *E. coli* to the bladder epithelium, FimH, in a complex with its chaperone, FimC, was solved to 2.5 Å resolution. FimH consists of an NH_2-terminal mannose-binding domain and a COOH-terminal pilin domain used for incorporation of the adhesin into the pilus. The pilin domain of FimH has the same immunoglobulin-like topology as the NH_2-terminal domain of PapD-like chaperones, except that the seventh strand is missing. This creates a deep scar on the surface of the domain, leaving part of the hydrophobic core exposed. A donor strand complementation mechanism was revealed in which the chaperone donates a strand to the pilin domain. We propose that an extension at the NH_2-terminus of pilins participate in a donor strand exchange mechanism in pilus assembly. The donor strand complementation mechanism provides the first example of a class of proteins for which the primary sequence does not contain all of the steric information needed for correct folding.

M13.BB.004 MAD STRUCTURE DETERMINATION AT THE CORNELL HIGH ENERGY SYNCHROTRON SOURCE. Steven E. Ealick, Department of Chemistry and Chemical Biology, Cornell University, Ithaca, NY 14853

Station F-2 at the Cornell High Energy Synchrotron Source (CHESS) is routinely used for MAD structure determination. Station F-2 provides rapidly tunable, doubly focused optics consisting of a Si(111) double crystal monochromator with a fixed offset and a vertically focusing mirror. The second monochromator crystal is saggitally focused. The station is equipped with an oscillation camera, a Quantum-4 CCD X-ray detector, a low temperature apparatus, computers for data collection and data analysis and hardware for monitoring and calibrating the station energy. The station has been used to solve dozens of MAD structures, primarily utilizing the Se absorption edge. However, structures have also been solved using the absorption edges of Br, Cu, Fe, Hg, Ho, Pt, Tb and others. As MAD structure determination has become more and more routine, structures of greater and greater complexity are being solved. During the past few years much of our research and development effort has focused on solving MAD structures with weak anomalous signals or structures containing large numbers of anomalous scattering atoms. The former requires accurate data, free from systematic errors, while the latter is limited by the ability to locate the positions of the anomalous scattering atoms. Accurate data is facilitated by combining synchrotron radiation, CCD detectors and cryocrystallography. Location of large numbers of anomalous scattering atoms is made possible through direct methods. The CHESS facilities will be described and several recent examples of MAD structures will be presented. These include the structure determination of the 1:3 interferon-gamma/receptor complex, which contains six ordered Se atoms in 120 kDa of protein and the structure determination of ADP-L-glycero-D-mannoheptose 6-epimerase, which contains 70 Se atoms in an asymmetric of 370 kDa. In the case of the receptor complex, the Se atoms positions were located by molecular replacement by positioning the known structure of interferon-gamma in the unit cell. In the case of the epimerase, 66 Se atom positions were located using the Shake-and-Bake method based on Hauptman's minimal function.

M13.BB.005 THE STRUCTURAL BIOLOGY CENTER'S 19ID UNDULATOR BEAMLINE AT APS: MAD PHASING. R. Sanishvili, R. Alkire, N. Duke, G. Evans †, S. Ginell, L. Keefe*, G. Rosenbaum, F. Rotella, M. Walsh‡, R. Zhang, and A. Joachimiak. Structural Biology Center, Argonne National Laboratory, Argonne, IL 60439, USA. †Currently at MRC-LMB, Cambridge, UK. ‡Currently at IRBM, Rome, Italy. * Currently at IMCA, Chicago, USA.

Multiple wavelength anomalous dispersion (MAD) is rapidly becoming the method of choice for initial phasing in macromolecular crystallography. The major reasons for this are the growing availability of synchrotron radiation sources and improvements in the experimental and theoretical techniques. Undulators, producing high flux, high brilliance X-ray beams at third generation synchrotrons, have not been extensively tested for MAD phasing. Hence, the success of this method was one of the major criterion for commissioning of 19ID undulator beamline of Structural Biology Center (SBC) at the Advanced Photon Source (APS).

To date, a wide variety of elements have been successfully used as anomalous scatterer, with K and LIII absorption edges in the energy range from 7.1 to 17.16 keV utilizing the undulator's 1st (fundamental) and 3rd harmonic radiation.

Typically, fluorescence scans are taken from macromolecular crystal changing (increasing) the monochromator energy in small steps. The choice of wavelengths can be made directly from the scans. Alternatively, f' and f" values can be calculated based on these scans using Kronig-Kramers transformations and plotted against energy. Then 3-4 wavelength MAD data is usually collected from a fresh crystal.

Thus far, about 10 successful MAD experiments have been carried out by members of the SBC staff and more than 20 by user groups participating in the commissioning of the beamline. Various experimental configurations have been used, such as mirror plane and inverse beam geometries, collecting data in small rotational wedges or in one continuous scan for each wavelength etc.

Crystallographic statistics of these MAD experiments, along with the details of most representative examples, will be presented.

P13.BB.001 ATOMIC RESOLUTION MAD PHASING. A. González, R. Morris, V. Lamzin, P. Alzari*, EMBL, Hamburg Outstation, Notkestrasse 85, 22603 Hamburg, Germany. *Unite de Biochimie Structurale, Institut Pasteur, 25 rue du Dr. Roux, F-75724 Paris.

One of the greatest advantages of using anomalous dispersion methods for phasing protein structures is the achievement of unbiased accurate phases to as high resolution as the crystals diffract. Collecting MAD data to very high resolution has several advantages:

High resolution maps are easier to interpret. It becomes possible to build up automatically a large part or all of the structure with modern electron density interpretation techniques.

Totally model-independent phases can be used for evaluation of the solvent structure, structure validation purposes and to study the structural changes induced by binding of heavy atom compounds.

We have collected a three wavelength MAD data set from a mercury derivative of Endoglucanase A (CELA) to 1 Å resolution on the EMBL Hamburg beamline BW7A. From these data, we were able to obtain high quality phases and maps at atomic resolution. The analysis of the model built in the MAD

map and the comparison between this model and the refined native structure will be presented.

P13.BB.002 TRICHROMATIC CONCEPT FOR MAD METHOD AT SPring-8 RIKEN BEAMLINE I. M. Yamamoto and T. Kumasaka, The Institute of Physical and Chemical Research (RIKEN), Mihara, Mikazuki-cho, Sayo-gun, Hyogo 679-5143, Japan, E. Yamashita, Institute for Protein Reseach, Osaka University, Yamadaoka, Suita, Osaka 565-0871, Japan, H. Moriyama and T, Ueki, Japan Synchrotron Radiation Research Institute (JASRI), Mihara Mikazuki-cho, Sayo-gun, Hyogo 679-5198, Japan

At SPring-8, RIKEN beamline I (BL45XU) is designed and developed to accumulate a number of three-dimensional structures with multi-wavelength anomalous diffraction (MAD) method. We have proposed the trichromatic concept as a new solution for MAD phase determination. This concept is that MAD data sets at three different wavelengths are easily taken for the same protein crystal without changing any beamline setting by use of a tandem vertical undulator and a trichromator. The MAD method has the big advantages for accuracy and convenience in phase evaluations. The essential requirement for the MAD method is the tunability of the wavelength. High flux and high energy resolution are also important for the MAD. These requirements are satisfied by the features of third generation synchrotron radiation facility. However, the development of the MAD method as a routine macromolecular crystallography is not so straight forward because of the contribution of the anomalous diffraction is minimal. To insure the accuracy in the MAD experiment, it is essential to minimize systematic error so that actual signals in Bijvoet and dispersive differences are precisely measured as possible. In the MAD experiment, at least three sets of diffraction data have to be collected with three different wavelengths. The wavelengths also have to be tuned as quickly possible with good reproducibility.

Trichromator consists of three pairs of transparent diamond double crystal monochromators and collinearly introduces three monochromatized wavelengths on the identical beam direction. To choose the any combination of each three monochromatic beams, a beam chopper is installed. A cylindrical bend mirror determines the final beam direction and focus. We have finished the initial construction of the beamline and trichromatic undulator beams have been utilized for the MAD data collections. The current experimental station consists of a 4-circle offset goniometer and imaging plate detector R-AXIS IV. We have collected MAD data sets including several anomalous compounds (zinc, mercury, selenium, etc.) and successfully determined MAD phases. The present status and some results of RIKEN beamline I will be presented.

P13.BB.003 MULTIWAVELENGTH ANOMALOUS DISPERSION: DATA COLLECTION STRATEGY. V. Stojanoff, European Synchrotron Radiation Facility, G. Sainz, EMBL Grenoble Outstation and ESRF, G. Leonard, European Synchrotron Radiation Facility, A. Teplitsky, Hebrew University of Jerusalem, S. McSweeney, EMBL Grenoble Outstation and ESRF, G. Shoham, Hebrew University of Jerusalem, Y. Shoham, Technion-IIT and A. Thompson, EMBL Grenoble Outstation and ESRF.

Macromolecular structure determination by the multi-wavelength anomalous dispersion (MAD) method has been increasingly used in recent years. Several data collection strategies have been employed, but the most frequently used is the one originally established by Hendrickson and co-workers [1]. This method is based on minimising systematic errors in data collection by collecting Bijvoet and dispersive differences as close in time as possible. This can be achieved either by positioning the crystal to record Bijvoet pairs on the same frame or by using ïnverse beam" geometry. Data is collected in either case by dispersive differences in small angular wedges at different wavelengths with rapid wavelength cycling. However, good results have also been obtained at the ESRF from completely random crystal orientations by collecting highly redundant data sets or from the collection of complete data sets for each wavelength. This strategy allows to maintain the wavelength constant for long periods of time thus making the MAD method accessible to non-rapidly tunable beam lines.

We present a comparison of data collected with several commonly used strategies for the same crystal, beam line and detector : a) Sample aligned to give Bijvoet pairs on the same image; b) inverse beam geometry, random geometry but data collected by measuring Friedel pairs at ϕ and (ϕ+ 180^o); c) Random geometry; d) Data collected in angular wedges with the wavelength corrected between each wedge, inverse beam geometry.

Results showing the quality of the final maps as well as the relative ease of structure determination will be presented for each method, and discussed in the light of recent results obtained on ESRF beam lines.

P13.BB.004 MAD PHASING 370KDA FROM 70 SELENIUM ATOMS: THE STRUCTURE OF ADP-L-GLYCERO-D-MANNOHEPTOSE 6-EPIMERASE. Ashley M. Deacon [1], Yisheng Ni, William G. Coleman, Jr. [2], Steven E. Ealick [1], [1] Department of Chemistry and Chemical Biology, Cornell University, Ithaca, NY 14853, [2] Laboratory of Biochemistry and Genetics, National Institute of Diabetesand Digestive and Kidney Diseases, NIH, Bethesda, MD 20892

ADP-L-glycero-D-mannoheptose 6-epimerase catalyzes the NADP dependent interconversion of ADP-D-glycero-D-mannoheptose and ADP-L-glycero-D-mannoheptose. The latter is a key intermediate in the biosynthesis of the lipopolysaccharide inner core in several genera of pathogenic and non-pathogenic gram-negative bacteria.

ADP-L-glycero-D-mannoheptose 6-epimerase from E. Coli crystallises in the presence of the catalytic inhibitor ADP-glucose, with two pentamers in the crystallographic asymmetric unit. The crystal structure has been determined by MAD phasing using the selenomethionyl protein. The computer program SnB (Shake and Bake) was used to locate 65 out of the 70 selenium atoms found in the asymmetric unit. A model, comprising 10 molecules of the enzyme, each with tightly bound NADP and less tightly bound ADP-glucose has been refined to 2.0A resolution.

The monomer subunit is arranged in two domains, a large N-terminal domain consisting of a seven-stranded Rossmann fold, associated with NADP binding and a smaller alpha/beta C-terminal domain involved in substrate binding. The overall fold is very similar to UDP-galactose epimerase and GDP-4-keto-6-deoxy-D-mannose epimerase/reductase, although both these enzymes are observed as dimers.

Details of the structure determination and of the catalytically important NADP and substrate binding sites will be presented.

P13.BB.005 WAVELET DENOISING OF POWDER DIFFRACTION PATTERNS. V. Jorík and M. Ďurík, Ľ. Smrčok, Department of Inorganic Chemistry STU, SK-812 37 Bratislava, Slovak Republic and Institute of Inorganic Chemistry SAS, SK-842 36 Bratislava, Slovak Republic

X-ray powder diffraction patterns taken under very different experimental conditions were denoised by the method

called thresholding of wavelet coefficients. The patterns were first transformed by discrete wavelet transform (DWT, Coiflet4 wavelet) [1,2] and then the level-dependent soft-thresholding method (MAD) was applied [3]. The example given below shows denoising of a pattern of a coke with two sharp peaks from a Ni-holder (N-number of points, I in counts). It was found that wavelet denoising in contrast to polynomial filters neither shifted nor distorted the diffraction profiles [4].

13CC SYMMETRY

M13.CC.001 SYMMETRY APPROACHES TO APERIODIC CRYSTAL STRUCTURES. Janssen T., Institute of Theoretical Physics, University of Nijmegen, The Netherlands

The symmetry of well ordered but aperiodic crystal structures can be described in several ways. One can mention representation theory, colour symmetry, superspace and the Fourier space approach. A summery and comparison of the various methods will be given and a number of examples, of compounds and structures, will be discussed.

Because the various approaches are, to a large extent, equivalent it is worthwhile to consider ways of translation of the notations used for these different approaches.

M13.CC.002 MAGNETIC FRIEZE, ROD, AND LAYER GROUPS. Daniel B. Litvin, Department of Physics, The Pennsylvania State University, Penn State Berks Campus, P.O. Box 7009, Reading, PA 19610-6009, U.S.A.

The magnetic subperiodic groups, i.e. the 31 types of magnetic frieze groups, 394 types of magnetic rod groups, and 528 types of magnetic layer groups have been re-derived and symbols defined in analogy to the Opechowski-Guccione symbols for magnetic space groups. For one group of each type of magnetic subperiodic group, information is given of the group's diagrams of symmetry elements and of the general positions/spins, asymmetric unit, symmetry operations, generators selected, positions, with site symmetry, coordinates, and spins, and symmetry of special projections.

M13.CC.003 STRUCTURE OF A QUASICRYSTAL WITHOUT ATOMIC CLUSTERS. Eiji Abe and An Pang Tsai, National Research Institute for Metals, 1-2-1 Sengen, Tsukuba 305, Japan

It is now believed that the quasicrystals could all be explained by some atomic clusters having the same point symmetry of the corresponding quasicrystalline phase. Here we report the first quasicrystal structure without these atomic clusters.

High-resolution transmission electron microscopy (HRTEM) has been applied to study the real atomic structure of the decagonal (*d*-) quasicrystal in the Zn-Mg-rare-earth (RE) system, which is the first *d*-phase based on Frank-Kasper phase. The phase revealed a high-structural perfection comparable to that of the *d*-AlNiCo which is known as the best *d*-quasicrystalline phase (the tenfold symmetry diffraction patterns of these phases are analogous [1]). We have found that the *d*-ZnMgRE phase has a novel structure in which the atomic arrangement in the tenfold symmetry plane can simply be interpreted as the Penrose tiling decorated by individual atoms - the simplest realization of the Penrose tiling as a real atomic structure. This is supported by the fact that a similar local atomic configuration exists in the Zn_7Mg_4 crystal structure. This simple structural model is in sharp contrast to the idea of atomic clusters, which has been successfully used to describe the structure of quasicrystals till now. It is suggested strongly that the symmetric atomic clusters are not an essential factor for quasicrystal formation.

Instead of the atomic clusters, a new idea of *quasi-unit-cell* and its *covering* [2] is applied for structural description. We discuss the structural similarity between the *d*-ZnMgRE and the *d*-AlNiCo based on their corresponding crystal structures of the Zn_7Mg_4 and the $Al_{13}Fe_4$ compounds. In order to confirm further a validity of the *quasi-unit-cell* description for the *d*-AlNiCo, we employ a through-focus imaging of HRTEM with atomic resolution to judge whether the symmetry breaking fashion [2] is due to chemical disordering of the atomic cluster [3] or not.

We thank Prof. P. J. Steinhardt for valuable advice regarding the overlap tiling. Stimulating discussions with Drs. T. J. Sato, H. Takakura, K. Saitoh are greatly acknowledged. This work is partly supported by CREST, Japan Science and Technology Corporation.

M13.CC.004 CLUSTER COVERING OF OCTAGONAL MnSiAl QUASICRYSTALS. S.I. Ben-Abraham, Department of Physics, Ben-Gurion University, IL-84105 Beer-Sheba, Israel and F. Gähler, Institute for Theoretical and Applied Physics, Stuttgart University, D-70550 Stuttgart, Germany.

A likely mechanism for the formation of quasicrystals is by maximally covering space with overlapping stable atomic clusters, thus minimizing the energy and producing long-range correlations and order [1]. The geometric counterpart was put forward by Gummelt [2] who constructed the Penrose tiling by covering the plane with overlapping copies of a single decagonal patch. Octagonal quasicrystalline phases closely related to the β-Mn structure have been observed in the CrNiSi, VNiSi, MoCrNi and MnSiAl systems [3,4]. Jiang, Hovmöller and Zou [5] have experimentally determined the structure of $Mn_{80}Si_{15}Al_5$: octagonal layers *A* alternating with tetragonal layers *B'* and *B"* (mutually rotated by 45°) with an 8_4 screw axis. The layers can be described as decorations of the arrowed octagonal Ammann-Beenker tiling (ABT↑) [6-8]. We represent the decoration abstractly by a novel two-color version of ABT↑. The covering cluster of the quasicrystal corresponds to an octagonal patch of the colored tiling. The patch appears in two variants with complementary colors. The complete 3D quasicrystal has a centered octagonal translation module (the generalization of the lattice concept). The space group is $I8_4/mcm$.

M13.CC.005 ALLOTWINNING AND ITS IDENTIFICATION IN MICAS THROUGH THE MINIMAL RHOMBUS APPROACH. M. Nespolo (Natl. Inst. Res. Inorg. Mat., Tsukuba, Ibaraki 305-0044 Japan) T. Kogure (Tokyo Univ., Grad. Sch. Sci., Mineral. Inst., Tokyo 113-0033 Japan) H. Takeda (Chiba Inst. Techn., Res. Inst., Tsudanuma, Chiba 275-0016, Japan) G. Ferraris (Torino Univ., Dept. Sci. Mineral. Petrol, 10125 Torino, Italy)

The oriented association of two polytypes of the same compound is called *allotwin*[1]. While twin operations are point group operations not belonging to the crystal symmetry, allotwin operations can be symmetry or pseudo-symmetry operations belonging to the crystal symmetry as well[1].

The presence of twins in micas can be anakyzed from their diffraction pattern by means of the *minimal rhombus*[2,3]. This is an asymmetric unit containing nine geometrically independent reciprocal lattice rows parallel to *c**. Reflections along the single-layer repeat ($0.1Å^{-1}$) on each of the geometrically independent rows depend on the number and relative orientation of twinned individuals. The number and position of the reflections identify the twin laws. In an oxybiotite sample from Ruiz Peak, New Mexico, two examples of allotwins involving $1M$ and $2M_1$ crystals (120º and 60º rotations respectively) have been discovered by means of single crystal X-ray diffraction method with a precession camera[3]. The 60º rotation is relatively rare in micas.

The polytype stacking sequence identification by means of the analysis of the periodic distribution of the intensities can be hindered by the presence of allotwinning involving two polytypes with the same number of layers and the same crystal lattice. The two lattices coincide and the measured periodicity results from the composition of intensity distribution of the allotwinned crystals. The allotwin may be mistaken for a single crystal and a wrong stacking sequence may be deduced. This problem, here illustrated for micas, can be present in any type of compounds showing polytypes and twins.

P13.CC.001 BOND-VALENCE DISTRIBUTIONS AND THE SYMMETRY OF CHEMICAL GRAPHS. J. S. Rutherford, Department of Applied Chemistry, National University of Science & Technology, Bulawayo, Zimbabwe.

The automorphism group of a chemical graph is isomorphic with some permutation group. This allows the classification of elements of the graph, such as the vertex set or the edge set, in terms of reducible representations of this permutation group, and the creation of vertex space or edge space vectors which transform as the irreducible representations of that group.

Using this approach, solutions to the bond-valence network problem may be expressed as a sum over symmetry-adapted basis vectors of the edge-space of the graph. This sum takes the form

$$\mathbf{s} = \sum_{i=1}^{\dim(U)} K(\Gamma_i)\,\mathbf{u_i} + \sum_{j=1}^{\dim(Z)} x(\Gamma_j)\,\mathbf{z_j}$$

that is a fixed sum of terms over the symmetrised cut-space, U(G), of the graph, and a variable sum of terms over the corresponding cycle-space, Z(G). The cut-space basis vectors, $\mathbf{u}_i$, are given by

$$\mathbf{u_i} = \frac{1}{\sqrt{\lambda(\Gamma_i)}}\mathbf{B}^t\,\mathbf{v}(\Gamma_i)$$

$\mathbf{B}^t$ being the transpose of the incidence matrix, $\mathbf{B}$, $\lambda(\Gamma_i)$ a non-zero eigenvalue of the singular square matrix $\mathbf{BB}^t$, and $\mathbf{v}(\boldsymbol{\Gamma_i})$ a corresponding eigenvector. The coefficient $x(\Gamma_j)$ is an arbitrary scalar, restricted only by the requirement that the bond-valences cannot be negative, while

$$K(\Gamma_i) = \frac{\mathbf{v}(\Gamma_i)\cdot\mathbf{f}}{\sqrt{\lambda(\Gamma_i)}}$$

f being a vector of the atom-valences.

P13.CC.002 GROUP-THEORETICAL METHODS FOR NONLINEAR DYNAMICS IN CRYSTALS. H.T. Stokes, A.D. Smith, and D.M. Hatch, Brigham Young University, Provo, Utah 84602, USA, and G.M. Chechin, V.P. Sakhnenko, and M.Yu. Zehtser, Rostov State University, Rostov-on-Don, Russia.

Nonlinear forces in crystals cause large numbers of normal modes to be coupled, resulting in a large set of coupled equations of motion. Group-theoretical methods can be used to effectively decouple (in some sense) small numbers of these equations from the rest, resulting in smaller, more manageable problems to solve. These isolated groups of dynamic variables are called “bushes” of modes. An excitation in a given bush will remain in that bush and not spread to any other modes in the crystal. This result is rigorous and does not depend on the strength of the nonlinearity nor the strength of the coupling between modes. Furthermore, the bushes can be put into universality classes, based on the form of the potential energy governing the dynamics of the modes in the bush. We found the universality classes of bushes with small number of modes for all possible crystals.

P13.CC.003 INTERPRETING A STRUCTURE OF REAL CRYSTALLINE MATERIALS. B.S.Semukhin, A.N.Sergeev, S.V.Rudnev Department Physics of Strength, Institute of Strength Physics and Material Science Siberian Branch of Russian Academy of Sciences,Tomsk,Russia, [2]Tomsk State Politechnical University, [3] Tomsk State Politechnical University

In the article method of crystalline structure description is proposed, based on organisations of space of crystal by means of the elliptical Riemannian space .It has been shown that kinematics approximation, by means of the small modification, correctly describes integral intensities X-ray diffraction reflexes and in this drawing near, however an invariant structured element has to be necessarily chosen as a scattering volume.

13DD AB INITIO STRUCTURE PREDICTION

M13.DD.001 MOLECULAR SIMULATION TECHNIQUES AND STRUCTURE PREDICTION. Clive M. Freeman, Alan M. Gorman, Steve M. Levine, Frank J.J. Leusen [1], Michael W. Deem, Marco Falcioni [2], John M. Newsam [1]; [1] Molecular Simulations Inc, 9685 Scranton Road, San Diego CA 92121, USA; [2] Chemical Engineering Department, University of California, Los Angeles, CA 90095, USA

Techniques for predicting and solving crystal structures based on powder diffraction data and simple descriptions of

interatomic interactions been employed for many years. Advancing computational capabilities combined with recent algorithmic developments have, however, resulted in greatly increased opportunities for structure solution in challenging crystallographic circumstances. Such procedures exploit standard techniques of computer simulation in combination with hybrid potential energy functions to yield structures that are sterically and experimentally plausible. These methods have been especially useful in the investigation of microcrystalline framework structured materials for which powder diffraction may be the primary experimental route to structural information. In contrast to traditional refinement procedures, which use rapidly convergent but locally biased least squares methods, analogy with physical simulations has prompted the use of simulated annealing and tempering as optimization methods in several recent studies. Metropolis Monte Carlo or Molecular Dynamics based annealing procedures provide the 'searching' characteristics that underlie the required global minimization of structure solution. Applications to framework structured solids, condensed metal oxides and molecular crystal structures will be described.

M13.DD.002 STRUCTURE PREDICTION OF SOLIDS VIA INVESTIGATION OF POTENTIAL ENERGY SURFACES. J. Christian Schön, M. Jansen Max-Planck-Institut für Festkörperforschung, Heisenbergstr. 1, D-70569 Stuttgart, Germany

Predicting the existence and structure of hypothetical compounds, and suggesting routes to their synthesis, is a major goal in the field of solid state chemistry. Already the first step, the prediction of compounds capable of existence, is highly complex, since a multitude of atomic arrangements are possible that corresponds to local minima of the (free) energy at some temperature. The approach presented here concentrates on the investigation of potential energy surfaces, identifying local minima, which are surrounded by high enough energy barriers and carry enough entropic weight, to give them sufficient kinetic and thermodynamic stability.

We will show applications of this approach both to ionic systems and compounds consisting, in addition to single atoms/ions, of fixed building units, such as molecules and complex ions. Using such units allows the introduction of charge carrying molecules on the one hand, and on the other hand avoids the optimisation moves that are needed otherwise for the creation of these building units.

M13.DD.003 THE PREDICTION OF INORGANIC CRYSTAL STRUCTURES USING A GENETIC ALGORITHM AND ENERGY MINIMISATION. S.M. Woodley and C.R.A. Catlow, Davy-Faraday Research Laboratory, The Royal Institution of Great Britain, 21 Albemarle Street, London W1X 4BS, P.D. Battle, Inorganic Chemistry Laboratory, University of Oxford, South Parks Road, Oxford OX1 3QR and J.D. Gale, Department of Chemistry, Imperial College, South Kensington SW7 2AY.

We successfully 'predict' the structures of a wide range of known binary oxides and various known ternary oxides, including perovskites, pyrochlores and spinels. The method, which is capable of reproducing different phases of a compound, is based upon that developed by Bush *et al* [1] who successfully predicted the previously unknown structure of Li_3RuO_4.

Initially a genetic algorithm is used to generate plausible structures from a knowledge of only the dimensions and constituents of the unit cell. The quality of the structures is assessed using a cost function which is based on the Bond Valence Model and the Coulombic interaction energy. Our cost function is a robust measure of geometry violation but at the same time it is cheap to compute; both necessary qualities for any genetic algorithm. The lattice energy, based on the Born model of a solid, for the more plausible candidate structures is then minimised using a local optimiser in order to increase the accuracy of the atomic co-ordinates predicted for the crystal structure. The method has been implemented within the General Utility Lattice Program (GULP) [2,3], thus facilitating the calculation of the physical properties (for example, elastic constants) of the phase.

M13.DD.004 DIRECT USE OF DATABASE INFORMATION FOR CRYSTAL STRUCTURE PREDICTION. J.P.M. Lommerse W.D.S. Motherwell Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, United Kingdom.

Currently, in organic chemistry most crystal structure prediction methods are based on the calculation of a (static) lattice enthalpy, assuming that the lowest energy structure coincides with the experimental crystal structure. Effects of pressure and entropy are usually neglected. But probably more importantly, the whole process of crystal growth is not accounted for. One approach to tackle this latter problem could be the use of Molecular Dynamics simulations, but there is still a long way to go before the actual simulation of crystal growth can be realised. Another approach might be the use of experimental data as stored in the Cambridge Structural Database[1]. Using these data one may implicitly account for kinetics as well as for other "hidden" factors determining the formation of the actual crystal structures. Here, we use data representing interactions between functional groups within the crystal structures. For each functional group a field that surrounds the molecule of interest can be set up and combined in order to predict the most likely orientations and contacts between molecules. Due to the amount of statistical data available, the accuracy of this method in terms of prediction of cell dimensions, position and orientation of the molecules in the cell is limited. In order to overcome this problem the method allows for "refinement" by empirical potential energy functions [2].

M13.DD.005 PREDICTING THE CRYSTAL STRUCTURES OF ORGANIC MOLECULES BY LATTICE ENERGY MINIMISATION. S.L. Price, Department of Chemistry, University College London, 20 Gordon Street, London WC1H 0AJ.

Many methods have been proposed for predicting possible crystal structures of organic molecules, using only the molecular structure, based on the assumption that the observed crystal structure will be that which has the most favourable lattice energy. We have been testing the validity of this approach by using particularly accurate models for the intermolecular forces to evaluate the lattice energy. The electrostatic contribution is evaluated from the atomic multipoles obtained from an ab initio wavefunction of the molecule. Using such a model potentials and the MOLPAK search procedure [1], we have found the low energy minima in the lattice energy for a wide variety of organic

molecules, such as uracil [2], alloxan [3], carboxylic acids, including polymorphic systems such as indigo [4]. This approach has been successful in making blind predictions, as in the case of 5-azauracil [5]. However, although the known structures are found at or near the global minimum, in many cases there are unknown structures within the energy range of possible polymorphs.

By combining the results of many lattice energy minimisation methods on a wide range of molecules, it is clear that having a lattice energy at or near the global minimum is a necessary, but often not sufficient condition, for the structure to be observed. This raises many questions as to the factors that control crystallization and polymorphism, and how these can be represented for more reliable predictive methods.

M13.DD.006 COMPUTER MODELLING OF COMPLEX MOLECULAR IONIC MATERIALS. R.A. Jackson and K.A. Mort, Chemistry Department, School of Chemistry and Physics, Keele University, Keele, Staffs ST5 5BG, UK.

Molecular ionic materials present a considerable challenge in computer modelling because any potential model employed must accommodate both ionic and covalent forces. Moreover, many such materials exist in a number of phases, making further demands on the potential.

This paper will describe how energy minimisation and molecular dynamics techniques have been used to model a series of these materials. Potentials have been obtained by empirical fitting to structures and properties of representative materials, and in the case of materials containing both molecular anions and molecular cations, potentials for each ion are obtained separately and then combined. This procedure is illustrated for the case of ammonium nitrate, where ammonium halides and alkali metal nitrates are modelled first, and the molecular ion potentials transferred.

Results will be presented of calculations of structural and lattice properties of metal phosphates, perchlorates, chlorates and nitrates, and of ammonium halides. Attention will then be focused on ammonium nitrate, where a potential was fitted to the low temperature phase, and molecular dynamics used to simulate the higher temperature phases. It will be shown that such complex materials can be reliably simulated by relative simple potential models, provided both ionic and covalent interactions, and the balance between them, are correctly represented.

P13.DD.001 THEORETICAL STUDIES OF THE STRUCTURE AND CATALYTIC PROPERTIES OF PLATINUM-GOLD CLUSTER COMPOUNDS. A.A. Bagatur'yants and S.S. Konyukhov, Photochemistry Center, Russian Academy of Sciences, ul. Novatorov 7a, Moscow, 117421 Russia, and O. Gropen, Faculty of Science, University of Tromsoe, 9037 Tromsoe, Norway, and L.H. Pignolet, Department of Chemistry, University of Minnesota, Minneapolis, MN 55455, USA

The electronic and geometrical structure of platinum–gold clusters of composition $[PtAu_6(PH_3)_7]^{2+}$ (I), $[Pt(CO)Au_6(PH_3)_7]^{2+}$ (II), $[Pt(H)Au_7(PH_3)_8]^{2+}$ (III), $[PtAu_8(PH_3)_8]^{2+}$ (IV), and $[Pt(CO)Au_8(PH_3)_8]^{2+}$ (V) and the frequencies of CO vibrations in II and V have been calculated using the density functional theory (DFT) within the LDA approximation. The structural and spectroscopic results have been compared with experimental data for related complexes. Potential energy surfaces for the reaction of oxidative addition of H_2 to I and IV have been investigated. Intermediate molecular complexes ($I...H_2$ and $IV...H_2$) and the final dihydride structures (H-I-H and H-IV-IV) have been located on the calculated potential energy surfaces. The experimental catalytic activity of $[PtAu_6(PR_3)_7]^{2+}$ and $[PtAu_8(PR_3)_8]^{2+}$ is analyzed on the basis of obtained results. The possible sites of the location of the hydride ligand in III have been determined on the basis of DFT calculations.

P13.DD.002 *AB INITIO* STUDY OF THE STRUCTURE OF A PURE (0001) SURFACE OF β-SILICON NITRIDE AND SURFACE GROUPS CHEMISORBED ON THIS SURFACE UNDER CONDITIONS OF CVD FROM DICHLOROSILANE AND AMMONIA. A.A. Safonov and A.A. Bagatur'yants, Photochemistry Center, Russian Academy of Sciences, ul. Novatorov 7a, Moscow, 117421 Russia; AOZT Soft-Tec, Nakhimovskii prosp. 34, Moscow, 117218 Russia, and A.A. Korkin, Predictive Engineering Laboratory, Semiconductor Products Sector, Motorola, Inc. 2200 W. Broadway Rd., Mesa, AZ 85202

The structure of a (0001) surface of β-Si_3N_4 has been investigated theoretically based on *ab initio* calculations within a cluster approach. It is shown that the dangling bonds on the surface are relaxed to form diatomic >Si=N– surface groups. The calculated Si=N bond length 1.62 A is considerably shorter than typical lengths of crystalline Si–N bonds (1.74–1.76 A), and the surface atoms of these diatomic groups are significantly displaced from their bulk crystalline positions. The >Si=N– surface groups are combined by threes through a central N atom to form a pattern of isolated quasi-planar seven-atomic islands at the surface. Examining the sequential hydrogenation of separate >Si=N– groups in such an island has indicated that each group can be considered as an independent surface site. Clusters modeling the silicon nitride surface covered by various chemically bonded groups (–H, –Cl, $–NH_2$, $–SiH_2Cl$, $–SiHCl_2$, >Si, –SiH, –SiCl) have been calculated. The mechanism of film growth in the chemical vapor deposition (CVD) of β-Si_3N_4 from NH_3 and SiH_2Cl_2 has been analyzed in detail. It has been found that the film growth is controlled by the following reaction steps: (1) H_2 or HCl abstraction from chemisorbed chlorosilyl ($–SiH_2Cl$ or $–SiHCl_2$) groups to form silylene (–SiH or –SiCl) surface groups, (2) coupling reactions between NH_3 and chemisorbed chlorosilyl groups or between SiH_2Cl_2 and chemisorbed $–NH_2$ groups with HCl elimination, and (3) similar coupling reactions between chemisorbed chlorosilyl and $–NH_2$ groups.

P13.DD.003 PREDICTIONS OF CRYSTAL PACKING FOR CARBOXYLIC ACIDS USING ACCURATE INTERMOLECULAR POTENTIALS. Theresa Beyer, Sarah L. Price, Centre for Theoretical and Computational Chemistry, University College London, 20 Gordon Street, London WC1H OAJ, U.K.

Carboxylic acids show a variety of packing motifs [1], based on chains and dimers and some are polymorphic. As current potentials have difficulty in reproducing the experimental crystal structures for this group of molecules, they represent an insufficient basis for crystal structure prediction [2] and understanding which motifs are found. We use an accurate model for the intermolecular forces based on a Distributed Multipole expansion (DMA) of an ab initio charge distribution for the dominant electrostatic contribution and an empirical atom-atom repulsion-dispersion potential. This potential reproduces the crystal structures and the available heats of sublimation of several carboxylic acid structures. Using this theoretically developed potential, we performed a systematic search [3] for minima in the

lattice energies for a variety of carboxylic acids and investigated the low energy structures in terms of their hydrogen bonding motifs. This both tests the structure prediction methodology and shows for which molecules the chain and dimer motifs are competitive in energy.

13EE DATA ACCURACY AND DETECTORS (sponsored by Stoe)

M13.EE.001 THE ACCURATE MEASUREMENT OF ANOMALOUS SIGNAL. A Thompson, EMBL Grenoble Outstation

One of the reasons that the technique of MAD (see for example, Hendrickson, Science 254, 51 - 58, 1991) has become such a successful method of solving the phase problem for macromolecular crystal structures is the huge improvements recently made in both X-ray area detection and processing software. The requirements for successfully measuring a small anomalous signal will be discussed in the light of recent data collected on ESRF BM14 using both image plate and CCD detectors. The limit of measuring very small anomalous signals under typical beamline conditions will be discussed, and some future possibilities in data collection suggested.

M13.EE.002 USE OF ONE WAVELENGTH ANOMALOUS DATA. Z. Dauter and M. Dauter, NCI Frederick and Brookhaven National Lab., Bldg. 725A-X9, Upton, NY 11973, USA.

The classic MIR method of solving macromolecular structures relies on isomorphous substitution of heavy atoms, where phasing is based on changes of reflection amplitudes for different derivatives with respect to the native data. The anomalous signal of heavy atoms, if measured, can be used in addition. MAD technique requires the presence of anomalous scatterers and utilises both dispersive differences between different wavelengths and anomalous differences within one wavelength data.

It is possible to obtain meaningful phases based purely on the anomalous signal contained in only one data set measured at a single wavelength. The anomalous signal may come from the scatterers inherently present in the native structure (metals or sulfur) or from the atoms introduced as derivatives or occupying ordered solvent sites.

The successful application of single wavelength dispersion (SAD) requires very high accuracy of the data, since the anomalous differences are usually small compared to the reflection amplitudes. The Bijvoet differences from ten sulfur and eight chlorine atoms present in the structure of tetragonal lysozyme amount on average to 1.5% of the reflection amplitudes, nevertheless they are sufficient to obtain the experimental Fourier map of very high quality. The six bromide solvent atoms in lysozyme give anomalous signal of about 5% of normal diffraction, which is enough to produce interpretable electron density to a resolution as low as 3 Å.

The anomalous scatterers partial structure usually has to be solved by direct methods. Recent advances in this field makes it possible to find positions of many, up to 100, anomalous scatterers. The subsequent phasing of protein amplitudes can be done with the direct methods or the maximum likelihood approach, combined with the electron density modification.

In the light of significant improvements in detector and software technology leading to a rapid acquisition of accurate X-ray diffraction data, the SAD technique may provide an attractive alternative for macromolecular phasing, since it requires less data collection time than other approaches.

M13.EE.003 REVIEW OF PRESENT AND FUTURE DETECTOR TECHNOLOGY FOR MACROMOLECU LAR CRYSTALLOGRAPHY. Edwin M Westbrook, Argonne National Laboratory.

The demands on detectors for macromolecular crystallography come from two directions: data collection at home and data collection at synchrotron sources. Each set of demands have unique features. For home facilities, pressure is to keep coats down, convenience and reliability up, and to be highly efficient recording weak diffraction. At synchrotrons beamlines, the demand is for high performance and the most important metrics of performance are to maximize the size of the sensitive area, and to minimize the time necessary to record “good” data. This latter demand incorporates the needs for high efficiency and for fast electronics.

This discussion will review existing detector technology (multiwire proportional counters; imaging phosphor plates; CCD systems) and systems now under development (counting and integrating semiconductor pixel arrays; amorphous Silicon TFT arrays), focusing attention on how attributes of each technology present solutions for home and synchrotron facilities.

M13.EE.004 CALIBRATION OF THE CCD DETEC-TOR. Zbyszek Otwinowski[1], Wiadek Minor[2], [1]DUT Southwestern Medical Center at Dallas, Dallas TX 75235, [2]Department of Molecular Physiology and Biological Physics, University of Virginia, Chariottedville, VA 22906, USA.

CCD detector characteristics can be incorporated into data reduction software by one of two mechanisms:

- diffraction image transformation into data that would result from a distortion-free, uniform-response detector;
- implementation of detector response function into date analysis software, and the applying the response function during autoindexing refinement and Bragg’s peak integration stages

The first approach is inferior, in performance, accuracy and precision. For basic reasons, geometric distortion corrections applied to pixel data cannot preserve the shape of the Bragg peaks. The misalignment of pixels before and after geometric corrections makes data from a group of raw data pixels contribute to a single corrected pixel. This introduces two artifacts: peaks are broadened and the random variations get averaged out, resulting in lower precision of the profile fitting procedure. if spots are very close, broadening of reflections increases impact of reflection tails on measurement of nearby reflections, resulting in loss of accuracy. However, there is very little impact on measurement of strong, well separated reflections. The information loss due to the geometric correction is similar in magnitude to information loss when 4 pixels are binned into one pixel.

The HKL.-2000 can apply detector spatial distortion and non-uniform response functions. The measured data are used to estimate the DC-offset and the readout noise from non-light sensitive part of the CCD.

M13.EE.005 ON THE USE OF CCD DETECTORS FOR VERY HIGH RESOLUTION X RAY DIFFRACTION AND CHARGE DENSITY ANALYSIS. Claude Lecomte[a], Sandrine Kuntzinger[a], Slimane Dahaoui[b], Nour Eddine Ghermani[a] [a]LCM3B,Upresa CNRS 7036, Univ Henri Poincaré , Nancy, F54506 Vandoeuvre-les Nancy cedex , France [b]Crystallography group, Dept of Chemistry, University of Durham, England.

Since three or four years, diffractometers equipped with two dimensional detectors, mainly CCD, are used for charge density analysis. Some results are reported using synchrotron sources (1,2) some others were obtained from laboratory machines, Nonius or Siemens-Brucker (3-6).

The crystals studied are minerals (1,6), organic (2,3,5) or organometallic (4) compounds using molybdenum or silver radiation for conventional sources or very short wavelengths in synchrotron experiments. All analyses revealed realistic electron density maps and electrostatic properties, but some of them are of slighthly less quality than those obtained from conventional 1D sealed tube diffratometers.Therefore, in this talk, the CCD results will be analyzed with a special emphasis on data reduction and on estimation of standard incertainties for intensity measurements. Strategy for data collection/reduction and results will be presented in the case of crystal with large unit cell parameters (7).

One important conclusion, to reach excellent quality results is that researchers in the charge density field and in any other very accurate domain, should have the possibility to study, to read, and to modify the data reduction routines (integration, scaling, corrections , sigma square calculations…etc) according to their specific problems.

P13.EE.001 DATA COLLECTION STRATEGIES WITH A CCD-DIFFRACTOMETER. Michael Bolte and Stephan Rühl, Institut für Organische Chemie, J.-W.-Goethe-Universität, Marie-Curie-Str. 11, D-60439 Frankfurt, Germany.

Diffractometers with position sensitive counters have sped up drastically the collection of X-ray reflections – but the question arises how to obtain an optimal data set in spite of a shorter data collection time. This was our motivation to test various data collection strategies using a CCD detector and evaluate the influence of the variable parameters.

All investigations were carried out on small organic molecules, common in routine structure determination. In the course of our experiments the impact of the following parameters was evaluated:

- time for measuring a single image,
- scan angle,
- size of the collimator,
- crystal to detector distance,
- resolution of the detector,
- scan mode (φ-scans or ω-scans),
- redundancy of the data,
- crystal size.

All these parameters were systematically varied in order to find optimal values for the crystal in question. Although using the default values recommended by the manufacturer leads to good results, adjusting the data collection parameters according to the actual problem can improve substantially the quality of the data without loss of precision.

The achievable improvement of the data quality is shown with four different compounds by comparison of several figures of merit, e.g. R(int), R(σ), R1 and wR2. The different data sets collected with a CCD detector were also compared with the data collected on a four-circle diffractometer using the same crystals.

P13.EE.002 DECONVOLUTION OF THE PSF OF AREA DETECTORS USING THE MAXIMUM ENTROPY METHOD. H. Graafsma and A. Puig-Molina, European Synchrotron Radiation Facility, BP 220, 38043 Grenoble, France and R.Y. de Vries, Chemical Physics Laboratory, University of Twente, PO Box 217, 7500 AE Enschede, The Netherlands.

One of the (many) design parameters of area detectors is the point-spread-function (PSF). One generally tries to either minimise the PSF to maximise the spatial resolution, or to match the PSF to other experimental conditions. However, a reduction of the PSF generally means a reduction of the conversion screen thickness and with that an undesired reduction of the detector sensitivity. A program has been written to apply the maximum entropy method (MEM) for deconvolution of the two-dimensional point-spread-function (PSF) of two-dimensional X-ray detectors. The goal is to increase the spatial resolution of existing area detectors, and therefore, improving the detector performance, without sacrificing sensitivity. The method is robust, model and image independent and only depends on the correct description of the two-dimensional point-spread-function and gain factor of the detector.

A significant enhancement of both the spatial resolution and the contrast ratio has been obtained for the phase contrast images recorded with an ultra high resolution X-ray imaging detector. The method has also been applied to Laue and monochromatic diffraction images of protein crystals, showing an important improvement in both peak separation of overlapping peaks and signal to noise ratio of medium and weak peaks.

The principle of the method will be presented and examples from both imaging and diffraction will be presented.

P13.EE.003 PROBLEMS WITH SIMPLE STRUCTURES CAUSED BY λ/2 CONTAMINATION. Horst Borrmann, Max-Planck-Institut für Chemische Physik fester Stoffe, Pirnaer Landstr. 176, D-01257 Dresden, Germany.

Characteristic radiation employed in a typical X-ray diffraction experiment with laboratory sources contains contribution from harmonics of λ, mostly λ/2. This contamination may be removed by energy discrimination when a scintillation counter is used to detect the scattered intensities. For area detectors based on CCDs or image plates, this effect becomes a potential source of errors. However, such errors were found negligible for routine single crystal data sets [1].

We found λ/2 contributions quite problematic in course of reinvestigating the structures of $LiOsF_6$ and $LiAuF_4$ from single crystal data. For $LiOsF_6$ doubling of all three axes was indicated by area detector data. The problem to determine the correct structure is enhanced by the fact that three rather closely related structure types are known for ABF_6 type compounds. An even more interesting case was found with $LiAuF_4$. The special structural arrangement together with λ/2 contamination results in severe difficulties with evaluation of the proper unit cell but also with space group assignment. Unexpected distortions within the published structure [2] are obvious artefacts from choosing too low symmetry. Although this consequence is frequently emphasized by R.E. Marsh and others, the particular case of $LiAuF_4$ is unusual as no centre of symmetry is added.

We found $LiAuF_4$ a very helpful test case throughout the evaluation process of an area detector system.

P13.EE.004 STANDARD REFERENCE MATERIALS FOR STRUCTURAL INVESTIGATIONS FOR SINGLE AND POWDER DIFRACTOMETERS. V.K.Ovcharov[1)] , B.N. Kodess[1,2)] , L.A. Butman[2)], I.L.Kommel[1)] , A. M. Balagurov[3)], V.A. Sarin[3)] , I. S. Smirnov[(1)], [1] Department of Crystal Metrology, VNIIMS, 46 Ozernaya St., 119361 Moscow, Russia, [2] ICS&E, Aurora, CO 80015, USA, [3] JINR, Dubna, Russia.

An interlaboratory experiment has been conducted on measurement of interplane distances, lattice parameters and intensity ratio for a set of pure elements (Si, Ge), low-quartz (SiO_2), Al_2O_3, silicide vanadium and yttrium cuprates. The data has been collected from a number of set-ups (more than 20 diffractometers) using X-ray and neutron radiation. The unit-cell parameters of single crystals quartz temperature a = 4.9130 (1) , c= 5.4050 (1) where cell parameters are in angstroms. Similar data for standard for internal pressure in diamond-anvil cells have been determined by single-crystal diffraction at ambient temperature a=4.91300 (11), c=5.40482 (17) A. [1].

Data for silicon was compared with such from PTB and NIST (neutron method). Moreover, similar interlaboratory (12-16 laboratories) experiment has been conducted for powder samples of Si-V and Y-Ba-Cu-O systems to determine their composition (mass ratios of major components and impurities) using various physical and chemical methods. Based on results of metrological certification, a number of batches of Si, SiV_3 gained the status of Standard Reference Materials.

Electron-difference-density maps of alpha-SiO_2 were calculated using custom-designed software. The maps feature notable similarities in the areas of Si-O-Si bonding and low variability in the interatomic areas. This data gives us also optimistic outlook on usage of samples of this type in the project of round-robin for measurement of electron density distribution.

[1] Angel, R.J.; Allan, D.R.; Miletich, R.; Finger, L.W. , Journal of Applied Crystallography, 1 Aug. 1997, vol.30, pt.4:461-6.

P13.EE.005 ON THE USE OF EQUIVALENT REFLECTIONS. T. Gustafsson, Inorganic Chemistry, Ångström Laboratory, Box 538, SE-751 21 Uppsala, Sweden.

Different strategies can be used for the collection of single-crystal diffraction data. It is common practise that only a unique data set is collected to reduce measuring time. If two or more sets of unique reflections are measured using reduced measuring times the total number of photons collected during the experiment can be kept constant with only a marginal increase in experiment time. Such a strategy will help detect random errors during the experiment such as multiple scattering or equipment malfunction. It will also produce a data set, which contains not one but several unique data sets. The subsequent treatment of such a data set can follow several different routes. That recommended when the resulting structure is intended for publication in *Acta Cryst.* is to merge the data into one unique set. The main reason for merging the data is to ensure that the equivalent reflections should not be treated as a set of independent observations in the least squares refinement. A second approach is then simply to use the unmerged data set in the least squares refinement. The main reason for doing this is that the extinction correction is generally not identical for all reflections within a set of equivalents.

It is difficult to find fully convincing arguments to favour the use of the one or the other of these two approaches. Both have therefore been followed for a data set collected on sodium nitrite. The respective differences in R-values, standard errors on refined parameters and $\delta\rho$- maps will be discussed.

13FF TOPOGRAPHY

M13.FF.001 IMAGING WITH THIRD GENERATION SYNCHROTRON X-RAYS. Jürgen Härtwig, Peter Cloetens, José Baruchel, E.S.R.F., BP220, F-38043 Grenoble cedex, France.

Imaging is based on the spatial variations, across a specimen, of (1) the absorption, and/or (2) the scattering, and/or (3) the optical phase of the beam.

The first third-generation synchrotron radiation facility in operation, the ESRF, includes beam-lines dedicated largely or totally to imaging, fed by insertion devices tailored and/or adjustable for the experiment, and supported by technical development in instrumentation, e.g. for operation at controlled temperature, or in detector systems. Beyond this essential practical novelty, features of third generation synchrotron radiation sources that are significant in relation with imaging applications are

a) the higher intensity of the X-ray beams in comparison with previous sources, with a larger fraction of photons with high energies (10-100 keV)

b) the fact that the source is small and far from the specimen.

The latter point, equivalent to the statement that the X-ray beams have low angular divergence as seen from any point in the specimen, or large spatial coherence, is qualitatively the most influential. In particular, it makes phase radiography, and its 3D companion phase tomography, instrumentally very simple, and lead to novel possibilities for diffraction topography.

The various new experiments correspond to a combination of (1,2,3) with (a,b). We will give more emphasis to examples performed using:

(1a)Absorption microtomography

(2a) X-ray Bragg-diffraction imaging (topography): real-time experiments, highly absorbing specimens (single crystals or quasicrystals)

(2b)High sensitivity determination of strain differences, e.g. in magnetically driven mechanical resonance effects

(3b) Phase radiography and phase tomography through simple propagation

(2,3b) Combination of phase radiography with Bragg-diffraction imaging, and the phase effects in Bragg diffraction images (in particular the direct determination of structure factor phase from twinned regions).

M13.FF.002 THE TOPOGRAPHIC SUITE : A TOOL FOR X-RAY TOPOGRAPHY STUDY OF MATERIALS. Yves Epelboin, A. Soyer LMCP, UMR 7590 CNRS, Universités P.M. Curie and D. Diderot, case 115, 75252 Paris Cedex 05, France and V. Mocella ESRF, BP 220, 38043 Grenoble Cedex, France

Third generation synchrotron have renewed the possibilities to use topographic settings for the study of materials, hence the necessity of versatile simulation programs to characterize their intrinsic quality.

A new generation of programs, based on the integration of Takagi-Taupin equations, has been designed on the principles of TRANSQ[1]: the computation of the deformation is made in a separate program allowing to easily change the model without modifying the simulation program. The optical characteristics of the source are correctly taken into consideration, assuming either an incident coherent plane wave or a distribution of incoherent point sources along the surface of the crystal in the case of white beam topographs[2].

The suite is made of TRANSQ (white beam topography in the Laue case), TOPLANE (plane wave Laue topography), TOPRC (computation of rocking curves in the Laue case), REFPLANE (plane wave Bragg topography), REFRC (computation of rocking curves in the Bragg case). This later has been especially designed to study epitaxial thin layers taking into

consideration both the deformation between the epilayer and the substrate and the differences in the structure factors of both parts.

Examples of applications will be shown: stroboscopic images of piezoelectric materials, 3 D defects in quasicrystals, influence of the heat load at ESRF and of the curvature of the sample on the rocking curve profile

M13.FF.003 TOPOGRAPHIC RETICULOGRAPHY, MICRORADIOGRAPHY AND X-RAY INTERFERENCE EXPERIMENTS ON LINE 7 AT THE SRS, DARESBURY. A. R. Lang and A. P. W. Makepeace, H. H. Wills Physics Laboratory, University of Bristol, Tyndall Avenue, Bristol BS8 1TL, UK.

The long beamline (80 m) at Topography Station 7.6 plus the small source vertical FWHM of 0.23 mm together facilitate novel techniques and observations. For crystal perfection assessments involving detection and measurement of lattice misorientations, reticulography yields quantitative data at arcsecond resolution more directly and speedily than double-crystal topography. In reticulography a fine-scale X-ray absorbing mesh is placed between a Laue-diffracting crystal specimen and the topograph-recording photographic plate. The mesh splits the diffracted beam into an array of individually identifiable microbeams. Direction differences between microbeams, which give the orientation differences between the crystal elements reflecting them, are measured from their relative shifts within the array when mesh-to-plate distance is changed [1]. Synchrotron X-ray microradiographic imaging is an essential prerequisite for the collection of diffraction data from a particular individual small crystallite embedded within a mat containing thousands of similarly small-sized crystallites, and is proving fruitful in studies of CVD diamond films [2]. At Station 7.6 the transverse coherence length is great enough in the vertical plane for informative X-ray interference experiments to be performed there. Biprism interference patterns have been successfully recorded at several wavelengths using an X-ray biprism formed from two similar polished rectangular-section diamond bars meeting edge-to-edge [3].

M13.FF.004 SYNCHROTRON WHITE BEAM X-RAY TOPO-GRAPHIC STUDIES OF SUPERSCREW DISLOCATIONS IN SILICON CARBIDE SINGLE CRYSTALS. Michael Dudley and Xianrong Huang, Department of Materials Science and Engineering, State University of New York at Stony Brook, Stony Brook NY 11794-2275, USA.

The use of Synchrotron White Beam X-ray Topography (SWBXT) to study superscrew dislocations in 4H- and 6H-SiC single crystals, commercially grown using the Physical Vapor Transport technique, is reviewed. Superscrew dislocations in SiC are shown to be growth dislocations, aligned parallel to the *c*-axis, with very large Burgers vectors of magnitude equal to n*c*, where n is an integer and *c* is the lattice parameter. Superscrew dislocations with b≥3*c* for 4H, and b≥2*c* for 6H are found to have hollow-cores (often referred to as "micropipes"). For hollow-core superscrew dislocations (micropipes) in both 4H and 6H, Frank's thermodynamically based, theoretical relationship between Burgers vector and core radius (F.C. Frank, Acta Cryst., 4, 497, (1951)) has been tested and found to approximately hold, confirming the screw dislocation nature of micropipes. The very large Burgers vector magnitude of superscrew dislocations provides an ideal system wherein X-ray topographic contrast formation mechanisms can be examined at a magnified level. This has enabled the development of a modified approach to dislocation image contrast formation under low absorption conditions. The contrast observed from superscrew dislocations on SWBXT images recorded in transmission, grazing-incidence reflection, and back-reflection geometry has been successfully simulated using this modified approach, providing further confirmation of the screw dislocation nature of micropipes. Possible origins of superscrew dislocations are also discussed.

M13.FF.005 DOUBLE CRYSTAL X-RAY TOPOGRAPHY: D-VALUE MAPPING OF CRYSTAL GROWTH DEFECTS. A.E.Voloshin, I.L.Smolsky, Shubnikov Institute of Crystallography of RAS, Moscow, Russia, N.P.Zaitseva, Lawrence Livermore National Laboratory, Livermore, CA, USA, A.G.Shtukenberg, St.Petersburg State University, St.Petersburg, Russia.

Quantitative characterization of point-to-point lattice parameter changes in crystals based on computer processing of plane wave X-ray topographs provides new possibilities in material science. Evaluation of crystal homogeneity is based on a relationship between the variations of point defect concentration and the deformation value near the sample surface. The near-surface distortions estimated as a result of calculations over the series of topographs provide data either for correct quantitative comparison with numerically simulated strain field, or for direct d-value mapping. This technique provides an observation of areas up to 10 cm^2, locality 3-10 μm and rather high sensitivity to crystal lattice distortions ($\Delta d/d$ up to 10^{-7}-10^{-8}).

The technique described was applied to the analysis of KDP group crystals grown from aqueous solution under different conditions. The problems investigated are: correct measurement and comparison of inhomogeneities in growth bands in traditionally and rapidly grown crystals, lattice distortions inside the vicinal sectors on dipyramidal and prismatic faces of rapidly grown KDP crystals, lattice mismatch between pyramidal and prismatic growth zones and it dependence on the growth temperature and growth rate. Moreover, the combined measurements of the lattice parameters and the deuterium concentration in different parts of rapidly grown DKDP crystal demonstrate that the most of possible reason of inhomogeneity in these crystals is hydrogen-deuterium non-stoichiometry.

Also the mixed crystals $(K,NH_4)Al(SO_4)_2 \cdot 12H_2O$ have been investigated. A composition of these crystals depends on growth conditions and determines the crystal internal stresses and some optical anomalies formation.

M13.FF.006 HIGH RESOLUTION X-RAY DIFFRACTION STUDY OF GaAs COILED MEMBRANES PRODUCED BY MICROMACHINING. Krishan Lal and Niranjana Goswami, National Physical Laboratory, New Delhi – 110 012, India, and J. Miao and H. L. Hartnagel, Institut fuer Hochfrequenztechnik, Technische Hochschule Darmstadt, D-64283 Darmstadt, Federal Republic of Germany.

Free standing GaAs coiled membranes produced for force sensor applications were characterized regarding real structure to evaluate their long term stability and quality of performance. Their fabrication involves photolithography, implantation by 2 MeV N^{++} ions followed by selective etching of (100) GaAs wafers which produced the membrane and a cavity beneath it. The membranes were 70 μm wide, ~ 5.3 mm long and ~2μm thick. Different segments of coil were separated by a gap of ~ 30 μm. A five crystal X-ray diffractometer developed at NPL was used in (+, –,

+) configuration with Mo $K\alpha_1$ exploring beam. High resolution X-ray diffractometry and topography experiments were performed in Bragg geometry with (4 0 0) (symmetric) and (5 $\bar{1}$ $\bar{1}$) (asymmetric) diffracting planes. For diffractometry, exploring beam dimensions were reduced to 1.2mm (height) x 10 μm (width) in order to selectively illuminate different sensor segments. However, due to geometrical considerations, at any linear position of the specimen, more than one segment of the membrane was irradiated. Therefore, the diffraction curves showed two or more peaks. From a set of thirteen different diffraction curves, peaks due to individual segments were identified. Their half widths varied in the range: 58 – 166 arc sec. Diffraction curve halfwidths for bulk crystals were ~ 26 arc sec. This shows that there is considerable broadening due to processing steps. Also, there were substantial angular tilts between sensor segments, which were determined through the analysis of diffraction curves. In a typical case, the tilt angles were in the range: 15 – 325 arc sec, which is quite significant. The high resolution diffraction topographs confirmed these tilts and at a time only two segments with tilt angle of 15 arc sec could be observed. Also, the topographs revealed that the walls of the of the cavity created by etching are tapered and its bottom was found to be uneven. A thin strip of the wafer is found to be freely hanging around the cavity.

P06.01.001 PROTEIN - MEMBRANE - FIBRE CRYSTALLOGRAPHY WITH SPALLATION NEUTRONS: Benno P. Schoenborn and Paul Langan, Life Sciences Division, Los Alamos National Laboratory, Los Alamos N.M. 87545, USA

Suitable instruments on spallation neutron sources are ideal for diffraction studies of protein crystals and oriented molecular complexes (1). With spallation neutrons and their time dependent wavelength structure, diffraction data may be readily selected electronically with an optimal wavelength bandwidth and cover the whole Laue spectrum as time (wavelength) resolved spectra. This optimizes data quantity and quality with best peak to background ratios and provides adequate spatial and energy resolution to eliminate diffraction peak overlaps.

To maximize flux within this energy range a partially decoupled moderator will be used (2). Such a diffraction station is now being built at the upgraded Los Alamos Spallation Neutron Source that will run at 800 MeV with a current of 200 micro amperes. The Station will use a kappa geometry goniometer with a large (2900 cm^2) position sensitive cylindrical He detector with a resolution of 1.3 mm and a counting rate exceeding 1 million neutrons/second.

The current status of the station development can be obtained from the Web site at: http://lsdo.lanl.gov/nsb/

P06.01.002 HIPPO, THE HIGH-PRESSURE PREFERRED ORIENTATION DIFFRACTOMETER AT LANSCE. R. B. Von Dreele [1], K. Bennett [2], H.-R. Wenk [3], [1] Lujan Center, Los Alamos National Laboratory, Los Alamos, NM 87545 USA, [2] Lujan Center, Los Alamos National Laboratory, Los Alamos, NM 87545 USA, [3] Department of Geology and Geophysics, University of California, Berkeley, CA 94720 USA

A consortium of University of California faculty and National Laboratory researchers is building a new time-of-flight neutron diffractometer, HIPPO, for materials studies at the Los Alamos Neutron Science Center (LANSCE) under the auspices of the Department of Energy. The instrument, which will become available in fall 2000, has the extremely high count-rates necessary to study materials under a wide variety of environmental conditions (10-2000K, 0-20GPa, 12T magnet) in small (1mm3) and large samples (2cm diameter). The 3D arrangement of detectors covering 4.6m2 area allows direct measurements of crystal orientation distributions in polycrystalline materials. The analysis of TOF diffraction patterns with versatile Rietveld codes provides simultaneous information on crystal structure, texture, microstructure and phase proportions. Some applications include kinetics of reactions, structure of glasses and melts, high-pressure investigations of complex systems, evolution of texture and anisotropy during deformation and recrystallization. The project is aimed at creating an instrument with high data throughput and easy access to researchers and students. While the HIPPO instrument will be part of the national user facility operated by LANSCE, the scientific program will be guided by the UCMRD consortium with the goal of satisfying national priorities and establishing an environment of scientific excellence.

P06.01.003 AN IMAGE-PLATE THERMAL-NEUTRON LAUE DIFFRACTOMETER FOR PHYSICS AND CHEMISTRY. G.J. McIntyre and C. Wilkinson, Institut Laue-Langevin, BP 156, 38042 Grenoble Cedex 9, France, D. Myles, EMBL Outstation Grenoble, BP 156, 38042 Grenoble Cedex 9, France, and J. Cowan, Chemistry Department, University of Durham, Durham DH1 3LE, UK.

The use of large-area neutron image plates and quasi-Laue diffraction with cold neutrons has been demonstrated, with the LAue DIffractometer (LADI) at the ILL, to offer a considerable speed advantage over conventional monochromatic-wavelength diffractometers for data collection from biological samples [1,2]. Trials with LADI on a thermal-neutron beam show that such an instrument also has a very promising future in small unit-cell crystallography, allowing very rapid data collection, typically a few minutes to one hour for single exposures that are frequently sufficient for full structure refinement to precision approaching that of conventional monochromatic data.

Following these trials, a modification of LADI, better suited to the demands of physicists and chemists, has been proposed. Like LADI, it will consist of a cylindrical image-plate detector, first held stationary while the crystal which lies on the axis of the cylinder is irradiated by the white beam, and then spun around its axis for on-line read-out by a laser. Unlike LADI, the axis of the cylinder will be vertical to facilitate access by heavy cryostats and pressure cells, and the irradiated surface of the image plates will be read directly to give a 2-3-fold gain in efficiency.

Thermal LADI will complement the more-precise traditional single-crystal diffractometers, offering the possibilities of extensive reciprocal-space surveys, particularly for detection of incommensurate nuclear or magnetic modulations, complete data collections through phase transitions, study of very small samples, and fast initial characterisation of topical new materials.

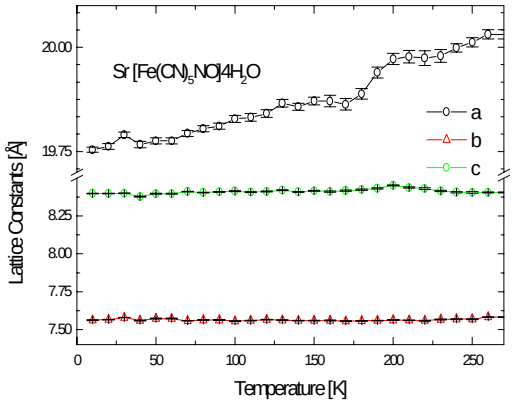
P06.01.004 HIGH-RESOLUTION NEUTRON FOURIER DIFFRACTION FOR POWDERS AND SINGLE CRYSTALS. A.M.Balagurov, V. Yu. Pomjakushin, V.G.Simkin [1] [1] Joint Institute for Nuclear Research, 141980, Dubna, Moscow region, Russia.

New ideas and novel electronics have renewed interest to neutron scattering correlation technique which has become again popular after a long period of disregard. In this paper, application of the correlation Fourier technique for diffraction experiments at long pulse neutron sources and the experience of operating the HRFD instrument, the first neutron high resolution Fourier diffractometer at the LPS-type source, the IBR-2 pulsed reactor in Dubna, are discussed. The relative full width of the resolution function of HRFD depends on the maximum modulation frequency of the incident neutron beam and now can be as small as 0.0009. At present HRFD is used for structure refinements of powders, for experiments with single crystals if it's a very high d-spacing resolution is needed, and for residual stress investigations in bulk samples. The recent results of high-resolution powder studies of Hg-based HTSC structures, investigation of phase separation phenomenon in La2CuO4+y, and semiconductor - metal phase transition in CMR compounds performed with HRFD are given in the paper.

P06.01.005 LIGHT STORAGE MATERIAL Sr [Fe(CN)5NO] 4·H2O. J. Schefer, PSI Villigen, Switzerland Th. Woike and M. Imlau, University at Cologn, Germany

Strontium nitroprusside tetra-hydrate is one of the candidates for understanding the mechanism of the metastable states produced by illuminating specific materials with visible light. We are presently investigating the ground state in the temperature range between 10 and 300K in order to clarify all phase transitions.

Sr $[Fe(CN)_5NO]$ $4H_2O$ (Strontium nitroprusside tetra-hydrate) yields metastable states if illuminated at low temperatures [1]. As the structure is very sensitive to the bonding of water (weak hydrogen bonds are present as shown in [2], we carefully checked for structural changes in the temperature range needed for future single crystal diffraction measurements.



Due to the big unit cell (C2/m, a=20.08, b=7.51 and c=8.42Å, β=98.4°, [3]), a detailed structure analysis is not possible with the DMC-diffractometer at SINQ due to the long wavelength (λ=2.559 Å) and medium resolution: We have to wait here for HRPT and TriCS. However, the DMC is excellent for the determination of phase transitions, lattice expansions and superstructures, which will be of importance in the interpretation of the structure of the metastable states. The results show, that no structural phase transitions are present down to 50 K. This is in contradiction to the DTA datain [4], which give hints for additional phases from di- and mono-hydrates. The absence in our sample could be due to our preparation method, as we made polycrystalline material by grinding single crystals, probably the best method in order to make very pure samples.

P06.01.006 EVOLUTION OF COHERENT γ′ PRECIPITATES IN A NI-12 AT. % AL ALLOY WITH A BIMODAL PARTICLE SIZE DISTRIBUTION. H. A. Calderon[1], J. Cruz[1] and J. Skov Pedersen[2], [1]Instituto Politécnico Nacional, México D. F., 07738, [2]RisØ National Laboratory, DK-4000, Roskilde, Denmark.

The evolution of coherent γ′ precipitates in a Ni-12 at. % Al alloy with a bimodal particle size distribution has been studied by means of small angle neutron scattering (SANS) and transmission electron microscopy (TEM). Oriented single crystals parallel to (100) and (110) have been used for TEM and SANS, respectively. Specimens have been aged at two different temperatures in order to form a bimodal particle size distribution. A first aging was carried out at 1113 K for 5 h to create large precipitates and a second aging was performed at 923 K for different times to create smaller precipitates. SANS patterns originating from the smaller particles show scattering anisotropy with strong correlation peaks in <001> directions. Such anisotropy increases with the aging time evidencing particle alignment and shape changes during the coarsening process. The experimental data have been used to obtain particle size distributions (PSD´s) of the smaller precipitates. The fitting routine uses a modified paracrystal cluster model in the local monodisperse approximation. This model reproduces the scattering intensity in different directions. During fitting the particle shape can be varied by adjusting the degree of faceting of spheres used for describing the particles. A smooth and positive size distribution is obtained by the fitting algorithm as well as quantities such as specific surface and volume fraction. TEM has been used to obtain PDS´s from direct measurements and also to determine the kinetics of the coarsening. The two sets of results are compared in the size range where both techniques are applicable.

P07.01.001 DOES CONVENTIONAL POWDER DIFFRACTION BEAT A SYNCHROTRON ? A. Le Bail, Laboratoire des Fluorures, Université du Maine, Avenue O. Messiaen, 72085 Le Mans, Cedex 9, France.

At a given complexity level, one expects Rietveld refinements from synchrotron data being less challenging than from conventional X-ray. *Ab initio* structure determinations are expected also to be easier by synchrotron powder diffractometry. A few years ago, it was said possible to make Rietveld refinements on much bigger structures than could be determined solely from powder data. Because of recent advances in methods for locating previously known molecules in crystalline cells, this statement was recently modified in "we can now determine structures biggest than we could refine without interatomic distance constraints".

The belief in synchrotron data superiority is unconditional. However, some studies are realized by selecting low-wavelength (down to 0.7Å) and small angular ranges (1-60°2θ). Such choices may correspond to lowest resolution than conventional equipment would provide with CuKα radiation. A modern in-laboratory powder diffractometer may give full width at half maximum as low as 0.04°2θ. This is mathematically as good as 0.02° at a synchrotron facility when choosing λ = 0.72 Å. A good example is that of sample 2 (tetracycline hydrochloride) of the **Structure Determination by Powder Diffractometry Round Robin** [1] for which one participant preferred to solve the structure by using the conventional rather than the synchrotron data (both were provided).

Of course the synchrotron superiority is quite real due to highest resolution, intensity and tunability. Anyway, superb conventional X-ray powder patterns will be shown at this congress, supporting the comparison with 'bad' synchrotron data, apart from the time for obtaining them (3 to 6 days).

P07.01.002 SUBTHRESHOLD STRUCTURAL DEFECT FORMATION OF CRYSTALS USING SYNCHROTRON RADIATION. H.N.Yeritsyan, A.A.Sahakyan, S.K.Nickogossyan, A.S.Hovhannisyan; Yerevan Physics Institute, 2 Alikhanian Brothers St., Yerevan, Armenia

The structural defect formation usually takes place in solids under superthreshold process if the external energy transfer (E) to the material atom is greater than energy (E_d) for an atom displacement and vacancy – interstitial pair production.

Under certain conditions (for example, at high level excitation of electron subsystem) the subthreshold defect production might have large probability .One of the most famous

in this respect is estimated an impurity –ionization mechanism (IIM) proposed by Klinger [1]. The IIM may be efficient when the Energy of Coloumb interaction E_c between the host atom and impurity atom ions exceeds Ed. In this case the Auger ionization of an host atom inner shell seemed to be high enough. The estimations showed high probability of this effect when using synchrotron radiation (SR): high intensity, sufficient time of positive charge localization of ionized host atom, required energy for inner shell ionization of host material atom, Synchrotron Radiation is suggested with related high sensitivity structural experiment to study the SR damage process in solids, i. e. to investigate the defect structure formation mechanism in-situ. Some previous results of experimental attempts with semiconductor crystals are optimistic.

P07.01.003 LIGHT INDUCED MAGNETIZATION OF $K_xCo_y[Fe(CN)_6]$ STUDIED BY SYNCHROTRON RADIATION. Hwo-Shuenn Sheu, Jyh-Fu Lee, Yuch-Cheng Jean and Ting-Wei Kang, Synchrotron Radiation Research Center, Hsinchu 30077, Taiwan

The aim of designing a molecular-based magnet is to increase the critical temperature and the tunability by applying external fields. Both T_c and field-induced properties have made big breakthrough in the development of Prussian Blue family compounds recently. The magnetism of $K_{0.2}Co_{1.4}[Fe(CN)_6]$ can be switched by shining blue (450nm) and red (650nm) light at the temperature below 20K. A proposed mechanism is via one e-jump between Co and Fe during light irradiation. X-ray absorption spectroscopy was employed to study the Co and Fe valence change as well as the spin sates during the light irradiation. XRD revealed that the space group is Fm3m with cell parameter ~10.41Ă. The thermochromism of this compound between room temperature and 90ºC have also studied by X-ray absorption spectroscopy.

P07.01.004 HIGH ENERGY, LOW TEMPERATURE RESONANT X-RAY DIFFRACTION STUDY OF CAESIUM IODIDE. A.M.T. Bell and J.P. Attfield, University Chemical Laboratory, Lensfield Road, Cambridge, CB2 1EW, UK.

The high X-ray energies available at the European Synchrotron Radiation Facility have been used to discover whether large resonant X-ray scattering effects, comparable to the normal scattering, can be observed at the K edges of heavy elements. High resolution powder diffraction data have been collected on a sample of CsI at ambient temperature and at 4 K on beamline BM16.

Synchrotron X-ray wavelengths were set at the Cs K-edge (0.3453 Å), I K-edge (0.3741 Å), and off the absorption edges (0.3900 Å). The 4 K data enable reflections to be observed to very high $\sin(\theta/\lambda) = 1.9$ Å^{-1}. Resonant scattering is evident from the enhanced intensities of the odd (h+k+l) peaks. The refined I f' from the 4K data is -6.2(2) electrons/atom. In comparison, the non-resonant scattering factor at the maximum $\sin(\theta/\lambda)$ is f = 8.8 electrons/atom, showing that resonant effects can be comparable to the normal scattering under such conditions.

P07.01.005 DANES AND ANOMALOUS STUDIES OF SPIN-LADDER COMPOUNDS BY USING MONOCHROMATIC AND DISPERSIVE DIFFRACTION. S. Bos, S. Pachot, V. Favre-Nicolin, P. Bordet, J.E. Lorenzo, H. Renevier, J.L. Hodeau, Lab. de Cristallographie-CNRS, BP 166, 38042 Grenoble Cedex 9 France, G. Dhalenne, A. Revcolevski, Lab. Chimie des Solides B‰t 414, 91405 Orsay France, O. Mathon, R. Tucoulou, ESRF BP 220, 38043 Grenoble France.

DAFS (Diffraction Anomalous Fine Structure) technique probes the energy-dependent intensity variations of a diffraction peak as the energy is tuned near an absorption edge of an atom of the sample: the long-range structural information contained in the diffraction peak is combined with the chemical and local structure selectivity of x-ray absorption spectroscopy. The intensities of reflections are sensitive to the relative contributions of the various anomalous sites and, in particular to the different valence states of the anomalous atom. Such an information can be obtained by studying the near edge region of the spectra (DANES).

This method is of particular interest for the study of transition metal oxides. We have used this technique to investigate the distribution of copper valence states in the spin-ladder compound $Sr_{14-x}Ca_xCu_{24}O_{41}$ (x=12) that contains both CuO_2 chains and Cu_2O_3 planes with two-leg ladders.

One set of experiment has been performed with monochromatic optics on D2AM beamline at the ESRF. As intensity variations of several Bragg reflections are collected versus energy, the data collection using classical monochromatic optics is quite long. For this reason, we have developed an experimental mode (Dispersive Diffraction) that allows simultaneous intensity collection over the whole energy range of interest. A Dispersive Diffraction experiment has been carried out on BM5 beamline at the ESRF. We will here present the results obtained using the two experimental strategies and discuss the data analysis developed for such methods.

P07.01.006 CCD-STUDIES OF DIFFUSE SCATTERING AT BEAMLINE F1 (HASYLAB/DESY). C. Paulmann, W. Morgenroth, D. Mathes and U. Bismayer, Mineralogisch-Petrographisches Institut, Universität Hamburg, Grindelallee 48, D-20146 Hamburg, Germany

The Kappa-diffractometer at HASYLAB/DESY (beamline F1) is equiped with a commercial CCD-detector system since summer 1997. The system includes software for diffractometer controlling, data collection and data processing. Besides standard data collections, the combination of a powerful radiation source with a fast area detector system recommends the beamline especially for studies of weak diffraction phenomena and time-resolved studies. CCD-studies were performed on several disordered minerals, covering a wide range of different types and distributions of diffuse scattering:

1) Incorporation of radiogenic elements in natural titanites gives rise to significant structural damages (Frenkel defects, quasi-amorphous regions) due to alpha-recoil collision cascades. This causes broad Bragg reflections (FWHM > 1.5°). Annealing of these samples (> 673 K) leads to a recrystallization of the damaged regions and to a progressive sharpening and an increasing integral intensity of the reflections. Below 673 K only Frenkel defects and associated lattice relaxations are annealed.

2) Sr-doped lead phosphate was studied below and above the ferroelastic transition point. At room temperature splitted Bragg reflections caused by the ferroelastic domain structure can be observed . Weak scattering between these reflections is induced by the domain wall volume. Above T_c the splitting disappears and the high-symmetry is adopted.

3) Detailed measurements of diffuse scattering in mullite show a broad and structured distribution of diffuse scattering which can be attributed to short-range ordering of anion-defects.

Special data processing routines were developed to handle problems which are difficult to solve by using the standard software (e.g. special background corrections, corrections for fluctuating primary beam intensity, data reduction routines, data conversion to different target formats, numerical values of rocking curve data). Further details about the studies and software will be presented.

P07.01.007 X-RAY DIFFRACTION AT SUB-MICRON SPATIAL RESOLUTION FOR MEASUREMENT OF THIN FILM STRESS. H. A. Padmore, R. Celestre, A. MacDowell and J. R. Patel, Lawrence Berkeley National Laboratory, MS 2-400, Berkeley CA 94720, USA, B. Batterman, Department of Applied and Engineering Physics, Cornell University, Ithaca, New York 14853, T. Marieb, Intel Corporation, 3065 Bowers Ave, Santa Clara, CA 95052

The advent of high brightness 3rd generation synchrotron radiation x-ray sources, together with recent advances in x-ray optics are for the first time allowing the application of x-ray diffraction techniques on the microscale. We have developed a system at the Advanced Light Source (ALS) in Berkeley based on a bending magnet source of synchrotron radiation, together with a 4 crystal monochromator, and elliptically bent grazing incidence mirrors. The 4 crystal monochromator is arranged in a + - - + configuration, and can be removed from the beam by simple rotation. It is therefore possible to produce monochromatic or white light co-linearly. Light is then focused by a pair of elliptical cylinders arranged in a crossed configuation, and a focus size of 0.8 microns has been achieved. Our initial studies have been of stress in thin films of Al-Cu and Cu under hydrostatic and electromigration induced stress. The measurements are carried out on thin film wires encapsulated in a passivation layer as used in interconnect structures in modern integrated circuits. Measurement of stress distributions in the individual grains in a polycrystalline wire is important in understanding failure mechanisms such as void formation during current flow. Grain orientation is derived directly from the Laue diffraction pattern, and stress is determined by measurement of the energy of several reflections. The complete strain tensor of each grain can then be deduced. This new method should have widespread application in materials science.

P07.01.008 STATUS OF TIME-RESOLVED SMALL-ANGLE X-RAY DIFFRACTION TECHNIQUE AT SIBERIAN AND MOSCOW SR CENTRES. P.M.Sergienko, V.S.Gerasimov, A.A.Vazina [1], V.N.Korneev [2], G.N.Kulipanov, V.M.Aulchenko [3], V.G.Stankevich [4], [1] Institute of Theoretical and Experimental Biophysics of RAS, Pushchino, Moscow Region 142292, Russia, [2] Institute of Cell Biophysics of RAS, Pushchino, Moscow Region 142292, Russia, [3] Budker Institute of Nuclear Physics, SD of RAS, Novosibirsk 630090, Russia, [4] Research Scientific Center "Kurchatov Institute", Moscow 123182, Russia

The improved version of small-angle diffractometer is described. It makes the focusing collimation of the SR beam: monochromator is situated in front of polysectional mirror [1]. The angle resolution is 0.2 mrad, the range of spacing of the measured reflections is 1.0-100.0 nm. The specimen cell lets to keep the muscle in living state, temperature range is 2-10°C. It is realised the isometric and isotonic contraction. The frog sartorius muscle can be stimulated by double pulse interval of 1-500 ms.

Optical and X-ray small-angle diffractometers were physically combined in the new version of set-up. The SR and laser beams were coaxially coincided on the same point of the muscle using the special semitransparent mirror, which reflected the laser beam and passed the X-ray beam. For registration of optical diffraction patterns the 2-channel principle was realised [2].

The new generation of fast, high efficient, parallax-free, one-coordinate, proportional detector OD-3 with counting rate up to 10 MHz at spatial resolution of 160 mkm and short time frame (1 mks) is used [3]. It is opened the absolutely new possibility for registration of short-living states in living systems.

P07.01.009 COHERENCE PROPERTIES OF THE ESRF MAGNETIC SCATTERING BEAMLINE: OBSERVING MAGNETIC SPECKLE PATTERNS. F. Yakhou[1], F.Livet[2], A. Letoublon[2], M. de Boissieu[2], F. Bley[2], C. Vettier[1], [1]ESRF, BP 220 F38043 Grenoble Cedex, France, [2]LTPCM-ENSEEG, BP 75 F38402 St Martin d'Hères, France

The coherence properties of a high brilliance beam from two phased undulators were analyzed at both 7.6 keV and 3.73 keV (uranium Miv absorption edge) on the ID20 magnetic scattering beamline. A coherent beam was obtained by properly collimating the 1.4 10^{-4} spectral bandwidth beam from a double Si (111) monochromator. The transverse coherence length could be matched to the collimating pinhole apertures by controlling the aperture d_s of a secondary set of slits placed after the optics. The high quality focusing optics of this ultra high vacuum beamline with two Be windows only provided a 350x80 μm^2 (HxV) spot size at the pinhole position, that resulted in a ~10^9 ph/s and 7.8 10^7 integrated coherent flux through ϕ10 and ϕ20 mm pinholes with a 60x60 μm^2 secondary source size, at 200 mA ring current, at 7.6 and 3.73 keV respectively. The coherence properties of the beam were retrieved from the statistical analysis [1] of the static speckle patterns produced by a silica aerogel that were recorded with a 384x576 pixel CCD camera. The degree of coherence β as given by the contrast of the speckle pattern was found to be around 50% at both energies, which is by far the highest and best coherent fluxes achieved up to now.
This high coherent flux enabled us to record a magnetic speckle pattern at 100 K arising from the disorder inherent to domain formation in the type-I antiferromagnetic system UAs, taking advantage of the huge enhancement of the magnetic scattering amplitude when the energy is tuned to the M-edges of Uranium.Such coherent scattering experiments on magnetic systems should give a unique insight on the physics of magnetic domains

P07.01.010 X-RAY NATURAL OPTICAL ACTIVITY AT THE Ni *K*-EDGE MEASURED BY USING AN X-RAY POLARIMETER WITH PHASE RETARDERS. Y. Ueji, The Graduate University for Advanced Studies, 1-1 Oho, Tsukuba, 305-0801 Japan, K. Okitsu, K. Sato and Y. Amemiya, University of Tokyo, 7-3-1 Hongo, Bunkyo, 113-8656 Japan.

We have successfully measured the x-ray natural optical activity of a single crystal of $NiSO_4 \cdot 6H_20$ at Ni *K*-edge by using a x-ray polarimeter[1] which consists of x-ray polarizer, phase retarder, and analyzer. In this experiments[2], x-ray natural circular birefringence (XNCB) and x-ray natural circular dichroism (XNCD) have been simultaneously measured by

analyzing the polarization state of the x-ray beam transmitted with the sample. The space group of the sample crystal belongs to one or the other of the enantimorphic pair $P4_12_12$ or $P4_32_12$ and it was known that this sample shows NCD in infrared, visible and ultraviolet regions[3].

The sample was a (001) plate of about 0.2 mm in thickness and the c-axis (optic axis) of the sample was set to be parallel with the x-ray beam axis so that the effects of the linear birefringence and linear dichroism were minimized. A small peak of 0.5 mrad was found at a pre *K*-edge, and a large peak of as much as 5 mrad was observed at the *K*-edge in the spectrum of polarization rotation, *i.e*., in the XNCB spectrum. In the spectrum of the polarization ellipticity , *i.e*., in the XNCD spectrum, the maximum ellipticity reached 0.004. It was found that the Kramers-Kronig relation holds between XNCB and XNCD spectra.

The XNCD spectrum of the same sample was also measured with a circular polarized x-ray beam whose helicity was switched alternately by using double phase retarders which compensate the spherical aberration[4]. The XNCD spectra didn't change against the rotation and the inversion of the c-axis of the sample with respect to the x-ray beam axis, ensuring that the effect of the linear birefringence and linear dichroism is negligible. The XNCD spectrum measured with circular polarized x-rays coincided with those measured by using the x-ray polarimeter.

P07.01.011 CCD DETECTORS FOR NON-CRYSTALLINE DIFFRACTION. J.C. Phillips, Bruker AXS, Inc., Madison, WI USA, L.Häming, Bruker AXS, Karlsruhe, Germany

CCD detectors have been successfully used in all types of crystallography in large numbers for some time. There is now a growing use of these detectors for other applications, often linked with synchrotron radiation as the X-ray source. These applications include powder diffraction, time-resolved diffraction and microdiffraction. Examples of such uses will be presented.

P07.01.012 DEVELOPMENT OF MICRO-AREA DIFFRACTION SYSTEM WITH MICRO-PINHOLES USING MONOCHRO-MATIC SR. K. Hagiya, M. Ohmasa and N. Haga, Dept. of Life Science, Himeji Inst. of Tech.,Hyogo 678-1297, Japan, K. Ohsumi, Inst. of Materials Structure Science, High Energy Accelerator Research Organization, Tsukuba 305-0801, Japan, Y. Kohmura, Harima Research Establishment, Inst. of Physical and Chemical Research, Hyogo 679-5143, Japan, K. Kusaka, K. Murakami and S. Noguchi, Dept. of Life Science, Himeji Inst. of Tech., Hyogo 678-1297, Japan and S. Arai, Dept. of Earth Science, Kanazawa Univ., Kanazawa 920-1192, Japan

Studies on inhomogeneity of rock forming minerals are important to elucidate growing and/or cooling process recorded in the minerals. Examinations of the phenomena are usually investigated by EPMA and/or optical microscopy. Most rock samples are mounted on slides and thinned to 30μm in thickness. Since the form of the samples is not convenient for diffraction studies, no diffraction study except Laue method has so far been carried out. As absorption of incident X-ray through slides was too large, Laue method (back-reflection type) has so far been employed [1,2] although indexing of Laue patterns of unknown sample is extremely difficult. Thus micro-area diffraction system has been developed to measure diffraction of the fine crystallites and/or domains in thin sections with high brilliance and high energy monochromatic X-ray beam.

The experiments were carried out on the R&D beamline BL47XU at SPring-8. The wave length of the incident beam from the undulator was adjusted to 0.7Å with Si double-crystal monochrometer. Pinholes with various sizes were prepared for the experiments. The diameters of the micro-beams through the pinholes were measured at three positions by scanning a slit before an ion chamber. The effective diameters of the pinholes and the divergence of the micro-beams were estimated from them. Two pinholes with diameters of 4.7μm and 3.2μm full width at half maximum are available. The divergence was 19μrad and 29μrad respectively. They were applied to measure diffraction patterns of a thin section (thickness: 30μm) of Cr-spinel crystals segregated from olivine host crystals in dunite from Iwanai-dake, Hokkaido, Japan. The distance between the pinhole and the sample was 10mm and the camera length was 79mm. Oscillation photographs of these minerals were successfully recorded on a flat imaging plate (Fuji Co. LTD.) and will be shown together with crystallographic analyses.

P07.01.013 HARD X-RAY PHASE-CONTRAST IMAGING WITH A MICROFOCUS SOURCE. A.W. Stevenson[a], D. Gao[a], T.E. Gureyev[b], A. Pogany[a] and S.W. Wilkins[a], [a]CSIRO Manufacturing Science & Technology, Private Bag 33, Clayton South MDC, Victoria 3169, Australia, [b]CSIRO Forestry & Forest Products, Private Bag 10, Clayton South MDC, Victoria 3169, Australia.

Since Röntgen's discovery of X-rays in 1895 the vast majority of radiographs have been collected and interpreted on the basis of absorption contrast and geometrical (ray) optics. In recent years the possibility of utilising phase-contrast effects has received considerable attention, much of this activity stemming from the possibility of producing X-ray beams of suitably high coherence at synchrotron sources (see [1] for example). A description of a phase-contrast imaging technique which utilises a laboratory-based microfocus X-ray source to achieve the required spatial coherence, and does not rely on there being a high degree of chromatic coherence, will be described [2]. The method employs a relatively large object-to-image distance to allow wave interference (Fresnel diffraction) to occur and manifest itself as contrast formation in the intensity distribution recorded at the image plane.

Various examples of phase-contrast images and a theoretical description of image structure in terms of the Kirchhoff formulation will be used to elucidate important features of the technique. These include the ability to provide improved information from weakly-absorbing features of an object such as soft tissue, including edge enhancement; inherent magnification; improved signal-to-noise.

P07.01.014 HIGH SPATIAL RESOLUTION X-RAY IMAGING SYSTEM WITH A CCD DETECTOR COUPLED WITH AN X-RAY MAGNIFIER. K. Sato, Y. Hasegawa, K. Kondo, K. Miyazaki, and Y. Amemiya, Department of Applied Physics, University of Tokyo, 7-3-1 Hongo, Bunkyo, Tokyo 113-8656, Japan.

Recently, Faraday rotation as well as linear birefringence in an x-ray regime were measured by using an x-ray polarimeter. In order to investigate the polarization effect in microscopic scale, the x-ray polarization microscopy is expected to be a promising

strategy. The development of a high resolution x-ray imaging system is essential for this microscopy.

We decided to use the CCD-detector. The CCD detector consists of (1) phosphor (Gd_2O_2S:Tb, 10•m thick on glass plate), (2) magnifying optical lens (×2.5, ×5, ×10), and (3) CCD camera cooled down to –50°. The CCD camera has an imaging area of 1024×1280 pixels of 6.7•m×6.7•m.

The experiments to evaluate the performance characteristics of the high resolution x-ray imaging system were performed at BL-15C, Photon Factory (KEK). The energy of the incident beam was tuned at 7.709 keV by Si (111) pre-monochromator. The knife-edge technique was applied for the evaluation of the spatial resolution. The spatial resolution of the detector of 7.9•m was obtained in terms of full width at half-maximum (FWHM) of line spread function (LSF). We intended an x-ray magnification for higher resolution with the use of asymmetric Si (111) Bragg reflection. The crystals with the magnification factors 1.0, 3.3, 6.3, and 12.8 were used. The spatial resolution of this imaging system was improved up to 1.2•m.

This 2D x-ray imaging system will be applied to the polarization microscopy.

P07.01.015 ATOM RESOLVING X-RAY HOLOGRAPHY: RECENT PROGRESS IN THEORY AND EXPERIMENT. D.V.Novikov [1], F.N.Chukhovskii, B.Adams, T.Hiort, E.Kossel, G.Materlik, Hamburger Synchrotron-strahlungslabor HASYLAB at Deutsches Elektronen-Synchrotron DESY, Notkestr. 85, D-22607 Hamburg, Germany [1]also H.C.Orsted Lab. Universitetsparken 5, DK2100 Copenhagen Denmark.

Atom resolving X-ray holography is a novel method for direct imaging of atoms in solids. We discuss the basic ideas of direct fluorescent (XFH) and multiple energy (MEXH) X-ray holography and the latest theoretical and experimental progress in this field. A rigorous theory of X-ray holography based on classical electrodynamics is developed. The equations obtained take into account second-order X-ray scattering effects and can be applied for restoration of the electron charge density from holographic data. The influence of wave coherence properties, absorption and sample dimensions as well as atom position determination from incomplete data sets are considered . Experimental holograms of Cu_3Au and Fe in XFH, MEXH and modified MEXH schemes are presented, together with reconstructed images, obtained by a simple Fourier transform based reconstruction algorithm. The dependence of the accuracy and precision of the images on the experimental conditions, problems of artefact suppression and possible application fields of the method are discussed.

P07.01.016 A TOPOGRAPHIC METHOD FOR DETERMINATION OF THE RESONATORS VIBRATION AMPLITUDE USING THE RS AT ESRF B. Capelle, J. Detaint, Y. Epelboin LMCP, CNRS, case 115, Universités P.M. Curie and D. Diderot, 75252 Paris Cedex 05, France

X-ray topography is one of the most powerful techniques to assess the vibration modes of the piezoelectric devices. We have previously demonstrated that stroboscopic topographies of vibrating thickness shear resonators made using the time structure of the synchrotron radiation contain contrasts which can be used to determine very accurately the vibration amplitude mode when the amplitude of the vibration is sufficiently small. In this communication, we present a new method that allows the direct determination of the vibration amplitude of devices used in most of their applications ranging from some µW up to several mW. This method is based upon the use of a white beam with an extremely small divergence. The distortion of the lattice planes due to the vibration is by several order of magnitude larger than the width of the intrinsic rocking curve so that each region with a different deformation diffracts a radiation with a different wave length. It means that the diffracted rays are deflected with different angles according to the local Bragg angle. For an incident beam delimited by a very thin slit (of the order of 20 mm) in the symmetric arrangement, the width of the diffraction image obtained on a film is thus a function of the local rotation of the lattice plane. So, we obtain a direct recording of the vibration amplitude along the slit.To obtain further details on the vibration modes, the stroboscopic technique was employed. On the whole, this new method which makes use of the very improved characteristics of the beam delivered by the third generation synchrotron at ESRF, allows to directly determine the vibration amplitude of the piezoelectric devices with a very high precision in the case of thickness shear modes.

P08.01.001 ULTRA LOW TEMPERATURE CRYST-ALLOGRAPHY USING AN OXFORD-CRYOSYSTEMS HELIX OPEN-FLOW HELIUM CRYOSTAT. M.A. Leech, J.A.K. Howard and A.E. Goeta, Department of Chemistry, University of Durham, South Road, Durham, DH1 3LE, UK.

The measurement of X-ray diffraction data at temperatures lower than 80 K, has until recently been limited to the use of closed-cycle helium refrigerators. Although this has become a well established technique [1] for temperatures down to 10 K, it has its drawbacks: the equipment is expensive and needs considerable maintenance; the crystal must be enclosed within two or three evacuated shrouds, resulting in high X-ray backgrounds and difficulties in centring the crystal; the crystal must be cooled slowly, making it difficult to handle sensitive samples. Using the HELIX cryostat, temperatures down to 30 K can be obtained in an open flow of He gas. The open-flow nature of the device gives it a number of advantages: crystals can be flash cooled, enabling air or moisture sensitive samples to be handled easily; Crystals can quickly screened for quality; the crystal is visible, so can be centred easily and if necessary, can be exposed to a number of external influences, such as a light source.

The work presented in this poster includes the commission and calibration of the HELIX device on the laboratories Bruker SMART-CCD diffractometer, together with a number of examples of its use.

[1] Larsen, F. K. (1995). *Acta Cryst*. **B51**, 468-482.

P08.01.002 LOW TEMPERATURE X-RAY STRUCTURE DETERMINATION USING COMPRESSED AIR INSTEAD OF LIQUID NITROGEN. Jamie F. Bickley, Gavin T. Lawson, Frederic Rivals and Alexander Steiner, Department of Chemistry, University of Liverpool, Crown Street, Liverpool L69 7ZD, UK

It has become standard that X-ray structure analysis is carried out at low temperature. In general crystallography laboratories rely upon applying a cold nitrogen gas stream to cool crystals. The gas is usually supplied from a storage vessel containing liquid nitrogen. However, using liquid nitrogen is a rather expensive method, which can lead to large bills somewhere in the region of several K$ per diffractometer per year. In addition, the storage container has to be refilled regularly which cost precious working hours.

We present a low-temperature device that avoids the usage of liquid nitrogen, but instead uses pre-dried compressed air. This system can provide temperatures from +100°C down to -80°C, which is sufficient for routine structure determination of air and moisture sensitive materials. The cooling unit consists of the XR Sample Cooler supplied by FTS Kinetics {for a detailed view see http://www.ftssystems.com}. It only requires a compressed air supply, which is available in most research laboratories.

This device is built onto an image plate diffractometer (STOE-IPDS) and is in constant use. The system is virtually maintenance free and highly cost efficient, due to the low purchase price, which is a fraction of the price of a liquid nitrogen based cryosystem. On our poster we will present the set-up described above in more detail, accompanied by some interesting structures which have been determined using this system.

P08.01.003 A PORTABLE CRYOSTREAM TO TRANSFER CRYSTALS. F. Wien, T. Rutherford, M. Bennett, and M.R. Sanderson. Division of Biomedical Sciences, Randall Institute, King's College London. WC2B 5RL UK.

A portable cryostream, the King's Cryogun, has been developed in our laboratory for the transfer of crystals at cryogenic temperatures. The cryogun provides a constant stream of nitrogen vapour at a temperature of 130K. The King's cryogun has been tested on a variety of macromolecular crystals and used succesfully to transfer crystals between goniometer and storage cryovials. Experiments with protein and DNA crystals have revealed no significant deterioration of diffraction quality or increase in mosaicity after repeated transfer steps. The use of the King's cryogun has become essential for our synchroton experiments: crystals are tested in-house for diffraction quality, the best crystals are transferred to cryostorage and remounted at the synchroton using the cryogun (1,2). This retrieval technique has proved to be time-saving and reliable.

P08.01.004 DEVELOPMENT OF A COOLING SYSTEM FOR SINGLE CRYSTAL MEASUREMENTS AT 4 K. Ch. Mensing, M. Wörle, P. Corrodi and R. Nesper, Inorganic Chemistry Laboratory, ETH Zürich, CH.

We developed a cooling system based on commercially available helium cryostats [1] which allows us to perform single crystal and powder measurements at temperatures of 4.3 K and ambient pressure, and below 4 K with reduced pressure. The cooling system is mounted on a standard image plate diffraction system [2]. The temperature can be stabilized and controlled very accurately. The cryostat can easily be removed to allow standard measurements as well. The working principle and first results are presented.

P12.01.001 WAVELENGTH SCANNING DIFFRACTOMETRY WITH A QUADRUPLE MONOCHROMATOR. M. Hashihayata, K. Munakata, S. Kuwajima, A. Okazaki and Y. Soejima, Department of Physics, Kyushu University, Fukuoka 812-8581, Japan

In order to make high-resolution measurements of X-ray resonant scattering such as XANES, EXAFS and DAFS, the wavelength-scanning type of diffractometry has been developed. For getting high quality incident X-ray beams, a germanium quadruple monochromator made by Philips (PW1754) is used: two channel-cut monochromators are rotated by stepping motors at the minimum step of 1.2 μrad. At the wavelength $\lambda \sim 0.15$ nm, the resolution $\Delta\lambda/\lambda=2\times10^{-5}$, and the angular divergence 2.4 μrad are attained. The software for controlling the wavelength scanning is combined with that for controlling the four-circle goniometer. Therefore, the intensity measurement as a function of incident wavelength can automatically be made for absorption, scattering and diffraction experiments. By using the X-ray generator with an Au rotating-anode operated at 50 kV- 40 mA, the wavelength of incident X-ray is covered in a range 0.06 - 0.20 nm with the 440 diffraction of the monochromator; the intensity is 500 cps for the beam size 0.3×3 mm^2 at the position of the specimen. In the present paper, examples of the application to high-resolution EXAFS measurements will be demonstrated; the details of the system will also be discussed. Because the incident intensity is not sufficient for the experiments, the system will be more effective if coupled with synchrotron X-ray source.

P12.01.002 INSTRUMENTAL EFFECTS UPON THE GLANCING ANGLE XRD MEASUREMENTS. D. Rafaja, R. Kuzel and V. Valvoda, Faculty of Mathematics and Physics, Charles University, Ke Karlovu 5, CZ-121 16, Prague, Czech Republic and G. Cappuccio, INFN-LNF-Lab. Dafne Luce, Via E. Fermi 40, P.O. Box 13, I-00044 Frascati, Italy.

Diffraction techniques employing the glancing angle X-ray diffraction (GAXRD) are very popular in the last time, as they offer many features to study coatings and thin films. The main advantage of the GAXRD is that the thickness of the material being analysed can easily be changed varying the angle of incidence. Another benefit of the GAXRD is a very low sensitivity of the peak shift to the potential sample displacement. However, the instrumental effects are not completely summarised and explained yet. This fact, of course, causes problems if the splitting of the physical and instrumental effects in the diffraction pattern should be done with a very high precision.

The poster shows a systematic study of the instrumental effects such as line broadening or changes in the line shape and in the registered intensities. These effects, which are caused by the finite divergence of the primary beam and by the limited acceptance of a long Soller collimator placed in the diffracted beam, were investigated by using various “standard” samples. An explanation of the observed phenomena is offered, which is based on a “ray-tracing” calculation.

Besides, an application of this approach is illustrated. As an example, we have measured diamond coatings deposited on TiC substrates at glancing angles to estimate their thickness. The measured intensities must first be corrected for a limited sample size, for a finite divergence of the primary beam and for the real acceptance of the Soller collimator to arrive at the true diffracted intensities, which are modified just by the absorption (and the thickness) of the coating.

P12.01.003 X-RAY ROTATION-TILT METHOD (XRTM) - A NEW X-RAY DIFFRACTION TECHNIQUE. J. Bauch, H.-J. Ullrich and J. Brechbühl, Dresden University of Technology, Institute of Materials Science, Mommsenstr. 13, D-01062 Dresden, Germany.

A new X-ray diffraction technique, marked by the authors as X-ray Rotation-Tilt Method (XRTM) and based on an idea of our own from 1977, has been developed within the scope of a project of the Deutsche Forschungsgemeinschaft. The principle is briefly presented in the following: XRTM is a method where local X-ray interferences are produced by directing an X-ray or synchrotron beam from an external source with default

monochromatic radiation of high intensity and a small diameter (e.g. application of capillary optics) on a crystalline region of a sample. Thereby for each diffracting net plane set a cone can be indicated with the half-opening angle equal to ($90°-\Theta_{hkl}$) for which the Bragg equation is satisfied. Each time the incidenting monochromatic X-ray beam coincides with a shell line of the interference cone on the diametrically opposite side of the shell of the cone, a small spot is produced by the "reflected" beam. By means of a special movement of the sample it is possible to accumulate such cones spot-by-spot on a detector system (e.g. film, image plate or CCD-area-detector) located on the back. These reflexes imaged on the detector form the so-called XRTM lines. For the complete spot-by- spot accumulation of such lines on a detector system a scientific device has been developed, at which sample and detector are coupled at a defined distance and which are jointly and simultaneously rotated and tilted around the sample point investigated such that the normal vectors belonging to all net plane sets run through all directions in the half space successively. The XRTM technique has certain advantages compared to other X-ray diffraction methods (e.g. Kossel technique) with regard to informational content and high accuracy. It can thus be considered a global novelty. This method can be optimally used for an unlimited range of substances due to the free choice of wavelength and the fact that it requires no vacuum. The intensity-to-background ratio is extremely high in comparison to the Kossel technique. A further advantage is the possibility of selective "adjustment" of reflexes at high Bragg angles. Therefore, this technique can be applied for a wide range of problems in materials diagnostics, e.g.: high-accuracy determination of crystallographic orientations (for example small grain boundary angles of rotation and tilt angles ≥0.02°), dislocation density determination, determination of decrease in symmetry, high-accuracy determination of lattice constants ($\Delta a/a \leq 10^{-5}$), precision determination of interplanar spacings (local stresses/strains ($\Delta d/d \leq 10^{-5}$) and phase identification in microregions.

P12.01.004 X-RAY OPTICS FOR LABORATORY SOURCES. M. Kunz, H. Reifler, G. Böttger, R. Miletich, A. Friedrich, Labor für Kristallographie, ETH Zentrum, CH-8092 Zürich and P. Pattison, Institut de Cristallographie, Université de Lausanne, CH-1015 Lausanne.

The quality of lab-source X-ray beams can be improved without loss of intensity by the use of some simple X-ray optics. We present the combination of a Si(111)-Fankuchen monochromator with a pair of mirrors mounted on a sealed-tube 4-circle diffractometer.

A horizontally bouncing Si(111) monochromator selects only a narrow segment of the highly divergent X-rays generated by a Mo-tube, thus creating a highly parallel and monochromatic beam. Together with a small Darwin width of 4'', the virtual absence of mosaic spread of such a monochromator–causes an intensity loss of about 80% on a 0.1 mm sample compared to a standard pyrolitic graphite (002) monochromator. An additional intensity loss is created by the need to use only Kα1 radiation due to the horizontal monochromator- and diffraction-geometry. This loss can be compensated by a surface mis-cut of 4° with respect to the diffraction planes. Such a 'Fankuchen monochromator' causes a compression of the beam and thus an intensity gain in the diffraction plane.

In order to obtain additional intensity on the sample, a pair of horizontally tapered mirrors will replace the standard 0.3mm collimator. Using a Cr coating as reflecting surface and a taper of 3 mrad causes an optimal intensity gain of a factor of 5 on a 0.1 mm diameter sample when compared to a 0.3 mm collimator.

With this combination of Fankuchen monochromator and X-ray mirrors we are thus able to decrease divergence and improve monochromaticity of a Mo sealed tube X-ray source. This will further improve the accuracy of measurements of equation of states as a function of pressure and temperature as well as the quality of diffracted intensities.

P12.01.005 REMOTE CONTROL FOR SINGLE CRYSTAL DIFFRACTION IN MICROGRAVITY. James F. Fait, IMCA-CAT, Illinois Institute of Technology, 3300 South Federal St, Chicago, IL 60616 USA.

A single crystal diffraction system has been designed for use in the microgravity environment of the International Space Station. Control of the diffraction experiment by earth based scientists is a necessary requirement of the instrument. A protocol and software for remote control of a commercial CCD area detector and the associated goniometer and generator has been developed. Health and Status for the entire system is maintained and sent in a heartbeat message, and detailed status is mirrored both on the data collection computer and at the ground station. Details of the diffraction experiment are relayed to a local control system to be forwarded to the ground station, and the frame data is forwarded to the Ground Science Station for display. Local control of the system via a Crew Interface Port is available, as well.

The design criteria and the implementation of the control system will be explained, as well as examples of more conventional uses for this control system.

P12.01.006 NIST RUBY SPHERES AS SRM FOR DIFFRACTOMETER ALIGNMENT. T. Siegrist, Bell Laboratories, Murray Hill, NJ 07974 USA, and Inorganic Chemistry, Lund University, Sweden; W. Wong-Ng, M. Levenson, J. Armstrong, L.P. Cook, NIST Gaithersburg , MD 20899 USA; E.J. Gabe and G. Enright, SIMS, NRC, Ottawa, Canada, K1A 0R6; L. Finger, Geophysical Laboratory, Washington DC 20015, USA; H. Evans, US Geological Survey, Reston, VA 22092, USA; G. DeTitta, Hauptman-Woodward Medical Research Institute, Buffalo, NY 14203, USA, and C.R. Hubbard, Oak Ridge National Laboratory, Oak Ridge, TN 37831, USA.

X-ray structural determinations using automatic data collection and structure solution schemes require accurate initial cell parameter data. A lattice parameter reference standard is critical for alignment of single crystal diffractometers. Small ruby spheres have proven to be an excellent reference material. The high hardness of ruby allows the grinding of 150μm diameter spheres, which produce strong reflections at high angles for copper as well as for molybdenum radiation. From centred reflections at high angles, high precision lattice parameters can be obtained.

A series of 42 rubies were measured on three Enraf-Nonius CAD-4 and a Picker diffractometer. The data were corrected for thermal expansion and for refraction. The average unit cell parameters obtained are $a = 4.76080 \pm 0.00029$ Å (expanded uncertainties), and $c = 12.99568 \pm 0.00087$ Å. Five different samples of powdered rubies were also measured on a Guinier camera, giving good agreement with the values obtained from the single crystal spheres, $a = 4.76093 \pm 0.00031$ Å, and $c = 12.9959 \pm 0.0023$ Å.

P12.01.007 MICROFOCUS X-RAY TUBE AND INTER-CHANGEABLE FOCUSING OPTICS: ACHIEVEMENTS NOW AND FUTURE PROMISE: U.W.Arndt and A.C.Bloomer, MRC Laboratory of Molecular Biology, Hills Rd, Cambridge CB2 2QH, UK

Data will be presented from the novel MicroSOURCE X-ray generator [1] installed in our laboratory with ellipsoidal specularly reflecting mirrors. We have studied the performance

of both the tube [2] and the mirrors [3]. Results are compared with those expected theoretically.

Diffraction data from proteins show the power of this device, especially for smaller crystals. Suitable choice of mirror enables the size and divergence of the X-ray beam to be altered readily to match the different requirements of successive samples. Present performance is limited by imperfections in the mirrors; improved mirrors are now in production. Other types of mirrors, such as multi-layer optics, and mirror arrangements, are under consideration. Higher output from the tube is confidently expected with clear developments which are already in progress. The modular nature of this system enables simple incorporation of such changes on-site in a laboratory setting.

For crystals of sizes 300 micron or less, needing a small well collimated beam with low divergence, the output from this X ray tube running at 24 watts (i.e. 48kV and 0.5mA) the flux is similar to that available from much larger and more complex rotating anode generators. The relative performance of the microfocus tube and mirror system becomes increasingly advantageous with the study of ever smaller crystals.

P12.01.008 BEAMLINE ID14 EH2 FOR MACRO-MOLECULAR CRYSTALLOGRAPHY AT THE ESRF. E. P. Mitchell, H. Belrhali, W. P. Burmeister and S. Wakatsuki, European Synchrotron Radiation Facility, BP-220, F-38043 Grenoble Cedex, France and S. McSweeney, European Molecular Biology Laboratory, Grenoble Outstation c/o ILL, BP-156X, F-38042 Grenoble Cedex, France.

Beamline ID14 [1] at the ESRF is a dedicated resource for protein crystallography. There are a total of four stations planned on the high-b undulator section, one of which is ID14 EH2. The radiation sources for the beamline are presently a 23mm undulator, peak output at 13300keV, and a tunable 42mm period undulator. X-ray beams for the side stations are produced using the (111) reflections from three thin transparent monochromator diamond crystals positioned in the white beam and the straight through beam provides X-rays for the final station.

Station EH2 is a fixed energy beamline (0.932Å), using either Laue or Bragg synthetic diamond crystals and a planar Ge (220) crystal to bring the beam back parallel with the straight through beam. The beam is focused onto the sample position with a 35cm long rhodium coated fixed radii toroidal mirror.

The experimental hutch is equipped with a CCD detector (X-Ray Research 160mm, 3.5 second read out for 2048 x 2048 pixels) and a single axis phi spindle goniometer. The goniometer has motorised crystal alignment axes to allow automatic and remote positioning of samples.

The station is presently (December 1998) undergoing commissioning and limited user operation is expected in Spring 1999. To date satisfactory data has been collected from tetragonal lysozyme crystals in unfocused mode on an image plate system.

P12.01.009 THE SOFT X-RAY SIX-CIRCLE DIFFRACTOMETER FOR SCATTERING / DIFFRACTION. C. K. Chen , C. H. Chung, C. H. Shu, Y. R. Lee, and S. L. Chang, Department of Physics, National Tsing Hua University, Hsinchu, Taiwan 300, R. O. C. Y. C. Jean and K. Y. Liu, Synchrotron Radiation Research Center, Hsinchu, Taiwan 300, R.O.C.

A six-circle soft x-ray diffractometer with κ-φ geometry has been constructed and commissioned with 1-9 Kev DCM (Double Crystal Monochromater) beam line at Synchrotron Radiation Research Center. The Fifty degree inclined κ-axis provides more degree of freedom and momentum coverage in reciprocal lattice space, as specially designed. The diffractometer is usually operated in high vacuum chamber, because soft x-ray is strongly absorbed by atmosphere. Both sphere errors and angular positional errors have been verified within the values of specification. Four experiments, including powder diffraction, θ-2θ scan, reflectivity of multi-layer thin films, and multiple diffraction, will be discussed. All experiments have been done at the vacuum of 10^{-6} torr. The quartz standard powder, zeolites, Ti_2O_5 / SiO_2 /Zerdur multi-layer thin films, and Si(111) single crystal are investigated. The excellent capability of the diffractometer in characterizing both mesoscopic and microscopic materials structure analysis is shown.

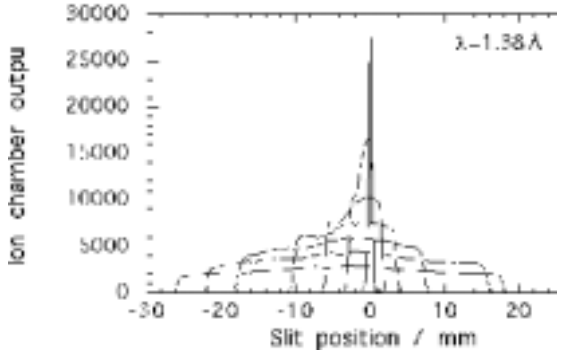
P12.01.010 SYNCHROTRON DIFFRACTION WITH VARIABLE WAVE LENGTH FOR INVESTIGATIONS OF SEMICONDUCTOR HETEROSYSTEMS R.M.Amirzhanov, A.V. Kolesnikov, M.A.Revenko,E.M. Trukhanov [1], S.G. Nikitenko [2], [1] Institute of Semiconductors Physics, 630090, Novosibirsk, Russia, [2] Institute of Catalysis, 630090, Novosibirsk, Russia.

The results of diffraction investigations of semiconductor heterosystem structure using the variable wave length of the incident synchrotron beam are presented. For such kind X-ray investigations, the wave length becomes constant, but the angle between the incident beam and the sample surface is changed. As a rule, the rocking curves obtained from semiconductor layer systems contain two or more peaks, and the angular distances between the peaks permit us to analyse the heterosystem structure state. This state can be pseudomorphic or plastically relaxed depending on the density of misfit dislocations. The advantageous in measuring of crystal lattice distortions and superlattice structure parameters associated with using the synchrotron radiation are demonstrated. The proposed method is potentially suitable for in situ diffractometry registrations during the molecular beam epitaxial growth due to the angle of beam incidence is constant and the sample remains immobile. The formulas for determination of tetrahedral and rhombohedral distortions of an epitaxial heterosystem from data of spectral rocking curves are presented. The nature of rhombohedral distortions are discussed for the first time. The main structural parameters of superlattices are also determined from the mentioned spectral data. The experimental results are obtained for semiconductor systems GaAlAs/GaAs grown by molecular beam epitaxy.

P12.01.011 ROTATED-INCLINED FOCUSING MONOCHROMATOR FOR PROTEIN CRYSTALLOGRAPHY. Nobuhisa Watanabe[1], Mamoru Suzuki[1], Yasuo Higashi[2] and Noriyoshi Sakabe[3,] [1]Photon Factory, Inst. of Materials Structure Science, High Energy Accelerator Research Org., Tsukuba, Japan, [2]Mechanical Engineering Center,High Energy Accelerator Research Org., Tsukuba, Japan, and [3]Tsukuba Advanced Research Alliance, Univ. of Tsukuba, and Foundation for Advancement of International Sciences,Tsukuba, Japan.

A new single-crystal focusing monochromator for protein crystallography has been developed. In order to achieve simultaneous tuning of the beam demagnification rate and the radius of curvature for focusing over a wide wavelength range, the surface of an inclined monochromator was cylindrically bent.The monochromator is able to tune these two parameters simultaneouslywith a single rotation of the crystal about the azimuthal axis. A new monochromator incorporating this idea has been developed for beamline BL6B at the Photon Factory. The monochromator was designed for use in the wavelength range 0.87 to 1.90 Å and beam focusing was tested at wavelengths of 1.04, 1.38 and 1.74 Å. A well compressed and focused beam was obtained at all three wavelength by rotation about the azimuthal axis only. Horizontal intensity profile of the focused beam with the azimuthal axis rotation at 1.38 Å is shown in the figure.The monochromator could focus the X-ray beam to less than 0.8 mm FWHM in the horizontal direction.



P12.01.012 PROGRESS TOWARDS COLLABORATORY SOFTWARE FOR MACROMOLECULAR CRYSTALLOGRAPHY AT A SYNCHROTRON BEAMLINE. R.M. Sweet and J.M. Skinner, Biology Department, Brookhaven National Laboratory, Upton, NY 11973, sweet@bnl.gov

Development of software tools to allow collaboration by remote scientists will help to drive this golden age for synchrotron macromolecular crystallography (PX). The development of MAD phasing and crystal freezing, new area-sensitive detectors, flexible diffractometers, and good software are responsible for an unprecedented wave of productivity. A collaboration between the Biology Department and the National Synchrotron Light Source aims to provide hardware, software tools, methods, and personnel to provide new resources for PX at Brookhaven.

Several possible uses for collaboratory software are to allow the professor at home to help his students at the beamline to make tactical decisions about data collection, to allow workers at home to carry some of the burden for data reduction and monitoring of data collection, to assist local beamline scientists in monitoring and tutoring student operators, and possibly to allow complete data collection from a remote site with a technician mounting specimens at the synchrotron.

The principal collaboratory software tool is a Java-based browser program. The current status of the experiment is displayed, including the sweep of data chosen, the status of the x-ray ring and beamline alignment, and details about the most recent image taken. Controls exist that allow rudimentary control of the beamline and data-collection apparatus from the Java applet.

A VRML/Java tool has been constructed that can be used either to simulate the data that would be collected with a particular data sweep, or to display the data being measured at a moment in time at the beamline. Primitive data are shown in one color; those generated by space-group symmetry appear in another.

The Biology/NSLS collaboration at Brookhaven is funded by the OBER and OBES of the US Dept. of Energy, and by grants from the NIH and NSF.

P12.01.014 NEW SYNCHROTRON RADIATION BEAMLINE AT CHESS. D.H. Bilderback[1,2], H.D. Abruna[3], J.D. Brock[2], B.H. Cooper[4], K.D. Finkelstein[1], E.F. Fontes, Jr. [1], S.M. Gruner[1,4], R.L. Headrick[1], S. W. Kycia[1], C.K. Ober[5], Q. Shen[1,5], K.W. Smolenski[1]. [1]CHESS, [2]School of Applied & Engr. Physics, [3]Dept. of Chemistry and Chemical Biology, [4]Dept. of Physics, [5]Dept. of Materials Science & Engr., Cornell University, Ithaca, New York, 14853.

A new wiggler beamline is to be constructed at the CHESS laboratory over the course of the next 2 years. The ultra-high flux x-ray beamline, called G-line, will serve both Cornell faculty and general CHESS users. The new facilities will be contained in a one floor, 3000 ft^2 (300^2 m) partially underground building. Three stations in tandem (two of which can operate simultaneously) will use the x-rays to study dynamically evolving materials, including thin film growth, patterned surfaces, electrochemical interfaces, polymers, liquid crystals, biomaterials, and systems with novel electronic properties. A new 49-pole wiggler will feed both the G-line (from positrons) and the present CHESS A-line (from electrons) which will undergo further upgrade as well. The wiggler will have a 15 keV critical energy during 5.3 GeV, 500 ma/beam operation of CESR. The design, construction, and operation of the new G-line will occur with the help of Cornell faculty members, CHESS, and the Cornell Center for Materials Research. A completion date of 2001 is anticipated.

We also describe very preliminary plans for a possible dedicated CHESS II ring in the context of a larger long-range plan to build a new dual-bore collider for B-meson physics with 3 A circulating currents in the same tunnel as the present CESR machine. CESR would then become dedicated to producing synchrotron radiation.

P12.01.015 THE CANADIAN LIGHT SOURCE. J. Wilson Quail[1], Louis T.J. Delbaere[2], Emil L. Hallin[3], Barry Hawkins[4], Ronald G. Cavell[5] & Dennis M. Skopik[3]. [1]Dept. of Chemistry, University of Saskatchewan, Saskatoon, S7N 5C9 Canada, [2]Dept. of Biochemistry, University of Saskatchewan, Saskatoon, S7N 5E5 Canada, [3]Saskatchewan Accelerator Laboratory, University of Saskatchewan, Saskatoon, S7N 5C6 Canada, [4]UMA Projects, Saskatoon, S7H 0V1 Canada, [5]Dept. of Chemistry, University of Alberta, Edmonton, T6G 2G2 Canada

For over eight years the Canadian Institute for Synchrotron Radiation (CISR) has been working to establish a synchrotron radiation facility in Canada. In 1996, after site visits by an international evaluation team to consider two proposals for a Canadian Light Source (CLS), the CISR endorsed the recommendation of the evaluation committee that the CLS be constructed at the University of Saskatchewan in Saskatoon. Funding for the CLS will be finalised by April, 1999 and construction will begin in the summer of 1999, with completion within 5 years. The CLS will be a 2.9 Gev 3rd generation storage ring using an existing 300 Mev linear accelerator at the Saskatchewan Accelerator Laboratory as an injector. Twelve beam lines will be part of the initial construction, including two beamlines for protein crystallography. There will be capacity for over 60 beamlines in the facility. A website has been created (http://cls.usask.ca/) to provide information about the Canadian

Light Source. Details of the design of the synchrotron and the beamlines will be described in the poster.

P12.01.016 SAMPLE ENVIRONMENTS FOR THE CURVED IMAGE-PLATE DETECTOR ON STATION 9.1 AT THE SRS DARESBURY. M.A. Roberts, E.J. MacLean and G. Bushnell-Wye, CLRC Daresbury Laboratory, Daresbury, Warrington, Cheshire WA4 4AD, UK, M. Ellerby, W.A. Steer and J.L. Finney, Department of Physics and Astronomy, University College London, Gower Street, London WC1E 6BT, UK.

The development of the curved image-plate technique for X-ray diffraction that we [1, 2] and others [3, 4] have undertaken has enabled data to be collected in minutes opposed to hours, since a complete diffraction image is collected in a single exposure. Integration around a significant fraction of the Debye-Scherrer cones means even further reductions in data collection times and enhanced visibility of weak features. This rapidity also broadens the scope for time-resolved experiments involving, for example, structural changes associated with thermal treatment of materials.

We have designed both a high temperature furnace (1125K) and a closed cycle helium cryostat (15K) that will allow data to be collected from a rotating capillary sample. A number of materials have been investigated as a means of characterising these environmental chambers and will be presented here.

P12.01.017 THE FUTURE POWDER DIFFRACTION STATION AT THE SWISS SYNCHROTRON FACILITY (SLS). F. Fauth, B. Patterson, C. Brönnimann, Swiss Light Source, Paul Scherrer Institut, CH-5232 Villigen-PSI, Switzerland; P. Pattison, Université de Lausanne, CH-1015 Lausanne, Switzerland.

The Swiss Light Source (SLS) is a 2.4 GeV synchrotron radiation facility presently under construction in Switzerland [1]. The powder diffraction (PD) station is one part of the materials science beamline, which is also dedicated to computer microtomography and glancing-incidence X-ray techniques. The beamline insertion device is a 65-pole minigap wiggler (2 m long, magnetic gap=7.5 mm, B_{max} = 2T), implying E_{crit}=7.5 keV and K=9.2. The operating energy range extends from 5 to 40 keV. The beamline optics consist of a vertically collimating mirror, a sagitally double monochromator and a vertically focusing mirror. The focal lengths of the monochromator and second mirror can be adjusted to the position of the different experimental stations. The PD station is located at the 1:1 demagnification position (37m) of the beamline optics. Here, the initial vertical collimation and focusing yields a high energy resolution (0.014%) with a vertical FWHM-divergence of 0.23 mrad. The expected flux at 15 keV is 4.6 x 10^{14} photons/sec/($d\lambda/\lambda=10^{-3}$) into a focus of 0.5 x 0.5 mm^2. A high precision 2-circle θ-2θ diffractometer will allow high resolution powder-diffraction measurements using capillary and flat-sample holders. Texture and strain measurements will be possible by further using an Eulerian cradle. In parallel to a moveable scintillation detector (with and without analyzer crystal option), we wish to include a position-sensitive Si-microstrip detector covering a 60° angular range with high resolution (0.01°). Such a detector is under evaluation, and preliminary tests on a prototype have been performed under real experimental conditions at the Swiss-Norwegian Beamline of the ESRF. Results are presented here.The main challenges for this type of detector are signal-to-noise ratio at low photon energy and the electronic read-out of up to 20000 strips on time scale of milliseconds. First operation of the SLS is forseen in the summer of 2001.

1. see `http//www1.psi.ch/www_sls_hn` for further details

P12.01.018 X-RAY INSTRUMENTATION FOR BEAMLINES AT KURCHATOV SR SOURCE IN MOSCOW. M.V.Kovalchuk, S.I.Zheludeva, Yu.N.Shilin, V.V.Lider, O.P.Aleshko- Ozhevsky, D.M.Kheiker, E.M.Pashaev. I.G.Arutunian. A.V.Shubnikov Institute of Crystallography RAS, Leninsky pr., 59, 117333 Moscow, Russia.

We present six X- ray experimental stations that will be installed by the Institute of Crystallography at Kurchatov SR source in Moscow.

Station *"Protein Crystallography*" is designed for studies of atomic structures of macromolecular single crystals, namely, proteins, etc.

Station X- ray *"Structure Analysis*" is intended for studies of atomic structures and electron density of single crystals of organic and inorganic compounds.

Station "*High- precision X- ray Optics*" is designed for implementing modern high- resolving X- ray diffraction methods of investigation of real crystals and crystalline objects: triple-crystal diffractometry, X- ray standing wave method with recording fluorescence and secondary photoelectrons, surface diffraction, multibeam diffractometry. The station can be used in studies of different practically important objects, including semiconductor single crystals and heterostructures, multilayer structures, Langmuir- Blodgette films.

Station *"X- ray Crystallography and Material Science*" is aimed on high- precision structural studies of crystalline matter by X- ray multi- crystal topography and diffractometry: determination of dislocation and microdefect concentration and arrangement, mosaic structure parameters, deformation fields; investigation of diffuse scattering; characterization of heterostructures, superlattices, multilayers.

Station *"X- ray topography*" is designed for *in situ* ivestigations of real crystal structures using TV- system or photographic plate. Construction of the station permits to use various attachments for subjecting sample to high (low) temperature treatments, magnetic and electric fields, mechanical stresses, etc.

Station *"Photoelectron X- ray Standing Wave*" is intended to study structural perfection of crystal surface- bound layers using XRSW method with the detection of photo- and Auger electrons.

P12.01.019 THE DIFFRACTION EXPERIMENT: FROM PICOSECOND EXPOSURE TIME TO PICO-SECOND TIME RESOLUTION. B.P.Tolochko, O.V.Evdokov [1], A.N.Aleshaev, M.V.Fedotov, V.A.Kiselev, G.N.Kulipanov, P.V.Logachev, N.A.Mezentcev, S.I.Mishnev, I.Y.Protopopov, M.A.Sheromov [2], [1] Institute of Solid State Chemistry and Mechanochemistry, Kuteteladze 18, Novosibirsk, 630128, Russia, [2] Budker Institute of Nuclear Physics, Novosibirsk, 630090, Russia

For implementation of experiments with a nanosecond time resolution we use fast displacement of a electron beam in the storage ring by electromagnetic field impact [1]. The fast change of orbit of electrons results in displacement of a beam of synchrotron radiation. The parallel displacement of synchrotron radiation beam happens with a speed near 200 km/sec. It allows to conduct scanning a synchrotron radiation beam on a sample (or an angle). By establishing after a sample a positional sensitive X-ray detectors we received diffraction patterns with a time resolution equal to time between electrons bunches (250 nsec on VEPP-3

and 5 nsec on VEPP-4 and exposition time 1 nsec and 100 psec respectively). The described scheme used for research with a nanosecond time resolution the behaviour a crystal structure under fast external influence. We made theoretical estimations which shown a practical capability, of the
scheme at VEPP-4, which will allow to realise a beam scanning of synchrotron radiation with speed near 10000 km/s that will allow to receive a 10 picosecond time resolution (period between frames) and the same exposure time.

1. S.G.Nikitenko, B.P.Tolochko, A.N.Aleshaev, G.N.Kulipanov, S.I.Mishnev. J. DE PHYSIQUE IV, (Supplement au Journal de PhysiqueIII, 4), (1997),Vol. 7, C2, 549-552.

P12.01.020 BEAMLINE 14: THE NEW MULTIPOLE WIGGLER BEAMLINE FOR PROTEIN CRYSTALLOGRAPHY ON THE SRS. E. Duke, M. Wardell, M. Bailey, S. Buffey, S. Kinder, A. Grant, M. MacDonald, C. Nave. CLRC Daresbury Laboratory, Warrington, Cheshire. WA4 4AD. U.K.

Beamline 14 is a new multipole wiggler beamline on the SRS at Daresbury Laboratory. The insertion device, a 2.0T multipole wiggler magnet will provide radiation for two stations dedicated to protein crystallography. A description of the station components will be given. Preliminary results from the beamline commissioning will be presented.

P12.01.021 SEARCHING FOR THE BEST PROTEIN CRYSTALS: SYNCHROTRON-BASED MEASUREMENTS OF CRYSTAL QUALITY. Gloria Borgstahl [1], Eddie Snell [2], Henry Bellamy [3], Walter Pangborn [4], Chris Nielson [5], Andy Arvai [5], Jeff Ohren, [1] Matt Pokross [1], [1] Department of Chemistry, University of Toledo, Toledo, OH 43606-3390, [2] Marshall Space Flight Center, Huntsville, AL 35812, [3] Stanford Synchrotron Radiation Laboratory, CA, [4] Hauptmann-Woodward Institute, Buffalo, NY, [5] ADSC, Poway CA

We are developing X-ray diffraction methods to quantitatively evaluate the quality of protein crystals. The ultimate use for these crystal quality assessments will be to optimize crystal growth and freezing conditions to obtain the best diffraction data. We have combined super-fine phi slicing with highly monochromatic, low divergence synchrotron radiation and the ADSC Quantum 4 CCD detector at the Stanford Synchrotron Radiation Laboratory beamline 1-5 to accurately measure crystal mosaicity. Comparisons of microgravity- versus earth-grown insulin crystals using these methods will be presented.

P12.01.022 THE STRUCTURAL BIOLOGY CENTER AT THE ADVANCED PHOTON SOURCE. Gerd Rosenbaum, Randy Alkire, Norma C. Duke, Stephan L. Ginell, Frank Rotella, Ruslan Sanishvili, Rong-guang Zhang, and Andrzej Joachimiak, Center for Mechanistic Biology and Biotechnology, Argonne National Laboratory, Argonne, IL 60439 USA.

The Structural Biology Center (SBC) is a Collaborative Access Team funded by the U.S. Department of Energy that operates a national user facility for macromolecular crystallographic research at the Advanced Photon Source at Argonne National Laboratory. The SBC operates an insertion-device beamline, 19ID, and a bending-magnet beamline, 19BM. Each beamline is equipped with a fully tunable monochromator, collimator slits, high-precision sample and detector positioning systems, and high-resolution x-ray optics designed to deliver a stable, intense, highly focused x-ray beam with low angular divergence onto crystal samples. The intensity of x-rays on the crystal is monitored with a beam-intensity monitor. The monochromator is designed to reach most absorption edge energies used in macromolecular crystallography. For MAD experiments the absorption spectra are monitored with a fluorescence detector. Crystals are mounted on a miniaturized Kappa goniostat, aligned using dual video cameras, and maintained at 100K with a liquid nitrogen cryosystem. Diffraction images are collected at high speed with a 3x3 mosaic (3072 x 3072 pixels) CCD area detector that has been optimized for short exposures. Data are collected and processed efficiently with either HKL2000 or d*TREK which take advantage of high-throughput computing environment. Highlights of recent data collection will be presented and the general user program will be introduced.

This work was supported by the U.S. Department of Energy, Office of Biological and Environmental Research, Under Contract W-313-109-ENG-38.

P12.01.023 THE BIO-CRYSTALLOGRAPHY BEAMLINE (BL41XU) AT SPRING-8 N. Kamiya [1], M. Kawamoto [2], Y. Kawano [1], and S. Park [1], [1] RIKEN Harima Institute, The Institute of Physical and Chemical Research (RIKEN), Mikazuki-cho, Mihara, Sayo, Hyogo 679-5143, Japan, [2] Japan Synchrotron Radiation Institute, Mikazuki-cho, Mihara, Sayo, Hyogo 679-5143, Japan.

The Bio-Crystallography beamline1) dedicated for macromolecular crystallography (BL41XU) was opened at SPring-8 on October in 1997 for public users from domestic and overseas countries. The X-ray source is an invacuum-type standard undulator at SPring-8, from which highly brilliant X-rays is available as the fundamental and third-harmonics emissions in a wide energy range of 7-38 keV. One of the most serious problems for beamline commissioning was high heat-load over 10 kW from the undulator, and the problem was overcome by using a standard monochromator system at SPring-8, a rotated-inclined double crystal monochromator (RIDCM) with a pin-post water cooling mechanism. The RIDCM works as the first cooling optics on which the high heat-load is deposited. The monochromatized beam from the RIDCM is focused by two X-ray mirrors independently in horizontal (H) and vertical (V) directions. The focal spot size was about 200 (H) x 300 (V) micrometer at a storage ring current of 70 mA. On this condition, the photon flux was measured to be 2 x 10^12 at an X-ray energy of 12.4 keV. The highly brilliant X-rays around 12.4 keV were very useful for accurate data collections from small crystals less than 100 micrometer with relatively large unit cells over 200 A. After the beamline commissioning for automatic change of X-ray energy, the multiple isomorphous replacement technique with optimized anomalous scattering (MIROAS) has just been available for new structure determinations, which is an objective for this beamline construction. Because some imperfection remains in the silicon crystal of RIDCM at fabrication of the pin-post structure, unfortunately, the energy resolution of BL41XU is at present about 5 x 10^-4 and not optimized yet. Another remarkable feature of BL41XU is an availability of high-energy X-rays up to 38 keV. As well known, barium is a main component of imaging plate (IP) phosphor. Data collections on barium K-edge, 37.6 keV, and those around Xenon K-edge, 34.6 keV, are tested using IP detectors.

P12.01.024 STRUCTURE REFINEMENT BASED ON INTENSITIES OF LAUE SPOTS OBTAINED BY POLYCHROMATIC SYNCHROTRON RAD. K.Ohsumi [1] T.Osaka [2] K.Hagiya and M.Ohmasa [3] [1] Inst. of Materials Structure Science, 1-1 Oho, Tsukuba, Ibaraki, Japan [2] Faculty of Science, Unv. Tokyo [3] Faculty of Science, Himeji Institute of Technology, Kamigoori, Akou, Hyougo, Japan

Intensities of Laue spot obtained by polychromatic synchrotron radiation(SR) are represented by the equation below. Those of each Bragg reflection are modified not only by Lp factor, absorption (A(l)) and extinction(E(l)) effects but also a spectrum of incident SR (Io(l)) and quantum efficiencies of a detector with respect to wavelengths (P(l)).

A product of the last two factors at the sample position could be expressed as an Gaussian function indicated below, which is confirmed by modifying the spectrum of SR of the radiation point at the bending magnet with absorption due to Be windows and vacuum path.

Io(l)a1(J(l)) =exp(-a (l-lm)2)(J(l))

In the process of a structure refinement, the IoP(l) is optimized simultaneously together with the structural parameters, that is the structural parameters are determined based on the IoP(l). But their parameters, as, al and lm, are optimized in different values for each refinement.

We have examined whether errors in measurement of diffracted intensities much affect the parameters of structure or those of IoP(l) using five Laue intensities, free from absorption effect, of molybdenum(Mo) sphere with a diameter of 8 mm. As the result, the errors change the parameters of IoP(l) but do not alter those of structure significantly, taking into account of their standard deviations.

K.Ohsumi, K.Hagiya and M.Ohmasa: J. Appl. Cryst.,(1991).24, 340-348.

P12.01.025 CRYSTALLOGRAPHY ON DIAMOND. A PROPOSED 3RD GENERATION SYNCHROTRON RADIATION SOURCE IN THE UK. C. Nave, S.L. Bennett, S.P. Collins, SRS Facility, CCLRC Daresbury Laboratory, Daresbury, Warrington WA4 4AD, UK

DIAMOND is a proposed new synchrotron radiation source to be built in the United Kingdom. The machine could be equipped with a variety of insertion devices including multipole wigglers, undulators and wavelength shifters. These will provide X-rays covering a wide energy range, suitable for crystallographic investigations in the field of biology, chemistry, physics, material science and surface science. A description of the machine will be given, together with examples showing the type of x-ray beamlines which could be constructed to cover crystallographic requirements in these areas of science.

P12.01.026 AUTOMATIC IP DATA COLLECTION SYSTEM FOR TIME-RESOLVED PROTEIN CRYSTALLOGRAPHY USING MONOCHROMATIC SR XRAYS. N.Sakabe[1,5,6], K.Sakabe[1,2,6], Y.Miyamoto[1,6], K.Sasaki[2,6], T.Higashi[3,6], J.Miyahara[4], N.Igarashi[5,6], M.Suzuki[5,6], N.Watanabe[5,6]. [1]FAIS,305-005,Japan, [2]Nagoya Univ.,464-8601,Japan, [3]Rigaku corp., 186-8603,Japan, [5]KEK,PF,305-0801,Japan, [6]Guest researchers of TARA Sakabe project in TARA, Tsukuba Univ.,305-8577,Japan.

We construct a new type of on-line data collection system for installation at BL6C at the PF. This system consists of a Weissenberg type camera with a rotation mechanism to change the recording frames of a cylindrical IP cassette having a radius of 400mm,an image reader equipped with five reading heads, an eraser, a cassette transportation mechanism, a control console, computers and a data server.In order to collect a full data set continuously, two IP cassettes are employed. While the images recorded on one cassette are being read, diffraction images are recorded on the other cassette automatically. A large IP is stuck onto the inside of the IP cassette. The cassette has 36 small rectangular holes at equal intervals along the circumference to allow the primary beam to pass(Sakabe et al. J. Synchrotron Rad.(1997)4,136-146).The exposure area (frame) on the IP can be selected by upper and lower adjustable screens. The frame exchange time is only 1sec and reading time is 8 min. Normal exposure time is 1 min using 1A X-ray at the PF. Thus, a full set of the data (18 frames)at 2.9A resolution can be recorded within 19 min. However the exposure time reduces 1 sec using very brilliant SR X-ray such as Spring8 BL41XU. Thus we will be able to record the full set of data within40sec.In this condition this system can be applied to time-resolved protein crystallography Some applications will be presented. This work was supported by JSPS-RFTF96R14501.

P12.01.027 DESIGN OF A HIGH-PRECISION, MONOCHROMATIC BEAM POSITION MONITOR FOR 5-25KEV SYNCHROTRON RADIATION. R.W.Alkire, Gerold Rosenbaum [1], G. Evans [2], [1] Center for Mechanistic Biology and Biotechnology, Argonne National Laboratory, Argonne, IL, 60439, USA, [2], MRC Laboratory of Molecular Biology, Hills Road, Cambridge, CB2 2QH, England.

To take full advantage of the highly intense undulator radiation and very low source emittance available at the Advanced Photon Source, a novel monochromatic beam position monitor with 1-2micron sensitivity has been developed. Design consists of four PIN diodes positioned upstream of a 0.5micron thick metal foil placed in the X-ray beam. X-rays absorbed by the metal foil generate fluorescence radiation, which is then detected by the diode array. Using conventional difference over the sum techniques for vertical and horizontal diode pairs, two-dimensional position information is obtained. The device is compact, inexpensive to construct, operates in vacuum and has a working range of 8mm x 10mm that can be expanded with design modifications. Although optimized for use in the 5-25keV energy range, the upper limit can be extended by changing metals and/or adjusting foil thickness. This device is currently in use at the Structural Biology Center, beamline 19ID, at the Advanced Photon Source.

P12.01.028 ON THE ADVANTAGES USING AN AREA DETECTOR FOR THE MEASUREMENT OF TRIPLET PHASES FROM PROTEIN CRYSTALS. R. Müller, E. Weckert, J. Zellner, Institut für Kristallographie, Universität Karlsruhe (TH), D-76128 Karlsruhe, Germany and M. Drakopoulos, ESRF, F-38043 Grenoble, France.

It has been shown [1] that in principle a protein structure of 15kDa can be solved by using measured triplet phases [2]. About 850 triplet phases were determined experimentally.

Because of radiation damage at maximum 150 triplet phases can be measured from one crystal. At the current state of experiment about 5 triplet phases per hour can be determined (synchrotron radiation). Therefore a sufficient number of low mosaicity crystals is needed.

A new method of measuring many triplet phases simultaneously using an area detector was suggested and, therefore, the rate of measured triplet phases was supposed to be increased drastically [3].

In this method the interference profiles of several primary reflections with one centered secondary reflection are collected simultaneously. Up to now only experiments in one GaAs crystal have been published. Our goal was to test the efficiency of this method on protein crystals.

The interference profiles might be affected by: (i) neighbouring three-beam cases, (ii) scaling problems, (iii) mosaicity.

The method has been simulated by using a scintillation detector. The lack of angular resolution of an area detector, which integrates the rocking curves of the primary reflections, would cause the even low mosaicity to influence the interference profiles seriously so that many profiles become uninterpretable.

P12.01.029 PROPOSED CRYSTALLOGRAPHIC BINARY FILE AND IMAGE-SUPPORTING CIF WITH API AND DICTIONARY. H. J. Bernstein [1], P. J. Ellis [2], A. P. Hammersley [3], A. J. Howard [4], J. W. Pflugrath [5], R. M. Sweet [6], J. D. Westbrook [7], [1] Bernstein + Sons, Bellport, NY, USA, [2] Stanford Synchrotron Radiation Laboratory, SLAC, Stanford, CA, USA, [3] European Synchrotron Radiation Facility, Grenoble, CEDEX, FR, [4] Center for Synchrotron Radiation Research and Instrumentation, IIT, Chicago, IL, USA, [5] Molecular Structure Corporation, The Woodlands, TX, USA, [6] Biology Dept., Brookhaven National Laboratory, Upton, NY, USA, [7] Dept. of Chemistry, Rutgers, The State University of New Jersey, Piscataway, NJ, USA

The Crystallographic Binary File (CBF) format is a complementary format to the Crystallographic Information File (CIF), supporting efficient storage of large quantities of experimental data in a self-describing binary format. The Image-supporting Crystallographic Information File (imgCIF) format is a proposed pure-ASCII extension to CIF to assist in ASCII debugging and archiving of CBF files. It also will allow for convenient and standardized inclusion of binary images such as maps, diagrams, and molecular drawings into publication CIFs. It is our expectation that, for large images, the raw binary CBF format will be used both within laboratories and for interchange among collaborating groups. For smaller chunks of binary data either format should be suitable, with the ASCII imgCIF format being more appropriate for interchange and archiving. The initial aim is to support efficient storage of raw experimental data from area-detectors (images) with no loss of information compared to existing formats. A DDL2-based dictionary of extensions to the mmCIF dictionary defining imgCIF/CBF has been developed. The dictionary includes tags to define the structure of arrays of image data and the relationship between the images and the parameters of a data collection. A software library to support imgCIF/CBF has been developed. CBFlib is a library of ANSI-C functions providing a simple mechanism for accessing Crystallographic Binary Files (CBF files) and Image-supporting CIF (imgCIF) files. The CBFlib API is loosely based on the CIFPARSE API for mmCIF files.

P12.01.030 USE OF A MICROSOURCE X-RAY TUBE AND GENERATOR WITH A FOUR-CIRCLE DIFFRACTOMETER. Paul Champkin and William Clegg, Chemistry Department, Bedson Building, University of Newcastle-Upon-Tyne, Newcastle-Upon-Tyne, NE1 7RU, U.K.

A four circle Stoe diffractometer is being fitted with a new type of X-ray generator and tube manufactured by the microsource division of Bede Scientific Instruments Ltd. This hardware will replace an existing generator and brings with it many new advantages.

The new compact, low power, high brightness X-ray generator and tube with focussing optics(1) uses X-ray radiation from a copper target with intensity comparable to that of a rotating anode source. With a power consumption of only tens of watts (compared to around 2-3kW for a normal generator) this generator uses a microfocus of the electron beam onto the target along with ellipsoidal mirrors for collection and concentration of the generated X-rays to bring about this outstanding efficiency.

Once in operation this setup will allow for the study of small, weakly diffracting samples that before may have called for synchrotron radiation. The customisation work involved in fitting the new equipment along with some preliminary results will be reported. The potential use of the new generator with other single crystal diffraction equipment will also be discussed.

P12.01.031 MACROMOLECULAR CRYSTALLOGRAPHY WITH A 7.5 T WIGGLER ON A 1 GEV SOURCE. T. Rabedeau[1], P. Kuhn[1], G.-A.Voss[2], E. Weihreter[3], & H. Winick[1] [1]SSRL Stanford, USA [2]DESY Hamburg, Germany, [3]BESSY Berlin, Germany

The majority of macromolecular crystallography (PX) experiments can be conducted effectively on low to medium energy storage rings equipped with high-field wigglers. For a typical protein crystal with 0.1-0.3mm transverse dimensions and 0.2° or greater mosaicity, the relevant measure of source performance is flux into the ~$(0.5\text{mm-mrad})^2$ sample acceptance phase space. Since this acceptance phase space is significantly larger than the ~0.05mm-mrad x 0.001mm-mrad source phase space of a typical undulator on a high energy, third generation storage ring, the sample does not require nor fully utilize the undulator brightness.

Consider a 13 pole, 7.5T wiggler on a 1GeV upgrade of BESSY-I (termed BESSY-Ia). Such a wiggler produces 1.1e13 photons/sec*0.1%bp in the sample acceptance phase space at 12keV for the ring parameters noted below. This compares reasonably to the performance of PX sources on many higher energy rings: 6.1e13 for the BW6 wiggler at HASYLAB, 7.1e12 for the BL9 wiggler at SSRL (1.7e14 with the SPEAR3 upgrade), and 5.4e12 for an NSLS bend magnet. The corresponding figure for an APS undulator A is 4.8e14.

This high useful flux from a low energy ring is achieved by using a super-conducting wiggler (Ec=5keV) on a high current ring designed to produce small beam dimensions at the source point. We have conducted a study of such a source, based on the BESSY-I 0.8 GeV storage ring. This ring will be closed at the end of 1999 due to BESSY-II being fully operational. We propose a modification of this ring to achieve the following parameters: 1.0 GeV, 0.7 A stored current, horizontal/vertical emittance 50/1.5 nm-radians, horizontal/vertical source dimensions and divergence's (1 sigma) at the wiggler location of 0.45/0.028 mm and 0.11/0.05 mrad. The lifetime is expected to be about 4 hr and can be extended by increasing the bunch length and/or the vertical beam size.

P12.01.032 THE SWISS LIGHT SOURCE PROTEIN CRYSTALLOGRAPHY BEAMLINE. C. Schulze-Briese, C. Broennimann, G. Heidenreich, H. Auderset, Q. Chen, G. Ingold, M. Janousch, M. Lange, C. Pradervand, M. Shi [1], U. Lienert, A.K. Freund [2], [1] Swiss Light Source at PSI, CH-5232 Villigen PSI, Switzerland, [2] European Synchrotron Radiation Facility, BP 220, F-38043 Grenoble Cedex, France

The SLS protein crystallography beamline is designed for the measurement of X-ray diffraction data from biological crystals with large unit cell dimensions as well as protein micro-crystals. It is fully MAD compatible and will be well suited for atomic resolution protein crystallography. Design and test of the main components - in-vacuum minigap undulator, decoupled, dynamically focussing optics and large area, fast read-out pixel detector - will be described in detail. SLS will be the first synchrotron which makes explicit use of the high harmonics from in-vacuum minigap undulators. The proposed undulator realisation and expected performance will be reported. The contradicting requirements of micro-focussing and high beam parallelism are overcome by the use of two dedicated diffractometers at 8:1 and 2.5:1 demagnification position. The flexibility of the optics allows the beam to be focussed at these

positions or to focus on the detector. The prototype components yielded a focal spot size of 15 µm x 25 µm and dynamical focussing was demonstrated. The energy range of 5 to 17.5 keV covers all relevant K- and LIII-absorption edges and the energy resolution or 0.02% compatible with the requirements of the MAD technique. The dedicated pixel detector is based on a silicon pixel sensor connected to an Application Specific Integrated Circuits (ASIC) read-out chip is under development in collaboration with the PSI High Energy Physics Group. It will combine fast frame rates and high dynamic range (*15 bit counter) on a large area. The analog and digital part of the pixel architecture as well as the bump-bonding were successfully tested. First photons on sample are expected in the fall of 2001.

P12.01.033 CHARACTERIZATION OF A LOW POWER X-RAY SOURCE FOR USE IN CRYSTALLOGRAPHIC DATA COLLECTION. Lance Weise [1], John Wall [2], Neil Loxley [2], Mark Taylor [2], Craig Smith [1], [1] Center for Macromolecular Crystallography, University of Alabama at Birmingham, Birmingham, Alabama, 35294-0005 USA, [2] Bede Scientific Ltd., Bowburn South Industrial Estate, Bowburn, Durham, DH6 5AD, United Kingdom

A microfocus X-ray source based on the work of Uli Arndt et al, and developed by Bede Scientific Ltd. was characterized in terms of intensity, divergence, spectral purity, and beam profile. The Bede Microsource was run at 25 to 30 Watts of power and utilized the unique Reflex ellipsoidal shaped mirror optic. A comparison was made to conventional rotating anode systems using a standard graphite monochromater, double focusing mirror systems, and a multilayer focusing system. X-ray diffraction data were collected from a number of protein crystals using a Bruker CCD area detector. The data were processed and reduced with the program SAINT. The results indicate the X-ray system and CCD detector combination gives results comparable to that which can be collected using conventional laboratory X-ray sources running at 4-5 kilowatts of power.

P12.01.035 BIOLOGICAL CRYSTALLOGRAPHY AT THE ADVANCED LIGHT SOURCE Gerry McDermott[1], Carl Cork[1], Li-Wei Hung[1], Keith Henderson[1], Natasha Khlebtsova[1], Trey Simmons[1], Howard Padmore [2], and Thomas Earnest [1], [1] Macromolecular Crystallography Facility at the Advanced Light Source, Physical Biosciences Division, Lawrence Berkeley National Laboratory, Berkeley, CA 94720, [2] Advanced Light Source Division, Lawrence Berkeley National Laboratory, Berkeley, CA 94720

The Macromolecular Crystallography Facility at the Advanced Light Source has been operational as a national user facility for biological crystallography since November, 1997, when the initial beamline was commissioned. This beamline was optimized as a high-throughput beamline for multiwavelength anomalous diffraction experiments. The MAD experiments benefit greatly from the low emittance and positional stability of the ALS which promote high energy resolution and lack of energy drift even between storage ring refills. To date over 200 users from more than 50 research groups have used this beamline. Two monochromatic beamlines are under construction, one of which will be built as a high-throughput, robotics-based beamline for Novartis Institute for Functional Genomics [Stevens, Schultz, Santarsiero]. Furthermore three more MAD beamlines are under development based on superconducting bending magnets as sources. We are also collaborating with LBNL and UCSD scientists and engineers to develop a massively-parallel pixel-array detector with high dynamic range and photon-counting capabilities. A scientific program concentrating on the structural biophysics of signal transduction and large biomolecular complexes takes full advantage of this technology and gives further scientific motivation to the development of instrumentation.

The Macromolecular Crystallography Facility at the Advanced Light Source is principally funded by the Office of Biological and Environmental Research of the Department of Energy with other funding from Amgen, Roche Biosciences, University of California at Berkeley, Lawrence Livermore National Laboratory, and the Genetics Institute.

P13.01.001 BACKGROUND REDUCTION BY A VACUUMCHAMBER FOR AREA DETECTORS. H.-G. Krane[1], A. Kirfel[1] and W. H. Morgenroth[2]; [1]Mineral.-Petrol. Institut, Universität Bonn, [2]Mineral.-Petrogr. Institut, Universität Hamburg, Germany.

Area detectors combined with intense X-ray sources suffer from a relatively high background due to their large aperture. Close to the primary beam, this background is further enhanced by air scattering. In order to avoid this unwanted effect, the sample can be mounted and investigated in a vacuumchamber [1]. An improved version was constructed and built for the HUBER 512 Eulerian cradle at HASYLAB beamline D3. The X-ray beam (≤ 1mm in diameter) enters the chamber through a collimator tube sealed into it. The scattering produced by the 75 µm Kapton foil entrance window is shielded by a 2 mm pinhole ending about 13 mm in front of the sample. The diffracted radiation leaves the chamber through a secondary 75 µm Kapton foil detector window of effectively 75 mm diameter. The beamstop catches the beam inside the chamber. For high temperature applications, the chamber can be equipped with a removable graphite furnace up to 1300 K at the sample position. A special vacuum seal provides free sample rotation about the Φ-axis. For $\omega = 2\Theta = 0^{\circ}$, also the χ-circle can be freely rotated. With the shortest sample-detector distance of 50 mm, it is possible to record reflections with scattering angles up to $2\Theta = 30^{\circ}$. Using $\lambda = 0.40$ Å, a (usually sufficient) data resolution of 0.65 $Å^{-1}$ can be achieved. Even for samples of low symmetry (e.g. monoclinic), all independent reflections can be recorded with one revolution of Φ at $\chi = 0^{\circ}$.The vacuumchamber was tested using a SMART-CCD-detector. The background is generally reduced and air scattering in the vicinity of the primary beam disappears after evacuation. The equipment is useful for the investigation of weak scattering phenomena such as diffuse scattering, superlattice reflections and structure determination of small samples, both at room and elevated temperatures.

[1] R. B. Neder et.al.: Z. Kristallogr. **211** (1996), 591.

P13.01.002 RAPID X-RAY DIFFRACTION MEASUREMENT AND STRUCTURE ANALYSIS USING MICRO STRIP GAS CHAMBER. H. Uekusa, Y. Ohashi, A. Ochi, T. Tanimori, Faculty of Science, Tokyo Institute of Technology, Tokyo 152, JAPAN.

Rapid X-ray diffraction measurement is an essential technique to realize the time-resolved observation of crystalline-state reactions. By using an accumulating type two-dimensional detector (IP or CCD), total measurement time can be cut down to a few hours or less in the laboratory system. However, to achieve a shorter time resolution of seconds or sub seconds, the use of a photon counting type two-dimensional detector is required.

Recently, MSGC (Micro Strip Gas Chamber) was developed for the rapid X-ray data collection. MSGC is a gaseous detector like MWPC, so it has both photon counting and two-dimensional imaging properties. The features of the detector are a large detective area of 10 x 10cm, a fine positional resolution of 100 micrometer and an excellent capability for high counting rate up to 10^7 cps by utilizing the fast data acquisition system. Thus

both positional and timing information can be stored for later image reconstruction and analysis.

X-ray diffraction measurement system consists of a MSGC detector, one axis goniometer and a laboratory X-ray generator was constructed in order to examine the ability of MSGC in X-ray crystallography. As the preliminary experiments showed the satisfactory accuracy and fast data acquisition speed, the diffraction data of the organic crystal were collected rotating the crystal continuously. The reciprocal space was constructed from the stored positional and counting data, and recognized reciprocal lattice points were easily indexed and integrated. The structure analysis using this intensity data gave the satisfactory results.

P13.01.003 AUTOMATED IMAGING PLATE DATA ACQUISITION FOR SMALL MOLECULAR CRYSTALLOGRAPHY. Tsuneyuki Higashi, Katsunari Sasaki, X-ray Research Laboratory, Rigaku Corporation, 3-9-12, Matsubara-cho, Akishima-shi, Tokyo 196-8666, Japan

Data collection on a four-circle diffractometer is highly automated. Together with the development of an easy-to-use structure analysis package, the technique of x-ray crystal structure analysis has been widely spread over many non-crystallographers but are interested in structures of small molecule compounds. However, imaging plate diffractometers are far from the automation.Even in the well-used data prcocessing package, users have to select functions in pull-down menus.We have developed an automated data-acquisition system for a Rigaku-Rapid Imaging Plate diffractometer. In the system, machine manupulation software and data processing software are combined. A series of functions are successively carried out; standard flows are indexing of intial images, refinement of the setting matrix, spot size estimation, integration, merging of individual intensity files, scaling, Laue symmetry determination, post refinement, and output of reflection data. The Weissenberg method in data collection and symmetry-related absorption corrections are options. Under the Weissenberg mode, suited crystallographic axes are selected and a sample crystal will be automatically aligned. The system works without any problem if crystal quality is good. A current goal of the automation is to have similar functionalities with a four-circle diffractometer.

P13.01.004 ONE AND TWO-COORDINATE DETECTORS FOR SSRC. V.M.Aulchenko, S.E.Baru, L.I.Shekhtman, V.M.Titov [1], B.P.Tolochko [2], [1] Budker Institute of Nuclear Physics, Lavrentev st. 11, Novosibirsk, 630090, Russia, [2] Institute of Solid State Chemistry, Novosibirsk, 630128, Russia

For last five years work has been in progress in BINP on the construction of one- and two-coordinate X-ray detectors: OD-3.1, OD-3.2, DED-5 and MSIC-detector for Siberian Synchrotron Radiation Centre [1].OD-3.1, (OD-3.2) - position sensitive parallax-free detectors, based on Multi Wire Proportional Chamber with focal distance 35 cm (150 cm) was developed for powder diffraction and SAXS experiments. DED-5 - area detector is intended for Laue diffraction, SAXS, protein crystallography (DED-5-P - parallax-free modification). MSIC - position sensitive parallax-free detector based on Micro-Strip Ionisation Chamber is under construction at this moment and test of the prototype.D-160 - position sensitive parallax-free detector, based on Multi Wire Proportional Chamber with focal distance 135 cm are developing for powder diffraction experiment. At this moment we finished the test of the prototype. The detectors are working with time resolution 1 microsecond in frame-by-frame mode. Detectors parameters (*-in scanning mode)

Detector	Aperture (mm)	FWHM (mm)	Number of channels	Count rate (MHz)
OD-3.1	200x10	0.18	3328	10
OD-3.2	200x25	0.15	3328	10
DED-5	384x384	1.5 x 1.5	65536	5
MSIC	100x10	0.1	1024	no limits
D-160	2760x5	1.2 (* 0.12)	6600	3300

1. V.M.Aulchenko et al, J. Synchrotron Rad. (1998).5, 263-267.

P13.01.005 MORE THAN ONE STRUCTURE FROM A SINGLE DATA COLLECTION? Christer Svensson, Inorganic Chemistry 2, Lund University, PO Box 124, S-221 00 Lund, Sweden.

In studies of small-molecule single crystals with area detector X-ray diffractometers, the detector is normally used very inefficiently in terms of the number of reflections sampled per frame and unit area. The largest part of each frame is an exposure of background only!

To increase the information density of an experiment with the present design of area detectors, data could be collected for several crystals simultaneously. A multi crystal method could be useful for example to increase the accuracy in comparative studies, where several samples are taken through the same cycles of temperature and/or pressure variations. It is probably also the cheapest solution towards a higher throughput for service crystallography facilities.

The Lund single-crystal diffractometer control program has been extended to handle frames from the Bruker SMART CCD-type detector: the location of spots, their indexing and integration, including the handling of twinned and modulated samples.

To investigate the feasibility of multi crystal experiments, and to test some of the functionality of the program, an aggregate crystal was prepared and mounted on a glass fibre by glueing three different single crystals together in arbitrary orientations. A hemisphere data set was collected using the SMART program and the narrow-frame method with "standard" settings of data collection parameters. Our local program was then used for evaluation of the frame data. In this first test of the method, the three crystals were rather large, with displacements of the order of 0.1 to 0.2 mm of their centres of gravity from the instrument centre. These displacements, which were refined by the program, identified which crystal gave rise to which diffraction pattern. After integration of the complete data set, which is in progress, output data files can be written which include either intensities from only non overlapped spots of one crystal (for structure solution) or a combination of non overlapped and overlapped spots from different crystals (for structure refinements).

For the multi crystal method to be successful, some further modifications are required in eg. absorption correction and structure refinement programs.

Progress on the data reduction and structure solution/refinement using the above and forthcoming multi crystal experiments will be reported.

P13.01.006 LATEST CRYSTALLOGRAPHIC RESULTS ON BIOLOGICAL SAMPLES WITH LARGE SINGLE CCD DETECTORS. E.R. Hovestreydt, Bruker-axs GmbH, Karlsruhe, Germany, M.R. Pressprich, S.I. Foundling and R.D. Durst, Bruker-axs Inc, Madison, Wisconsin.

After a very successful start of CCD technology in the Chemical (typically called small-molecule) Crystallography market, chip technology has advanced such that for some time CCD detectors have become available with very interesting specifications for Biological (formerly called protein) Crystallography.

Contrary to common belief, modern CCD detectors with their high resolution and ever larger size come very close to the orders of diffraction obtained with common imaging plate systems. Readout times that are almost an order of magnitude shorter will enable most efficient use of precious synchrotron or rotating anode measuring time.

The SMART 6000 CCD combines a large format 4K CCD chip with a 1.5:1 fiberoptic taper, optimised specifically for high sensitivity.

This new detector has a 135 mm diameter fiberoptics taper bonded to the largest available scientific grade 4K CCD (6.1 cm x 6.1 cm).

Combined with its large imaging area, the system will be of superior advantage in the collection of X-ray data using a copper target from micro crystals of biological macromolecules or organic compounds, and using a molybdenum target for charge density analysis or general chemical, mineral and materials structures.

Results of measurements done with this novel detector will be presented.

P13.01.007 DATA COLLECTION WITH A DELTA-CIRCLE- IMAGEPLATE DIFFRACTOMETER. Thomas Huber and Hans Burzlaff, Lehrstuhl für Kristallographie und Strukturphysik, Universität Erlangen-Nürnberg, Bissmarckstr. 10, 91054 Erlangen, Germany

The description of the instrument was already presented on the Seattle Congress 1996. The construction of the instrument allows data collection at high angle regions up to 2-theta = 110 degrees since the imageplate detector is moved by the 2-theta axis. In the meantime several sets of data for crystal structures of different complexity have been collected. They are compared with four-circle diffractometer data conventionally measured. Special investigations refer to the accuracy of the imageplate data and its suitability for electron density determination. The properties of the data and the instrument will be discussed. As a practical example for electron density investigations a small molecule structure will be presented.

Following the present experiences with the system it is very probable that the instrument can also be used for data collection of big molecule structures like proteins.

P13.01.008 CCD DETECTOR SYSTEMS FOR SINGLE-CRYSTAL STUDIES: BENEFITS OF SCANNING FOUR AXES CONCURRENTLY. Leo H. Straver, Anita Coetzee, Rob W. W. Hooft, Frank van Meurs, Nonius B.V., Application Laboratory, PO Box 811, 2600 AV Delft, The Netherlands

The integration of 4-circle goniometer and a CCD detector offers unique features that optimise and extend the experiments possible on such a system; more efficient data collections using preferred crystal orientations. At a smaller crystal-to-detector distance, this strategy will avoid overlaps, thus enhancing the data collection efficiency. Aligned exposures around any vector. A preview of the lattice allows observation of lattice effects before starting data collection. In addition, it is an ideal tool to study time and temperature dependent crystal lattice changes. Visualisation of rocking curves and indexing using virtual axes scans (Phi-Chi Scans). Determination of profile centres and shapes from pairs of virtual axes scans. Powder emulation exposures. A super fast spinning combination of three concurrently scanning axes. Allows for quick confirmation of sample identity. All experiments were done on a KappaCCD system.

P13.01.009 MEASURING WITH Cu-RADIATION ON A SMALL CCD SYSTEM; FICTION OR PRACTICE? Frank van Meurs, Anita Coetzee, Rob W.W. Hooft, Leo H. Straver, Bram J. Schierbeek, Nonius BV, Application Laboratory, PO Box 811, 2600 AV Delft, The Netherlands.

Single-crystal diffraction systems equipped with small CCD detectors are generally considered being ideal for employing Mo-radiation. It should be noted however that, when equipped with the proper “phosphor” and a four-circle goniometer, these systems are equally good with Cu-radiation. Some implications of the choice of the radiation on the efficiency of data collection, completeness of the data set and quality of the data obtained shall be discussed. A comparison with serial diffractometer data shall be given.

P13.01.010 DEVELOPMENT OF ARRAYED CCD X-RAY DETECTORS WITH A 100% DUTY-CYCLE RATE FOR AUTOMATED PROTEIN CRYSTALLOGRAPHY. K. Ito and N. Sakabe, Institute of Applied Biochemistry, University of Tsukuba, Tsukuba, 305-8572 Japan, Y. Amemiya, Department of Applied Physics, School of Engineering, The University of Tokyo, 7-3-1 Hongo, Bunkyo, Tokyo, 113-8656 Japan

A 2 x 2 module (153.5 x 76.8 mm^2 active area size) arrayed CCD X-ray detector has been developed for automated protein crystallography with use of the synchrotron radiation at Photon Factory, Japan. One module of the arrayed CCD X-ray detector consists of a phosphor (Gd_2O_2S:Tb, 15 mg/cm^2) which is deposited on an aluminized sheet, fiber optic-taper (FOT) and a CCD as an image sensor. This FOT has a demagnification ratio of 3.2:1 and high X-ray resistant. The CCD has an imaging area of 25 mm x 25 mm with 1024 x 1024 pixels of 24 μm x 24 μm. Only the upper half area (1024 x 512 pixel) of each CCD is used as an active image area, whereas the bottom half is used as a data storage area. Image data recorded in the active area are transferred to the data storage area with a time of 1.6 ms. The next image data are recorded in the image area while the previous image data are transferred to a frame grabber in a computer with a time of 2 s. This scheme enables us to detect successive X-ray diffraction patterns with a 100% duty-cycle rate; Neither the interruption of the rotation of the sample crystal nor the X-ray shutter for intermitted exposures are required during the data acquisition. The CCD are cooled to -30 degree with Peltier devices.

Results of the evaluation of the performance characteristics of the detector will be shown as well as experimental results with actual protein crystal.

A 3 x 6 modules (230.4 x 230.4 mm^2 active area size) arrayed CCD X-ray detector is under construction based on the technique accumulated with the 2 x 2 module CCD X-ray detector.

P13.01.011 KM4RED – THE DATA REDUCTION PROGRAM OF THE KM4CCD SYSTEM. M. Meyer[*†], W. A. Paciorek[*§], G. Chapuis[*] and D. Kucharczyk[‡] *Institute of Crystallography, University of Lausanne, BSP-Dorigny, CH-1015 Lausanne; [†]Kuma Diffraction Instruments GmbH, PSE-Ecole Polytechnique Federal Lausanne, CH-1015 Lausanne; [‡]Kuma Diffraction Ltd., Al. Akacjowa 15b PL-53 122 Wroclaw; [§]Global Phasing Ltd., Sheraton House, Castle Park, Cambridge CB3 0AX, England

The KM4CCD system, a Kappa 4-circle goniometer with CCD area detector, originated in a collaboration project between the University of Lausanne and Kuma Diffraction Ltd. The

Institute of Crystallography is responsible for the software development of this instrument. With the KM4CCD system we follow an open software strategy, contrasting to most commercial systems. Interested users receive source codes and may extend the system capabilities for special applications (incommensurate crystals, quasi-crystals, high-pressure attachments and alike). These extensions may then be shared among the user community.

The framework of the development project we investigated in several works the instrument calibration of modern imaging diffractometers, especially the instrument description[1)] and distortion correction of tapered CCD detectors[2)].

The program KM4RED implements these achievements. The poster presents the program features. Besides the KM4CCD format the program also supports the MAR research image formats (image plate and CCD) and thus may be an interesting alternative for Denzo and XDS for the field of "problematic samples".

P13.01.012 AREA DETECTORS ON BEAMLINES – ABSTRACT INCORPORATING LARGE AREA DETECTORS INTO SYNCHROTRON BEAMLINES: THE CHESS EXPERIENCE. D. Szebenyi, M. Cook, A. Deacon, S. Ealick, C. Heaton, I. Kriksunov, J. LaIuppa, W. Miller, and D. Thiel; MacCHESS, Cornell University, Ithaca, NY 14853, USA

CHESS, the Cornell High Energy Synchrotron Source, has been, and continues to be, a leader in the use of innovative x-ray area detectors at its beamlines. We describe here the process of meshing a new detector with other beamline components to create a reliable and efficient system for collecting high-quality diffraction data. Important items include:

Customization of detector hardware and software - mounting detector on beamline, porting control software to local computer, establishing communication between detector control software and beamline hardware, special requirements for data collection at this particular beamline.

Safety - e.g. protection of detector from direct x-ray beam.

Data handling considerations - sufficient storage space, backup devices, and network bandwidth for raw data produced by the detector.

Data reduction software - available at the beamline for initial indexing and strategy calculations, and subsequent complete processing, and also available to users' home labs for later processing.

Training - thorough grounding of beamline staff in capabilities and operation of system, provision of manuals and other instruction for users.

Testing of entire system - collection and processing of multiple data sets by both expert and novice users, and resulting improvements in system's reliability, accuracy, and ease of use.

Continuing evaluation and improvement - modifications based on user comments, other hardware and software upgrades as they become available.

Having gone through all of the above, the three macromolecular beamlines at CHESS are now equipped with well-tested 2x2 mosaic CCD detectors from Area Detector Systems, and are producing excellent, biologically important, data. Future plans include continued incorporation of new detectors, as they become available.

P13.01.013 THE OPTIMAL GAIN AND DYNAMIC RANGE OF CCD DETECTORS FOR X-RAY DIFFRACTION. R. D. Durst*, P. Mueller†, C. Campana*, S. Foundling*, Z. Jin*, J. Phillips*, M. Pressprich*, *Bruker AXS, Inc, 6300 Enterprise Ln., Madison, WI 53719 USA †Universitaet Goettingen, Institut fuer Anorganische Chemie, Tammannstr. 4, D-37073 Goettingen, Germany.

Conventional CCD-based detectors for x-ray diffraction require large fiber-optic demagnification ratios in order to achieve useful active areas. Thus, these detectors exhibit modest single-photon signal-to-noise ratios (of order 1) which limits their ability to accurately characterize weak reflections. The application of large format CCDs has allowed newer generations of detectors to achieve higher sensitivity with a commensurate improvement in low-level data quality. Recently, by combining a wafer-scale CCD with an advanced x-ray phosphor true single-photon sensitivity has been achieved (that is, a signal-to-noise ratio sufficiently high so as to unambiguously distinguish a single x-ray photon from the detector noise background).

However, for an integrating detector such as a CCD the total charge storage per exposure is fixed and finite and thus an increase in gain implies a decrease in the dynamic range. This tradeoff between dynamic range and sensitivity is studied both theoretically and experimentally. The impact of the system gain, detector noise, scattered x-ray background, spatial resolution, binning ratio and rocking curve on sensitivity and dynamic range is derived.

The design of a prototype CCD detector with single photon detectivity is described and its experimental sensitivity and dynamic range are compared to these theoretical models.

P13.01.014 *AUTOMAR*: DATA REDUCTION SOFTWARE FOR MAR DETECTORS. Klaus S. Bartels and Claudio Klein, x-ray research GmbH, Segeberger Chaussee 34, D-22850 Norderstedt, Germany

In the last couple of years, considerable progress has been made to automate data reduction of area detector data. Traditionally, the most severe obstacle for getting the data processed has been the indexing step. Available programs differ mostly in the likelihood of obtaining the relevant crystal parameters required for integration. We concentrated our efforts mainly on this task and developed an entirely new data processing package called *autoMAR*. The program suite includes: Spot finding and autoindexing: Based on refinement of zone-axes the autoindexing features new algorithms for fully automatic determination of cell parameters and lattice types as well as crystal orientation and mosaicity. The method is extremely reliable and has very high success rates for indexing anything from ruby (5 Ang. cell axes) to virus patterns. Spot prediction and integration with various degrees of sophistication including site-dependent experimental and Bayesian profile fitting Summation of partials, post-refinement and scaling of intensities Calculation of data collection strategies for optimizing data collection time and/or completeness. Graphical user interface based on X-Windows/Motif with intuitive look & feel. Visual feedback from all stages of data processing and graphical output of results. The processing results of a number of data sets from both Image Plate and CCD-detectors will be presented.

P13.01.016 THE MULTIPLE-DETECTOR SYSTEM FOR THE POWDER DIFFRACTOMETER AT BEAMLINE B2 (HASYLAB). W.-H.Kaps, J.Ihringer, W.Prandl, M.Schilling, Institut für Kristallographie der Universität Tübingen, Charlottenstr.33, 72070 Tübingen, Germany

We have designed and manufactured a multiple-detector system with four flat Si (111) crystal analysers and four scintillation counters. Using the small divergence of the incident

beam the Bragg reflection angles (2theta) are measured with highest angular resolution and independent of the sample position.

A single stepping motor simultaneously adjusts all crystal analysers. In addition the relative positions of the angles are set by individual drives. Due to the identical design and the simultaneous control of the four analyser diffractometers data corrections are not needed. Simultaneous profile refinement of the four data sets is done by program SIMREF [1] which has been particularly designed for powder data from different sources.

The multiple-detector system is intended for a wavelength range of $0.4<\lambda<1.7$Å. Cross talk between the entrance and the exit of the analysers at short wavelengths is eliminated by adjustable lead shields. Special analyser shielding houses adapted to the beam path enhance the typical peak / background ratio to 300 to 1.

An important application are experiments with different wavelengths to use the anomalous scattering of X-rays for phase determination and to differentiate different groups of atoms.

We acknowledge financial support by the BMBF (05SM8VTA3).

02. METHODS FOR STRUCTURE DETERMINATION

P05.02.001 A NOVEL RIETVELD REFINEMENT CODE FOR MOLECULAR MATERIALS. M.J. Jones and R.B. Hammond, Centre for Molecular and Interface Engineering, Department of Mechanical and Chemical Engineering, Heriot-Watt University, Edinburgh EH14 4AS.

Rietveld refinement[1] is an established method in powder diffraction. Presently several computer programs[2] for full profile refinement of powder diffraction data exist, none of which are designed specifically for organic, molecular crystalline materials. The main drawback of these existing programs is their lack of ability to define and maintain the *molecular* geometry in the course of structure refinement. Commonly, rigid body, and/or bond length (and thus, indirectly, bond angle) constraints are applied to molecules or molecular fragments. In many cases, however, these methods are not suitable, or indeed insufficient, for constraining the refinable atomic parameters to sensible or known molecular geometries.

We present here a new program for Rietveld refinement of powder diffraction data. The most important innovation of this program is the incorporation of molecular mechanics techniques to compute the total (lattice and molecular) energy for each refinement cycle. The calculated energy is used in a penalty function, thus avoiding unrealistic molecular geometries. The relative merits of employing systematic restraints based upon molecular mechanics 'observations' compared with formal constraints operating on atomic positions is under examination. In addition, the use of internal coordinates to define both atomic parameters and bond length and angle constraints is investigated.

The design and philosophy of the program are discussed.

P05.02.002 RIETVELD ANALYSIS ON THE HIGH RESOLUTION FOURIER DIFFRACTOMETER. V.B. Zlokazov, A.M.Balagurov, FLNP JINR, 141980 Dubna, Moscow region, Russia.

MRIA - a program for a full profile analysis of multiphase powder neutron diffraction was originally designed as the only peak shape independent and fast fit routine which made it indispensible for treating the time-of-flight RTOF (reversed time-of-flight) spectra on the Dubna High Resolution Fourier Diffractometer [1]. However, the area of applications of RTOF methods being growing gradually new features were added to MRIA which widely extended the class of problems being solved by this program. 1. The mode for the analysis of neutron diffraction spectra obtained from the conventional neutron diffractometers (λ = *const*) was implemented. 2. Techniques for taking into account the texture effects in the Rietveld analysis were added. 3. The treatment of magnetic diffraction for collinear structures was included. 4. The automatic three-dimensional peak search in Fourier synthesis has been developed [2]. The report goes over these new features in more detail.

P05.02.003 RIETVELD REFINEMENT OF INTER-MEDIATE PHASES IN THE Mo-Re SYSTEM OF ALLOYS. J.L. Garin and R.L. Mannheim, Department of Metallurgical Engineering, Universidad de Santiago de Chile, Casilla 10233, Santiago, Chile.

The existence of σ and χ phases in binary molybdenum-rhenium alloys has received much attention because of the important effects that the formation of these phases has on the properties of the industrial alloys [1].

In order to update earlier crystallographic data [2] and at the same time investigate the evolution of the σ/χ ratio upon non-equilibrium cooling of the alloy, a Rietveld analysis of X-ray powder patterns was conducted on the material.

The samples were synthesised by sintering mixtures of Mo and Re powders in the composition range of 80 - 87% Re, at elevated temperatures under controlled Ar-H_2 atmosphere.

The room temperature X-ray analysis was carried out over the range of 10 - 105° (2θ), with 4750 step intensities, assuming Pseudo-Voigt profiles for all reflections. A total of 16 groups of atomic co-ordinates and isotropic thermal parameters were refined, together with other operational parameters such as scale factors, preferred orientation coefficients, surface roughness, background polynomial coefficients and so on. There are five kinds of crystallographically equivalent positions for the 30 available atoms in the unit cell of σ and four positions for the 58 atoms in the cell of χ. Consequently both σ phase ($MoRe_2$, $D8_5$) and χ phase ($Mo_{13}Re_{45}$, A12) are structurally characterised by a disordered arrangement of Mo and Re atoms in space groups P42/mnm and I-43m respectively; owing to these facts the occupation factors were also varied to determine the right stoichiometry of each phase.

The study finally revealed that the σ/χ ratio for a given composition of the alloy increased with cooling rate during the sintering process.

P05.02.004 X-RAY DIFFRACTION STUDY OF THE QUATENARY INTERMETALLIC COMPOUND $YAl_8(Co,Cr)_{3.6}$. R.G.Zakharov, S.A.Petrova, V.L.Zyazev, and N.A.Vatolin, Institute of Metallurgy, Urals' Division, Russian Academy of Science, Ekatherinburg, 620 016, Russia.

X-ray structural investigation of the $YAl_8(Co,Cr)_{3.6}$ alloy was carried out with the use of an automated diffractometer DRON-UM1 ($Cu_{K\alpha}$-radiation, pyrographite monochromator on the diffracted beam). A crystal system determined by the TREOR autodetecting program [1] occurs to be a tetragonal one with lattice parameters a = 8.909(1)E, c = 5.097(1)E (F30=80 (.010, 39)). The intermetallic compound is isostructural to the RT_4Al_8 and RT_6Al_6 compounds (R – rare-earth metal, T – 3d-metal) with $ThMn_{12}$ structural type, I4/mmm space group (PSC: tI26) [2].

For the whole-profile-pattern crystal structure refinement with the Rietveld method DBWS-9411 program version [3] was used. The starting values for atomic occupation and position type were estimated with a 'heavy atom' method. From the calculations (R_{wp}=13.1%, R_p=10.8%, R_b=8.7%) it was established that atoms of yttrium are arranged the 2(a) sites, the 8(i) and 8(j) positions are occupied by atoms of aluminium, and 3d-metal atoms are situated at the 8(f) sites.

P05.02.005 NEUTRON POWDER DIFFRACTION STUDY OF NdOF BETWEEN 1.5 AND 300 K. M. Lastusaari and J. Hölsä, Department of Chemistry, University of Turku, FIN-20014 Turku, FINLAND, and J. Rodriguez-Carvajal, Laboratoire Leon Brillouin, (CEA-CNRS), Centre d'Etudes de Saclay, F-91191 Gif sur Yvette Cedex, FRANCE and L. Beaury and J. Derouet, Laboratoire de Chimie Appliquée de l'Etat Solide, UMR 7574 CNRS, ENSCP, F-75231 Paris Cedex 05, FRANCE.

A preliminary X-ray powder diffraction study carried out to explain the anomalous behaviour of the paramagnetic susceptibility of polycrystalline hexagonal neodymium oxyfluoride, NdOF, as a function of temperature revealed anomalous behaviour of the lattice parameters as well [1]. Since no structural details were obtained from the X-ray powder diffraction study a neutron powder diffraction investigation was found necessary.

The structure of NdOF was consequently studied at 1.5, 25, 55, 100, 200 and 300 K by neutron powder diffraction, Rietveld analyses and bond valence calculations. The Rietveld refinements yielded a good fit to the hexagonal space group R3m (No. 166). The unit cell volume and parameters *a* and *c* decrease with decreasing temperature, but the *a* parameter value reaches its minimum at 55 K, and thereafter starts to increase. The *c* parameter value decreases smoothly to 25 K but then drops sharply to 1.5 K to compensate for the change in the *a* value. The unit cell volume remains practically constant below 55 K. It is possible that the behaviour of the unit cell parameters is due to a small distortion from the centrosymmetric structure, but the possible distortions are too small to be observed from the powder diffraction data.

The bond valence calculations indicated that the maximum stability of the hexagonal structure is achieved at 1.5 K. The bond valence calculations give no explanation for the anomalous evolution of the cell parameters, however.

P05.02.006 POWDER DIFFRACTION EXPERIMENTS IN CAPILLARY GEOMETRY USING MULTIPLE-DETECTORS AT PHOTON FACTORY. S. Yamazaki and H. Toraya, Ceramic Research Laboratory, Nagoya Institute of Technology, Tajimi 507-0071, Japan

A synchrotron radiation powder diffractometer with a multiple-detector-system at the Photon Factory was originally designed for the use in a flat specimen reflection geometry (FSRG) using an asymmetic 2θ-scan mode at a fixed incident angle. In last year, an equipment became available for recording intensities from a capillary specimen in transmission geometry (CSTG). Profile intensities were measured using monochromatized beam with the wave length of 0.7Å and Ge(111) crystal analyzers. Angular resolution, preferred orientation, particle statistics and the accuracy of refined structural parameters were examined in a comparison with the data obtained in FSRG. Samples used for testing were coarse grained α-SiO_2, $CaCO_3$ and Mg_2SiO_4. FWHM's obtained in CSTG [$CaCO_3$, an inner diameter of capillary (ϕ) = 0.5 mm, 2θ = 10 ~ 70°] were generally smaller by 20 ~ 30% than those in FSRG. The minimum FWHM's were 0.009 and 0.016° for 112 reflections from the α-SiO_2 powders in capillaries with ϕ = 0.1 and 1.0 mm, respectively. In CSTG, the number of reflections, of which intensities were shifted by more than 5% by preferred orientation, was only 10% in a total of 181 reflections from $CaCO_3$, whereas they were 67% in FSRG. In re-packing tests using the coarse grained α-SiO_2, intensity variations of individual reflections, which would arise from particle statistics, were much smaller in CSTG (ϕ = 0.5 mm) than those in FSRG. The accuracy of structural parameters obtained in the Rietveld refinements of $CaCO_3$ and Mg_2SiO_4 using FSRG was, however, than in CSTG, and it will be ascribed to a better counting statistics in FSRG.

P05.02.007 OVERCOME THE LIMITATION OF RIETVELD METHOD USING ELECTRON DENSITY PLOT. A. A. Ramadan, S. Selman, A. T. Matter and S. T. Nasser, Physics department, Helwan University, Helwan, Cairo, Egypt.

The great limitation of Rietveld method is faced up due to the correlation between some crystallographic parameters such as displacement (temperature) factor and site occupancy. This may lead to a false minimum with reasonable reliability factors and final acceptable Rietveld plot. In order to avoid such limitation, means of single crystal structure determination, such as the Fourier electron density map, can be applied as a complementary approach. Therefore, instead of one step in the usual Rietveld method, three steps are required:

i) Full-pattern fitting by Rietveld method, and estimating of the values of F_{clc} and α_{clc} from the refined model,

ii) Estimation of the values of ?F_{obs} from profile matching method of LeBail which is not biased by the model, and

iii) Construct electron density plots (ρ_{obs}, ρ_{clc} and $\Delta\rho = \rho_{obs} - \rho_{clc}$) in one dimension. From these plots one can judge whether the obtained minimum is true or false. Any discrepancy in the refined values of displacement factor, or fractional coordinates or site occupancy can be identified.

Simulated diffraction patterns of spinel structures, with small and large differences in the atomic number of the constituent elements using Fe- and Mo-Kα radiation, were considered as the observed data. GSAS software and FullProf program were used. The sharpening or broadening of the peak in the Fourier plots and their shift as well as the positive and negative values in Δρ are the good indicators. Therefore, this proposed three-step procedure could be considered as a λ.

P05.02.008 TAKE CARE OF FOURIER-FILTERING TECHNIQUE FOR BACKGROUND REFINEMENT IN RIETVELD METHOD. M. El-Shabiny and I. S. Ahmed, Physics Dept., NRC, Cairo, and A. A. Ramadan, Physics Dept., Helwan University, Helwan, Cairo, Egypt.

In powder diffraction patterns fitting by Rietveld method, the total observed scattering is reliably modeled by convoluting calculated Bragg intensities with a instrumental resolution function and adding a background contribution. Poor estimates of the background lead to badly wrong and physically unreasonable values of thermal parameters and site occupancies. Background refinement is commonly accomplished through the use of empirical phenomenological functions such as polynomials. In case of non-monotonically varying background shown as broad oscillations, a particular interesting approach that is the Fourier-filtering technique is implemented recently in Rietveld programs such as FullProf program. What are the consequences to the Rietveld refinement?; a question given and answered by Richardson [1]. Another answer is discussed in this work. A simulated diffraction pattern of provoskite structure was considered as the observed data and FullProf program is used. A wrong model was then considered for the calculated diffraction patterns with crystallographic parameters far from the true values. It is known that the refinement of the step in the turn-on sequence of the refined parameters. Refinement of the background was accomplished by three-order polynomial while the other (wrong) parameters were kept fixed as the starting step in the refinement. Very clear difference in the Rietveld plot was observed with high value of R_{wp}. When the Fourier-filtering technique was used with FWINDOW parameter of 5 to 20 and also the other parameters were kept fixed, a perfect fitting in the Rietveld plot was observed with very law value of R_{wp}; which is, of course, a false minimum. Now, leaving the fixed parameters free, no change towards the

correct values was achieved and values of R_{wp} still law. Therefore, if this technique has to be applied, it should be used with very great care; it may give a good but misleading shape of Rietveld plot and law reliability factor but false minimum with completely wrong crystallographic parameters.

J. W. Richardson, Jr.(1993)."The Rietveld Method", Edt. R. A. Young, IUCr, Oxford Univ. Press, p. 102.

P05.02.009 SIMULATION OF X-RAY DIFFRACTION PATTERN OF $CuIn_xGa_{1-x}Se_2$ THIN FILMS BY RIETVELD METHOD. H. Pal, M. De and A. K. Pal, Department of Materials Science, Indian Association for the Cultivation of science, Jadavpur, Calcutta- 700 032, India

$CuIn_x Ga_{1-x}Se_2$ solar cell thin films have been prepared by vacuum evaporation technique. The main diffraction peaks observed correspond to the (112), (220) and (312) which confirm the tetragonal chalcopyrite structure of our films. There is a preferential orientation in the direction of the (112). We have simulated X-ray diffraction pattern of the films considering scattering factors of ionized atoms (Cu^{+1}, In^{+3}, Ga^{+3} and Se^{-2}). The intensity of the X-ray profile is corrected due to preferred orientation, crystallite sizes and microstrains. The simulated pattern contains extra lines compared to the experimental pattern. Secondly, we have simulated the pattern considering scattering factors of neutral atoms (Cu, In, Ga and Se) and on correcting the intensity due to the preferred orientation, crystallite sizes and microstrains, the pattern is found to fit well with the experimental pattern. It is expected that the experimental X-ray pattern should fit well with the first simulated pattern. But our observation is different. Attempts are being made to explain such anomalous observation.

P05.02.010 APPLICATION OF RIETVELD METHOD FOR STUDYING THE STRUCTURAL CHARACTERISTICS OF SUBSTITUTED COPPER FERRITE COMPOUND. S.M. Hammad*, I.S. Ahmed Farag*, M.A. Ahmed**, A.M. Moustafa*, * Physics Department National Research Centre, Dokky, Cairo, Egypt, ** Physics Department, Faculty of Science, Cairo University.

A series of ferrite samples of the chemical composition $Cu_{0.7}$ $(Zn_{0.3-x}Mg_x)Al_{0.3}Fe_{1.7}O4$ [x=0.05, 0.1, 0.15 and 0.2], prepared by ceramic technique at 1000°C, are found to have cubic spinel structure. On the basis of the Rietveld analysis and applying the full pattern fitting of Rietveld method using FullProf program, the exact coordinates of atoms, the unit cell dimensions, the oxygen parameter, the atom occupation factors, isotropic temperature factors, the profile shape parameters as well as the interatomic distances have been determined.

It was found that the lattice parameter decreases with increasing the Mg content this may be attributed to the influence of the difference between the ionic radius of Mg and Zn cations. Also the variations of the cation distribution has been discussed on the basis of site preferrence, size and valence of the substituting cations.

The residual isotropic microstrain in the samples may be attributed to the inversion behavior and the relative values of cation ionic radius in the tetrahedral and octahedral sites.

P05.02.011 BAYESIAN FOURIER MAPS FROM POWDER DIFFRACTION DATA. W.I.F. David and D S Sivia, ISIS Facility, Rutherford Appleton Laboratory, Chilton, Didcot, Oxon. OX11 0QX, UK.

Fourier maps from powder diffraction data are usually constructed using traditional Fourier transform techniques where the observed structure factors are obtained by the method originally proposed by Rietveld (1969). In this method, the observed structure factor magnitudes at a particular point in the diffraction pattern are apportioned according to the associated calculated structure factor magnitudes. This is an elegant approximation to the correct values but clearly biased towards the calculated structural model. Additionally no account is taken of observed structure factor uncertainties including the correlation between overlapping reflections. In this poster, a Bayesian method is proposed that uses an entropic prior with calculated structure factors from a Rietveld refinement and a likelihood constructed from the observed Bragg peak intensities and their correlation obtained from a simultaneous Pawley profile refinement. Examples from inorganic and molecular crystal structures will be shown.

Rietveld, H.M. (1969) *J. Appl. Cryst*. **2** 65-71.

P05.02.012 MAXIMUM ENTROPY IN LAUE. Yong Xie, Quan Hao Department of Chemistry, De Montfort University, Leicester LE1 9BH

1. In a Laue diffraction pattern, 10-20% of the spots result from the exact superposition of two or more reflections that are 'harmonics'; a high proportion of these are low-resolution reflections. For the solution of large or difficult structural problems, the intensities of the remaining 80-90% of the reflections may not be sufficient, thus the evaluation of the intensities of the components of the multiple spots is important.We developed a new method based on maximizing the entropy of the Patterson function subject to the constraint imposed by the observed intensities of overlapping reflection. This method does not need data redundancy and therefore is of particular interest for time-resolved studies on a short time scale. A new computer program (ME) was developed and tested with Laue diffraction data. It showed this new method gives good results.

2. In protein crystallography, low-resolution reflections are especially important in defining the molecular mask and polypeptide backbone. However, in Laue data collection, the loss of low-resolution reflection data can be as high as 40-50%. For evaluation the unobserved reflections, a new method is presented based on maximizing the entropy of the Patterson function subject to the constraint imposed by the observed and deconvoluted intensities. A new computer program (MES) was developed and tested with Laue diffraction data. It showed inclusion of unobserved reflections in low resolution significantly improved the connectivity of electron density map.

P05.02.013 MAXIMUM ENTROPY METHOD IN PROBLEMS OF X–RAY DIFFRACTION ANALYSIS. B. Z. Belashev, Institute of Geology, Karelian Research Centre RAS, Petrozavodsk, 185610, Russia, A. N.Yakovlev, Petrozavodsk State University, Petrozavodsk, 185640, Russia.

Burg's maximum entropy method (MEM) is commonly used along with Frieden's version of MEM designed to solve Rayleigh's inverse problem: reduction of observation data to a perfect instrument by eliminating the known apparatus function. The signal sought for is estimated by solving a variation problem, maximizing signal estimation entropy, the linear relation of the signal sought for being retained along with the blur and noise function. The working capacity of this version of MEM was demonstrated by recognizing singlets, doublets, and complex multiplets from blurred bands, using various blur functions and various Poisson and additive white noise levels.

Our modification of Frieden's MEM, which is connected with selection of approximated data blur functions, can be used to increase resolution and to determine the most probable structure of the blurred bands of spectra. The algorithm was used for short-

range identification of amorphous materials and liquids from available X-ray diffraction data. Ordered ice-like-structured clusters were found to exist in liquid water. Short-range identification of amorphous materials is possible, using an X–ray diffraction pattern and its autocorrelation function.

The use of MEM in the problem of determining the parameters of an elementary cell in the crystalline lattice of materials lowers noise level, allows to find out whether the peak of the X–ray pattern studied is structurally simple or complex, and to more precisely determine the position of peak constituents. In this case, the error in the parameters of an elementary cell in the crystalline lattice of materials proves to be much smaller than the one in the conventional method. MEM was used to determine the parameters of an elementary cell in a standard quartz sample.

P06.02.001 PROTONS IN PROTEINS: NEW HORIZONS IN NEUTRON CRYSTALLOGRAPHY. D.A.A. Myles and F.Dauvergne, EMBL-Oustation, Av. des Martyrs, F38042 Grenoble, France. and C. Wilkinson and P. Timmins, ILL, Av. des Martyrs, F38042 Grenoble, France.

A new protein crystallography instrument (LADI), dedicated to cold neutron Laue diffraction, is able to reveal key details of the hydrogen structure in large biological macromolecules, even at medium resolutions (>1.5Å) [1]. This is an important advantage since hydrogen atoms, which account for 50% of the atoms in a biological structure and mediate much of biological activity, cannot be seen at all at the medium resolution limits (>1.5Å) typical of most X-ray protein structure determinations. Moreover, as the scattered neutrons from hydrogen and deuterium have different phase, neutrons are uniquely able to distinguish between hydrogen (negative density) and deuterium (positive density) exchanged positions in the crystal. Analysis of the pattern and extent of H/D exchange can therefore provide a direct and elegant probe of group accessibility, mobility and of exchange dynamics

The great advantage and potential of the new LADI instrument is the speed with which data may be collected. The combination of a broad bandpass quasi-Laue geometry and a novel 2π, neutron sensitive image plate detector [2], provides order of magnitude gains in efficiency compared with conventional diffractometers. This makes feasible studies of larger biological complexes and/or smaller crystals than have previously been possible. The instrument is optimized for data collection to >1.5Å resolution from medium size proteins (~30kDa), sufficient to locate individual hydrogen atoms of special interest, water structures or other small molecules that can be marked with deuterium to be particularly visible. Current studies aim to answer specific questions concerning enzymatic mechanism, solvent effects, structure dynamics and their implications. Instrument performance and application will be illustrated by some recent results.

P06.02.002 STRUCTURE OF CONCANAVALIN A EXHAUSTIVELY EXCHANGED IN D_2O BY NEUTRON LAUE DIFFRACTION AT 2.4A RESOLUTION. Jarjis Habash, James Raftery, Rachel Nuttall, Helen J Price, John R Helliwell [1], Clive Wilkinson [2], Mogens S. Lehmann [3], A. Joseph Kalb (Gilboa) [4], [1] Deparment of Chemistry, University of Manchester, Manchester M13 9PL,UK, [2] EMBL, F38042, Grenoble Cedex, France, [3] ILL, F38042, Grenoble Cedex, France, [4] The Weizmann Institute of Science, Rehovot, Israel

Structural studies by neutron diffraction permit quantitative evaluation of H/D exchange and direct observation of hydrogen (deuterium), which can yield vital information on biochemical processes at the most intimate atomic level. Such an approach exploits the difference in neutron scattering lengths between hydrogen and deuterium, which is not feasible via X-ray diffraction. Hydrogen atoms can be found from protein crystallography via ultra-high resolution data collection involving synchrotron radiation, cryoprotection of the sample and fast CCD-based electronic detectors. Recently we have shown that both neutron and ultra-high resolution structural studies of the 25kDa protein concanavalin A are feasible. The neutron data collection involved Laue geometry, which harnesses a broader band of neutron wavelengths than a monochromatic neutron beam, and a very large IP detector thus allowing data collection in a reasonable period. In the most recent experiment we have studied a more fully H2O/D2O exchanged concanavalin A crystal, soaked in D2O over a period of 2 months, rather than vapour exchange over a period of 21 days used earlier. A deuterated concanavalin A crystal (space group I222, unit cell parameters a=88.7, b=86.5 & c=62.5A) was used to collect neutron Laue data at the Institut Laue Langevin in Grenoble with a neutron wavelength range of 2.49-3.5A. Also an X-ray based refinement to 1.8A of a deuterated crystal, prepared under the identical conditions to the one used in the neutron experiment, was used as the starting model for the neutron refinement to 2.4A resolution. The neutron refined model fits the neutron density maps well, as seen previously. All peptide NH's were investigated via a number of models for exchange. The best refinement residuals were for partial H/D exchange, which for such extensive beta sheet is not unexpected. The carboxyl proton on Asp 28 referred to previously appears now however to have exchanged for deuterium indicating that the method of deuterium exchange has indeed been effective in that respect. Most noticeably there is now much more positive density visible in the bound solvent region as expected for complete D2O solvent exchange as opposed to H2O cancellation effects, at these resolutions, for the solvent in the partially exchanged crystal of our previous study. The current experiment afforded the chance then to study the bound water deuterium atoms. Using the 148 water oxygen positions from the 1.8A X-ray model, deuterium atoms were afixed to them automatically by XPLOR. The positions of these deuteriums were then refined against the neutron data and they generally moved into density from positions initially often pointing out of neutron density. In particular the bound waters at the Mn site were investigated further whereby they were omitted from the model, model refinement continued and which then showed up clearly in the omit maps. These were not seen in the previous study. This is then an example of contrast variation and firmly shows the identity of these ligands as waters as well as orienting their deuterium atoms. This study is part of a programme of work involving the detailed elucidation of protein saccharide interactions at the molecular level.

Funding from The Wellcome Trust, BBSRC and EPSRC to JRH is gratefully acknowledged. The LADI diffractometer is at the Institut Laue Langevin in Grenoble, France.

P06.02.003 SUPERSTRUCTURES OF $M_2P_2O_7$ (TI, ZR) FROM COMBINED X-RAY AND NEUTRON POWDER DIFFRACTION DATA. Miguel A. G. Aranda, Sebastián Bruque and Enrique R. Losilla, Departamento de Química Inorgánica, Universidad de Málaga, 29071 Málaga, Spain, and Jesús Sanz, ICMM, CSIC, Cantoblanco, 28049 Madrid, Spain

MP_2O_7 (M=Si, Ge, Sn, Ti, Zr, Hf, …) compounds crystallize in a cubic substructure (s.g. P a $\bar{3}$, a ~ 8 Å) but they display a complex (3×3×3) superstructure. The interest of these materials is due to the low thermal expansion coefficients they present, that in some cases are negatives as for ZrV_2O_7. The cubic (3×3×3) structure is very complex with 50 atoms in the asymmetric part of the unit cell. To get precise and accurate structural parameters we have carried out joint Rietveld refinements of neutron and laboratory X-ray diffraction data at several temperatures. Although, the crystal structure of Ti^{4+} and Zr^{4+} compounds are usually quite similar, we will show that these superstructures are not very similar and that their thermal evolutions are quite different. This structural study will be related to the ^{31}P MAS NMR data of these samples. The superstructure is developed to relax many linear P-O-P groups (in the substructure) which yields 6 independent pyro groups due to 11 crystallographically different phosphorus atoms. Thermal expansion data and the relation between crystal structures and ^{31}P NMR spectra will be discussed.

P08.02.002 DISORDER IN CRYSTALLOGRAPHY. Alok Kumar Mukherjee, Department of Physics, Jadavpur University, Calcutta 700 032, India.

Disorder is usually an unmitigated nuisance in X-ray structural crystallography and often associated with poor quality of diffraction data leading to apparently high final R factor. But certain types of disorder are both esthetically appealing and potentially informative about the bonding and chemistry of the compounds in which they occur. The following examples taken from our recent crystallographic investigations of metaloorganic compounds reveal different types of structural disorder and possible strategies to tackle them.

(1) Solvent Disorder: In the Oxo-Peroxo molybdenum (VI) compound $[MoO(O_2)\ (QO_2\ )\ ]\ 0.5\ CH_2CL_2$ (QOH = quinoline-8-ol), space group P $\bar{1}$, Z=2, the dichloromethane (CH_2CL_2) solvent molecules are disordered statistically within interstitial holes between the ordered $[MoO(O_2)\ (QO_2)]$ molecules.

(2) Orientational disorder: In the dinuclear tungsten-sulfur complex, $[(W_2S_{12})\ (C_8H_{20}\ N)_2\ ]$, space group I $\bar{4}$ c 2, Z=8, the $(W_2S_{12})^{2-}$ anions are located at crystallographic two-fold sites. The terminal bidentate S_4 - ligands of the anion are disordered over two orientations with occupancy factors 0.61(1) and 0.39(1), respectively.

(3) Symmetry imposed disorder: The heterobinuclear sulfido complex, $[PPh_4\ ]_2\ [\ S_2WS_2Hg(C \equiv CH)_2\ ]$, crystallizes in space group P $\bar{1}$ with Z=1 . Since the anion, $[S_2WS_2Hg\ (C \equiv CH)_2]^{2-}$ containing dissimilar metals (Hg,W) and different terminal ligands (S,CCH) has no center of symmetry, the centrosymmetric space group P $\bar{1}$ has been accommodated by introducing a two fold disorder. The structure has been solved and refined using Hg/W and S/C atoms disordered over the same positions and having identical thermal parameters.

P08.02.003 CONSTRAINED REFINEMENT OF COMMENSURATELY MODULATED DIMETHYLTIN DICHLORIDE DIBENZYL SULFOXIDE, A.D. Rae, Research School of Chemistry, Australian National University, Canberra, ACT 0200, Australia, Seik Weng Ng, Institute of Postgraduate Studies and Research, University of Malaysia, 50603 Kuala Lumpur, Malaysia, M.W. Gluth, LG International Gmbh, 60528 Frankfurt, Germany.

The $P2_12_12_1$ average structure of Dimethyltin dichloride dibenzyl sulfoxide has been reported (S.W. Ng & A.L. Rheingold, *J. Organomet. Chem*., **378**, (1989), 339-345). We now report the superstructure, also in space group $P2_12_12_1$ but with the *a* axis increased 7 fold. This is a commensurate case of the 3+1 dimensional superspace group, $P2_12_12_1(\alpha 00)$, with α = 8/7 and a coherent overlap of satellite reflections with structure factors $F(\mathbf{g} + m\mathbf{q})$ and $F(\mathbf{g}' - (7-m)\mathbf{q})$. The asymmetric unit contains 7 pseudo translationally related molecules and the structural parameters of an asymmetric unit are given by

$$\Delta p_j(\mathbf{1},\mathbf{t}_m) = a_{j0} + \Sigma_{n=1,3}\,[a_{jn}\cos(n\omega(\mathbf{t}_m)) + b_{jn}\sin(n\omega(\mathbf{t}_m))],$$

where $\omega(\mathbf{t}_m) = 2\pi\,\mathbf{q}.\mathbf{t}_m$, $\mathbf{q}$ = 8/7 $\mathbf{a}_o^*$ and $\mathbf{t}_m = m\mathbf{a}_o$, m = 0 to 6. $\Delta p_j(\mathbf{1},\mathbf{t}_m)$ is the change from the parent structure value of the jth molecule based parameter describing the molecule defined by the parent structure translation operation $(\mathbf{1},\mathbf{t}_m)$ acting on the reference molecule. Sets of 7 modulation wave parameters, a_{jn} and b_{jn}, offer an alternative description to sets of 7 parameters $\Delta p_j(\mathbf{1},\mathbf{t}_m)$ and permit a hierarchical approach to structure determination and refinement. The program *RAELS96* was used for the refinement. Standard parameters, including those defining local axes used to define refinable local co-ordinates, are defineable in terms of extra parameters, in this case the modulation wave parameters. For an incommensurately modulated structure, parameters $a_{jn}+ib_{jn}$ can be changed by a global phase Φ to $\exp(in\Phi)\ (a_{jn}+ib_{jn}) = (a'_{jn}+ib'_{jn})$ changing structure factors $F(\mathbf{g} + m\mathbf{q})$ to $\exp(im\Phi)\ F(\mathbf{g} + m\mathbf{q})$. For our commensurate structure, this allowed comparative refinement to demonstrate the correctness of our model for $F(\mathbf{g} + m\mathbf{q}) + F(\mathbf{g}' - (7-m)\mathbf{q})$. The modulation appears to involve transverse waves allowing a more dense packing of molecules by shortening the *a* axis repeat and allowing the phenyl rings to have better contact.

P08.02.004 THE R2-CRITERION AS A FIGURE OF MERIT IN PATTERSON APPLICATIONS. Paul T. Beurskens, Gezina Beurskens, Randy Israel and René de Gelder, University of Nijmegen, 6525 ED Nijmegen, The Netherlands.

After 65 years of Patterson methods, Patterson applications play a major role in most crystal-structure investigations of small- or macromolecular, periodic or aperiodic, single- or polycrystalline materials.

In the DIRDIF-program system for the crystal structure analysis of inorganic, and small and medium-sized (metallo-)organic molecules two distinctly different types of Patterson methods are used.

I.For heavy-atom structures (ranging from an organic molecule with one sulphur atom to a coordination complex with 13 gold atoms) the heavy atom position(s) is (are) extracted from the Patterson synthesis. In those cases where more than one set of atomic positions are found to be compatible with the Patterson, the R_2 criterion can be used to select the most probable set.

II.For molecular structures where the approximate geometry of part of the molecule is known (or a limited number of configurations can be predicted) the vector-search strategy is used to find the orientation of the input molecular model, and its position relative to the symmetry elements. In many cases more than one possible solution is found, and the most probable solution (atomic coordinates of the model in the unit cell) can be selected using the R_2 criterion.

The conventional, unweighted R_2 value is

$$R_2 = \Sigma\,(F_o^2 - F_p^2)^2 / \Sigma\,F_o^4$$

where Σ is the sum over all reflections and F_p is the structure amplitude calculated for the trial partial structure (heavy atoms or molecular fragment). For the use of R_2 as a reliable criterion [1], F in this definition is substituted by F/g where g is the normalizing factor for F_o ($E_o = F_o/g$).

The use of R_2 as a figure of merit greatly enhances the applicability of Patterson methods in automated structure-solution procedures.

P08.02.005 PSEUDOSYMMETRY AND STRUCTURES WITH MORE THAN ONE MOLECULE IN THE ASYMMETRIC UNIT. Rita G. Hazell, Department of Chemistry, Aarhus University, DK 8000, Århus C, Denmark

Lately we have come across several structures with more than one molecule in the asymmetric unit, and with pseudosymmetry, and as it was pointed out by Carolyn Pratt Brock [1], this means that refinement is only stable if constraints are applied; in some cases some or all the restrictions can be lifted in the final stages, though. The programs we use for this are based on the principles outlined by G.S. Pawley [2] and will be described, and the use illustrated by examples.

The structures investigated fall into different categories, and we look for possible reasons for the behavior: in one type of optically active compound it seems to be the rule, that they crystallize in a non-centro- symmetric space group but in a nearly centrosymmetric arrangement, except that the chiral part destroys this symmetry. Another crystal grew from a racemic mixture under partial resolution, again in a pseudo-symmetric arrangement; in this case the hydrogen bond scheme favoured the non-centrosymmetric arrangement, but the packing was loose enough for mistakes to occur, so a disordered structure resulted, causing even more trouble for the refinement.

P08.02.007 REFINEMENT OF TWO TWINNED SINGLE CRYSTALS. Jürgen Kopf, Ulrich Behrens, Institut für Anorganische und Angewandte Chemie der Universität Hamburg, Martin-Luther-King-Platz 6, D-20146 Hamburg, Deutschland und Otto Jarchow, Mineralogisch-Petrographisches Institut der Universität Hamburg, Grindelallee 48, D-20146 Hamburg, Deutschland.

The existence of twinning has often prevented investigators from successfully measuring, phasing and completing the refinement of such structures, even though the X-ray intensity data were of very high quality. Two twinned structures, one example from organic the other from organometallic chemistry, with Z' = 3 were refined with SHELXL97 [1] and will be presented. The two solved structures belong to twin class IV [2]. In this class some reflections completely overlap and some behave as single crystal data. The common orthorhombic super-lattice of the twin individuals can be constructed from the monoclinic sub-lattice of the overlapped reflections. In our cases the single individuals belong to space group $P2_1/a$ and form a three-fold primitive (0,0,0; 1/3,0,1/3; 2/3,0,2/3) unit cell. We will describe how the twinning was recognized, measured and solved and how the twin matrix was derived. Different refinement strategies with the SHELXL97 program will be discussed.

P08.02.008 ABSORPTION CORRECTION OF CCD-DATA FROM WB (LIN.ABS.COEFF.=1370 cm^{-1}). M. Ruf, L. Häming, E. Hovestreydt Application Laboratory, Bruker-Analytical X-Ray Systems, Karlsruhe, Germany

A successful crystal structure determination depends upon the accurate analysis of the X-ray diffraction pattern of the single-crystal specimen. The measured intensities may often be affected by other factors, such as absorption of X-rays by the crystal being analyzed.

Appropriate corrections must be applied to the experimental data to account for such effects if accurate, publication-quality results are to be obtained.

The SMART 1000 CCD System has been used to carry out a structure determination of WB with a linear absorption coefficient of 1370 cm^{-1}.

For a specimen with well defined faces the SMART crystal face indexing routine has bee used, which allows the faces of the specimen to be indexed and measured through the standard video microscope. These crystal face indices have been used to apply a numerical Gaussian absorption correction.

The high redundancy of the data and calculated direction cosines for every reflection together with the Laue class were used to apply an empirical absorption correction using SADABS. The program performs absorption correction for incident and diffracted beam.

Both methods provide easy to use tools for appropriate absorption correction. The data from both, numerical and empirical, absorption corrections yield publication quality results whereas it is not possible to refine the structure against uncorrected data.

P08.02.009 DISORDER AND TWINNING OF THE REACTION PRODUCTS OF MELAMINE AND PCL_5. F. Belaj, Institute of Inorganic Chemistry, Karl-Franzens-University of Graz, A-8010 Graz, Austria.

By reaction of melamine with PCl_5 in $C_2H_4Cl_2$ a triclinic (**T1**) and a monoclinic (**M**) modification of 2,4,6-tris(trichlorophosphazeno)-1,3,5-triazine containing solvent molecules and PCl_6^- anions (and Cl^- anions in **M**) were obtained. Due to disorder of the solvent molecules the R-indices R1 were larger than 0.1 and the position of the positive charge could not be localized [1] although the single crystal data were collected at 95K. Recrystallization from $C_2H_2Cl_4$ resulted in another triclinic phase (**T2**) but did not solve the problem. Only when the disorder of the solvent molecules (and partly of $NPCl_3$ groups directed to solvent molecules) was resolved, the hydrogen atoms attached to a nitrogen atom of the triazine ring could be localized and the three compounds unambiguously identified as $H[C_3N_3(NPCl)_3]_2^+ PCl_6^- \cdot C_2H_4Cl_2$ (**T1**), $[HC_3N_3(NPCl_3)_3]_2^+ Cl^- PCl_6^- \cdot 3C_2H_4Cl_2$ (**M**), and $[HC_3N_3(NPCl_3)_3]^+ Cl^- \cdot C_2H_2Cl_4$ (**T2**).

From these ionic compounds the solvent-free molecular compound $C_3N_3(NPCl_3)_3$ could be synthesized by sublimation. The intensity-weighted reciprocal lattice shows 6/m symmetry but refinements in several hexagonal and trigonal space-groups resulted in R-indices R1 not smaller than 0.22. Finally the structure could be solved and a twinned model be refined to R1 = 0.0492 (7938 significant unique reflections, 381 parameters) without any constraints (except fixing the origin) in the space group P 3_1. The examination of the arrangement of the molecules in the unit-cell shows that there are good reasons for twinning of this compound. Whereas both molecules of the asymmetric unit of this trigonal compound show the most symmetric conformation, all the five independent cations determined in the three asymmetric units of **T1**, **M**, and **T2** show almost planar but asymmetric conformations with the H atoms always bonded to those N atoms of the triazine rings from which two $NPCl_3$ groups are turned away.

[1] F. Belaj, Phosphorus, Sulfur, and Silicon, **109-110**, 71-74 (1996).

P08.02.010 STRUCTURAL CHARACTERIZATION OF THE FAULTED PHI-TYPE ZEOLITE LZ-276. Richard M. Kirchner [1] and Robert W. Broach [2], [1] Manhattan College, Chemistry Department, Bronx, NY 10471, USA, [2] UOP Research & Development, 50 E. Algonquin Road, Des Plaines, IL 60017 USA

Structural characerization of the faulted phi-type zeolite LZ-276 was successfully accomplished using diffraction pattern simulations and statistical analyses. Powder x-ray diffraction patterns (PXRD) for LZ-276 display both sharp and broad peaks suggesting disorder. TEM selected area diffraction patterns show twin spots and considerable streaking parallel to {00l} indicating faulting along c. Attempts to model the disorder using Rietveld techniques were unsatisfactory. However, the PXRD pattern of LZ-276 was successfully simulated using the DIFFaX technique [1]. An all-silica model was presumed using idealized atom positions and cell coordinates taken from the structure of chabazite. Cell parameter a was determined from indexing the sharp peaks in the PXRD pattern, while c is an average value for similar chabazite-type (CHA) structures. Idealized atomic coordinates from a distance least-squares (DLS) refinement were used in the DIFFaX program to simulate the powder pattern. The simulated pattern agrees well with the experimental pattern and indicates a faulting probability of 0.10 (10% random faulting). The generation and distribution of new and different sized cages formed by faulting, and how these may affect physical properties such as sorption, will be described.

P09.02.002 LOW RESOLUTION PHASING OF SUPER OXIDE DISMUTASE (SOD) USING THE PROGRAM FSEARCH. D. Ockwell, M Hough and Q. Hao, De Montfort University, Leicester, LE1 9BH, UK, and S.S. Hasnain, CLRC Daresbury Laboratory, Warrington, WA4 4AD, U.K.

Solution of the phase problem is of primary importance in crystallographic structure determination and often the most difficult and time-consuming. Isomorphous and molecular replacement methods require the availability of an isomorphous heavy-atom derivative or the structure of a homologous protein, respectively, before the problem can be addressed. An alternative method utilising the low-resolution molecular shape determined from solution X-ray scattering data using the program FSEARCH had located the molecular shape of the three-fold axis molecule nitrite reductase (AxNiR) from Alcaligenes xylosoxidans within the crystallographic unit cell [1]. The heart of the method involves locating the molecule within the crystallographic unit cell by first using the program ALMN in the CCP4 suit [2] to ascertain the polar angles of the non-crystallographic axis followed by a four dimensional search (Eulerian angle γ and three translational parameters). In light of the success of this technique, the program FSEARCH is being developed and modified further to handle general structures from all space groups. As a test for the veracity of this method, work is under way locating the orientation of the two-fold axis molecule super oxide dismutase (SOD) within the unit cell. Systematic data absences in the experimental data would cause FSEARCH to fail in its search for the correct orientation solution. However, given a complete dataset FSEARCH produced the lowest R factors for *a priori* correct solution and high R factors for random incorrect orientation.

P09.02.003 AB INITIO PHASING OF A PROTEIN, PSEUDOAZURIN AT 1.55Å RESOLUTION BY DIRECT METHOD. Monika Mukherjee, Department of Solid State Physics, Indian Association for the Cultivation of Science, Calcutta 700032, India.

The direct method program MULTAN/SAYTAN has been successfully applied to solve three small known proteins, aPP (302 protein atoms, space group C2), rubredoxin (397 protein atoms, space group $P2_1$) and Rnap1 (808 protein atoms, space group $P2_1$) ab-initio with atomic resolution data (<1.2Å resolution). To explore the possibility of this methodology to lower resolution data and crystal having higher symmetry, the present study of ab-initio phasing of a known protein, pseudoazurin (space group $P6_5$,cell parameters a=b=50.0(1), c=98.5(3)Å; 917 protein atoms + Cu + 93 solvent water in the asymmetric unit and data to 1.55Å) was undertaken by direct method.

By making several 1000 trials at 1.55Å resolution with sets of initially random phases MULTAN88 yielded ab-initio phases for 1000 reflections with lowest mean phase error of 68.2^o (79.4^o for the enantiomorph pair). Using top 1000 peaks as input from the E-map, the unstrained least-squares refinements using the conjugate gradient algorithm (CGLS) were carried out by changing the range of resolutions. After the first 10 cycles of refinement the R value was 0.233 (for 6-2.5Å resolution). The corresponding values for the subsequent cycles with increased resolution ranges were R=0.226, 0.280, 0.303 for 9-2.5Å, 9-2.0Å, 9-1.55Å respectively. Interpretation of the Fourier map at this stage showed a distorted tetrahedral geometry around the copper site. Building of the protein model was however not successful due to poor connectivity of the map. Efforts are on to improve the quality of the maps by solvent flattening / density modification before any further least-squares refinement is contemplated.

P09.02.004 A TRANSLATION-PACKING FUNCTION FOR POSITIONING A PROTEIN MOLECULE USING VERY LOW ORDER REFLECTIONS. K. M. Andersson and S. Hovmöller, Dept. of Structural Chemistry, Arrhenius Laboratory, Stockholm University, S-106 91 Stockholm, Sweden.

A method for predicting the position of protein molecules in the unit cell based on the very low order reflections and packing considerations is presented. At very low resolution, the electron density is very blurred, such that a protein molecule may well be approximated as a sphere [1]. A sphere with the same volume as the unknown protein [2] was translated in small (2-3 Å) steps in the unit cell until maximum overlap between the amplitudes calculated from the sphere and the true protein was found.

A molecular packing using spheres can be calculated to restrain the allowable regions. This makes the positioning of the protein molecule even more reliable. Structure factors of the 10 or so lowest order reflections were calculated with a sphere at the best position. These structure factors agreed closely to those of the true structure [3]. The combined translation and packing algorithm has been successfully tested for 16 proteins. For 12 out of 16 proteins tested, the position of the center of the molecule was correctly predicted to within 5 Å. The phase error for these reflections are less than 40°.

Furthermore, a qualitative deduction of deviations from the spherical model can be gained by comparing structure factors from the spherical model and the true protein. This may be used to modify the initial spherical model to a non-spherical envelope. The very low resolution phasing obtained by this method may be used as powerful starting set for phase extension methods like maximum entropy [4].

P09.02.006 TOWARDS MACROMOLECULAR ENVELOPE DETERMINATION USING ANOMALOUS DISPERSION AND CONTRAST VARIATION. W. Shepard†, M. Ramin†, R. Kahn§, J. Vivat§, E. Girard§ & R. Fourme† † LURE, Bât. 209d, Université Paris-Sud, 91898 Orsay, France, § IBS, 41 Avenue des Martyrs, 38027 Grenoble, France

Contrast variation can be generated by diffusing an anomalous scatterer into the solvent regions of a macromolecular crystal and then tuning the X-ray wavelength in the vicinity of an appropriate absorption edge [1]. This method has been implemented as a low resolution variant of MAD known as MASC [2], an acronym for Multiple-wavelength Anomalous Solvent Contrast, where the anomalous partial structure is no longer punctual and ordered, but instead an extended density confined to the solvent region of the crystal. As such, the MASC method directly provides the structure factor moduli of the solvent regions in the crystal, an important step in determining the macromolecular envelope.

Test case studies [3] on proteins of varying size (molecular weights from 14kDa to 174kDa) and soaked in a variety of anomalous scatterers show good agreement with the expected anomalous signal: very strong in the lowest resolution shells and rapidly diminishing with increasing resolution. In virtually all of the cases studied, the anomalous effects also reveal the presence of the anomalous scatterer bound in ordered sites combining MAD and MASC signals.

Methods of general applicability for phasing the normal structure factors of the anomalous structure in the MASC case (equivalent to the $^{\circ}F_A$ in the MAD case) are being investigated. We shall report results obtained using different approaches, in particular with spherical harmonics, for reconstituting the macromolecular envelope from MASC data.

P11.02.001 CRYSTAL STRUCTURE DETERMINATION OF PHARMACEUTICALS FROM POWDER X-RAY DIFFRACTION. S.A. Murphy and R.B. Hammond, Centre for Molecular and Interface Engineering, Department of Mechanical and Chemical Engineering, Heriot-Watt University, Edinburgh, EH14 4AS, and R. Roberts, Zeneca Pharmaceuticals Ltd, Hurdsfield Estate, Macclesfield, Cheshire, SK10 2NA.

One long term goal of the scientific community is to be able to predict crystal structures ab initio from knowledge of the molecular structure (1). However, in the shorter term, development of a routine methodology to allow solution of crystal structures of molecular, organic materials by combining powder X-ray diffraction with molecular modelling seems more tractable. To achieve structure solution from powders, a major task is the generation of reliable trial structures to refine. A computer program carrying out a systematic search for packing arrangements in the unit cell has been developed, treating the molecule as either a rigid body or as a flexible entity with up to two internal rotations. Calculated lattice energies and the match of the theoretical and experimental powder patterns are employed to rank the trial structures. Structures already studied as rigid bodies include indigo, 6,13-dichlorotriphendioxazine, phenanthrene, and the pharmaceutical materials primidone and paracetamol. Two torsions describing the orientation of the phenyl moieties, have been treated explicitly in the case of benzophenone (2). Further studies have been undertaken for primidone in which the internal degrees of freedom are treated within the systematic search. Results will be presented for primidone which contrast the use of the systematic searches for trial structures in a fixed unit cell with a Monte Carlo, simulated annealing method, based on calculated lattice energies, which has also been developed.

P11.02.002 STRUCTURE DETERMINATION FROM POWDER X-RAY DIFFRACTION DATA: APPLICATION TO HYDROGEN-BONDED SYSTEMS. E.D.L. Smith, R.B. Hammond, and K.J. Roberts, Centre for Molecular and Interface Engineering, Department of Mechanical and Chemical Engineering, Heriot-Watt University, Edinburgh EH14 4AS, U.K and R. Docherty, Zeneca Specialties Research Centre, Hexagon House, Blackley, Manchester M9 8ZS, U.K.

When determining crystal structures of organic molecular materials from high-resolution powder diffraction data the key step is the generation of reliable trial structures for final refinement. Recent advances have been made with respect to this and there are presently several approaches: Metropolis Monte Carlo; genetic algorithms; systematic grid search. The systematic approach uses a grid based search of rotations and translations to assess **all** the possible packing arrangements within a given unit cell. Calculated lattice energies in conjunction with a quantitative comparison of the calculated and experimental diffraction pattern are used to rank the trial structures. The application of two independent ranking methods provides a more robust basis upon which to select trial structures. The strategy is applied to anhydrous theophylline, which contains both oxygen and nitrogen as possible hydrogen bonded atoms. A systematic search found two packing arrangements within the same unit cell, exhibiting clearly distinct hydrogen bonding motifs. These were 'indistinguishable' in terms of their calculated lattice energy or a comparison of their respective, calculated powder X-ray diffraction patterns. Subsequent to commencing this work, one of these structures was independently verified by single crystal techniques. However, in the literature there is evidence to suggest that there exists another polymorph. The research presented here seeks to determine whether this is the case. In addition, the methodology described above was applied to previously determined structures (with similar functional groups), in order to test the feasibility of alternative hydrogen bonding motifs for a given molecule without substantial change of the unit cell.

P11.02.003 AB-INITIO POWDER STRUCTURE ANALYSIS OF TWO POLYMORPHS OF DIHYDROXYSILICON PHTHALOCYANINE. Y.Kojima, Y.T.Osano, T.Ohashi, Yokohama Research Center, Mitsubishi Chemical Corporation, Yokohama 227-8502, JAPAN

We report ab-initio X-ray powder structure determination of two polymorphs of [$Si(OH)_2Pc$], where Pc=phtalocyaninato. We found that one of the polymorphs(Phase II) shows high sensitivity for an electrophotographic photoreceptor but the other(Phase I) doesn't have the photosensitivity. The difference in the sensitivity depends on only the crystal structures. This material has not been able to be grown to single crystal with enough size for single crystal X-ray analysis but it is very important to determine the crystal structures of the two polymorphs to understand mechanism of performance of the electrophotographic photoreceptor. In this work we carried out ab-initio X-ray powder structure analysis. The compound crystallizes in space group P-1

(Phase I), Z=1 with unit-cell parameters a=12.992(1)Å, b=7.2830(8)Å, c=6.861(1)Å, α=104.413(7)º, β=101.575(8)º, γ=96.973(6)º and in space group $P2_1/n$ (Phase II), Z=2 with unit-cell parameters a=12.749(5)Å, b=14.578(6)Å, c=6.7727(3)Å, β=94.353(2)º. Both phases have symmetry center in the molecules (on Si atom) and intermolecular hydrogen bonds (O-H...N). These hydrogen bonds modes of Phase I and Phase II are the same. The main difference packings was revealed between the crystals, Phase II crystal has the herringbone structure, on the other hand in Phase I all molecules form the parallel stack columns.

P11.02.004 CRYSTAL STRUCTURES OF REMACEMIDE BASE, NITRATE AND ACETATE FROM X-RAY POWDER DIFFRACTION DATA. L.McBride[1], K.Shankland[2], W.I.F. David[2], G. Steele[3]. 1. Pharmaceutical Sciences, University of Strathclyde, UK. 2. ISIS Facility, Rutherford Appleton Laboratory, UK. 3. Astra Charnwood, UK.

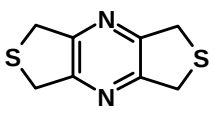
Powder X-ray diffraction data were collected for the Astra Charnwood compound remacemide base and its nitrate and acetate salts. The data were collected at 130K on BM16 of the European Synchrotron Radiation Facility (λ=0.85075Å). High quality simulated annealing solutions were obtained with ease for all three structures. Crystallographic data for the 3 compounds are given in the table.

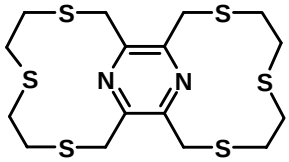
The remacemide molecule adopts similar conformations in the nitrate and acetate salts, and a markedly different conformation as the free base.

	Remacemide base	Remacemide nitrate	Remacemide acetate
Space grp	$P2_1/c$	$P2_1/a$	$P2_1/c$
a /Å	8.92452	11.72513	15.39513
b / Å	16.53619	8.93186	6.76487
c / Å	9.84803	15.87040	17.34326
β / °	93.806	95.955	93.134

P11.02.005 TRANSITION METAL COMPLEXES CONTAINING NEW PYRAZINE DERIVED LIGANDS: STRUCTURE DETERMINATION FROM LAB X-RAY POWDER DATA. A. Neels, T. Assoumatine and H. Stoeckli-Evans, Institut de Chimie, Université de Neuchâtel, 2000 Neuchâtel, Switzerland.

Pyrazine and its derivatives have been used in the formation of fascinating 1D, 2D or 3D polymeric structures. These compounds are studied for their interesting macroscopic behaviour such as molecular magnetism or photochemical properties.





Some new sulphur containing pyrazine derivatives have been designed and studied in complexation reactions with various transition metal ions. The ligand ***L1*** forms easily polymeric compounds with copper(I), silver(I) or gold(I). Since the gold complex could only be obtained in micro-crystalline form, its structure was solved by X-ray powder methods and then Rietveld refined. The diversity of the coordination possibilities of the ligand ***L1*** is documented by a structure comparison.

The new bis-macrocyclic ligand ***L2*** has been synthesised and used in the formation of some first row transition metal complexes. The reaction of ***L2*** with nickel(II) nitrate resulted in the formation of an insoluble micro-crystalline product, which was used in a X-ray powder diffraction experiment. The structure of this binuclear nickel(II) complex containing 21 atoms per asymmetric unit was determined from these laboratory X-ray powder data.

P11.02.006 CRYSTAL STRUCTURE OF 3,5-DI-*ISO*-PROPYL-4-NITRO-PYRAZOLE FROM X-RAY POWDER DIFFRACTION DATA. L.E. Ochando and J.M. Amigó, Departamento de Geología, Universidad de Valencia, Campus de Burjassot, Spain , J. Rius, Institut de Ciència de Materials de Barcelona, CSIC, Catalunya, Spain, and D. Louër, LCSIM - UMR 6511, Université de Rennes I, 35042 Rennes, France.

The crystal structure of the titled compound has been solved from laboratory X-ray powder diffraction data by Patterson Search methods [1]. Crystal data : monoclinic symmetry with the unit cell parameters a = 28.800(5) Å , b = 6.485(1) Å and c = 17.944(3) Å, β = 138.17(1)° , *C2/c* space group, $C_9H_{15}N_3O_2$, Z = 8 , 293 K. This new pyrazole derivative has not been studied before by diffraction methods. Because of difficulties in preparing single-crystals which were suitable for a classical single-crystal analysis, diffraction measurements in a limited scattering range were carried out on untreated powder sample. This study is a continuation in structural characterisation of pyrazole compounds as described previously [2]. Indexation of the powder diffraction data gave a high figures of merit: M_{20} = 20.3 and F_{30} = 35.1(0.0067, 127). Eighty-five unambiguously indexed and thirty-seven systematically overlapped integrated intensities were extracted by means of the whole pattern fitting program AJUST [3]. The search model was oriented in the monoclinic unit cell by the program ROTS96 [4]. The subsequent rigid-body Rietveld refinement will be performed with the program RIBOLS [5] and will be presented and discussed.

P11.02.008 *IN-SITU* STUDY OF THE SOLID STRUCTURE OF HCFCS AND HFCS BY X-RAY POWDER DIFFRACTION. M. Brunelli, European Synchrotron Radiation Facility, B.P. 220, F38043 Grenoble Cedex, France A. N. Fitch, European Synchrotron Radiation Facility, B.P. 220, F38043 Grenoble Cedex, Department of Chemistry, Keele University, Staffordshire, ST5 5BG, UK

The hydrochlorofluorocarbons (HCFCs) and the hydrofluorocarbons (HFCs) are the replacement refrigerant of the ozone-depleting chlorofluorocarbons (CFCs) which are being phased out as a result of the Montreal Protocol (1988). The advantage of these compounds is that they are more reactive chemically and break down at lower altitudes before they reach the ozone layer. Powder diffraction is a suitable technique because it is far easier to handle the fluids as powders. We studied the low temperature crystal structure of 1-Chloro-1,1-difluoroethane (142b, CF_2ClCH_3), 1,1-difluoroethane (152a, CH_3CHF_2) and 1,1,1,2-Tetrafluoroethane (134a, FCH_2CF_3) using high resolution synchrotron powder diffraction on beam-line BM16 at ESRF, Grenoble.

On BM16 we have built an *in-situ* gas-handling system that allows volatile compounds to be condensed directly in a thin-walled glass capillary mounted on the axis of the diffractometer. Following the condensation, the capillary can be disconnected from the gas line, and spun normally for powder diffraction studies. The *in-situ* experimental set-up will be presented. Powder

diffraction patterns of the solids phases have been measured down to 80 K using the Cryostream cold-nitrogen-cooler.

P11.02.009 SPACE GROUP DETERMINATION FROM A SAMPLE OF POWDER DIFFRACTION INTENSITIES USING A BAYESIAN METHOD. A.J. Markvardsen, W.I.F. David and D.S.Sivia, ISIS Facility, Rutherford Appleton Laboratory, Chilton, Didcot, Oxon. OX11 0QX, UK.

Space-group determination from powder diffraction data is often hampered by difficulties in reliably determining systematic reflection absences. This arises because powder diffraction patterns contain, almost without exception, Bragg peak overlap resulting from the projection of three dimensions of diffraction data on to the one dimension of the diffraction pattern.

We present a Bayesian method for reliably determining the probability distribution of different space groups from a least-squares integrated-intensity (Pawley) refinement of the powder diffraction data. The method involves the Monte Carlo integration technique to calculate the probabilities of different space group choices given a set of powder diffraction intensities, and the results indicate that it is possible to extract the space group reliably and quickly from powder diffraction data.

P12.02.000 DIRECT DETECTION OF BIJVOET DIFFERENCES FOR CU Kα RADIATION IN A LIGHT-ATOM MOLECULE. Shoichi Sato, X-ray Research Laboratory, Rigaku Corporation, Matsubaracho 3-9-12, Akishima, Tokyo 196-8666, Japan

Detection of Bijvoet differences of a light-atom molecule by means of common laboratory X-ray source is usually very difficult. In the present investigation on α-cytidine, however, the differences could be successfully detected by an application of routine method of structure analysis by four-circle diffractometry with a spherically shaped crystal. Inspection of the diffraction data collected on an AFC5 with Cu Kα radiation showed that many reflections had large intensity deviations from those of other Bijvoet pairs, especially as intensity enhancements of the weaker ones. Such intensity deviation of a particular reflection was similarly observed for its Friedel mate. This trend strongly suggested that the deviation came from not some accidental instability of the instrument but multiple reflection and that the angular settings of the crystal were very good in the course of data collection. After reflections with deviations of eight times its own esd from the mean value of the equivalents were removed, the rest was averaged to a set of Bijvoet pairs and used for the structure refinement. From 30 Bijvoet differences with large ΔF/esd, the absolute configuration of the molecule could be determined without ambiguity so that the observed and calculated differences had the same senses. The absolute configuration thus deduced was consistent with that already reported by Subramanian & Hunt [1] on a chloride crystal. The R values were R=0.0232, Rw=0.0312, S=1.60 and Flack parameter was 0.03(3) for the correct configuration; whereas those for the inverse structure were slightly large as R=0.0235, Rw=0.0319 and S=1.60. All the results showed no contradiction on the configuration of the molecule. [α-Cytidine: C9H13N3O5, orthorhombic, $P2_12_12_1$, Z=4; a=13.985(1), b=14.765(1) and c=5.117(1)Å; V=1056.6(2)Å^3.]

P12.02.001 DIRECT PHASE DETERMINATION FOR MACROMOLECULAR CRYSTALS BY STEREOSCOPIC MULTI-BEAM IMAGING. S.L. Chang, C.H. Chao, Y.S. Huang, F.J. Liang, Yu.P. Stetsko, H.C. Chien, and C.K.Chen, Department of Physics, National Tsing Hua University, Hsinchu, Taiwan, Y.C.Jean and H.S.Sheu, Synchrotron Radiation Research Center, Hsinchu, Taiwan, R.O.C. and H.S.Yuan, Institute of Molecular Biology, Academia Sinica, Taipei, Taiwan, R.O.C.

Phase information necessary for determining single-crystal structure is lost in the intensity measurement of x-ray reflection. For macromolecular crystals, anomalous dispersion (AD) and heavy atom derivatives are usually employed in phase determination. Here, without invoking AD and derivatives, we demonstrate the direct phase determination of a large number of reflections collected in a short time from macromolecular crystals using a stereoscopic oscillation-crystal imaging technique in a multi-beam diffraction geometry, where two crystallographic axes in opposite directions are employed as the rotation axes. The intensity contrast of the diffraction spots and of the diffraction profile (distribution) versus the varying tilt Bragg angle of the rotation axis in the stereoscopically-related two images yields qualitative and quantitative phase information, respectively. More than 1000 multiple diffraction profiles of tetragonal lysozyme are obtained at the rate of 100 profiles per 30 minutes and more than 500 phases are determined. This technique thus provides a new practical way for direct phase determination of macromolecular crystals.

P12.02.002 COMBINED DIRECT METHODS WITH ISOMORPHOUS REPLACEMENT AND ANOMALOUS SCATTERING TECHNIQUES. S.Banumathi and D.Velmurugan Department of Crystallography and Biophysics, Univesity of Madras, Guindy Campus, Chennai-600 025, INDIA.

In the past fifteen years, the role of anomalous scattering (AS) or isomorphous replacement (IR) technique when combined with traditional direct methods had been widely studied. Applications of these new formulae on error free data of macromolecules seem promising. Attempts are here made in combining both anomalous scattering and isomorphous data with traditional direct methods so as to strengthen the direct method formalism to macromolecular phasing. The joint and conditional probabilitiy distributions are derived for the triplet, quartet and sextet invariants using their first neighborhood for the above situation. Details of the mathematical derivation will be presented. Attempts are being made to apply these formuale with error free data of macromolecules.

P12.02.003 AUTOMATIC PATTERSON METHODS. FROM INORGANIC COMPOUNDS TO PROTEINS. F. Pavelcik, Department of Inorganic Chemistry, Faculty of Natural Sciences, Comenius University, 842 15 Bratislava, Slovak Republic.

The problem of crystal structure determination, usually formulated as the phase problem, can be reformulated as the problem of global optimisation

$$M(\{\mathbf{r}_i\}) = \Sigma_H [F_O^2 - \Sigma_k \Sigma_l f_k f_l \exp(2\pi \mathbf{H}(\mathbf{r}_k - \mathbf{r}_l))]^2, \qquad k, l=1,2,...,N.$$

The reasonable estimates of vector differences, $\mathbf{r}_k - \mathbf{r}_l$, can be obtained from the Patterson function.

Automatic Paterson methods have been developed for heavy atom (inorganic) structures [1] and later extended for organic structures [2]. Recently we have been successful in solving small proteins measured at atomic resolution by these methods.

The structure determination consists of three steps: (a) selection of one or more pivot atoms. Pivot atoms are

systematically generated by symmetry minimum or vector symmetry minimum functions. (b) Atomic minimum superposition function based on these pivot atoms. (c) Automatic Fourier recycling starting from peaks of the superposition map. Fourier recycling is combined with procedures for elimination of false peaks (e.g. holographic refinement). The three steps are repeated until the structure is solved. The best solution is completed by repeated least squares refinement and $2F_o$-F_c or F_o-F_c syntheses. Few examples are given here (2FDN - Ferredoxin, 1AB1 - crambin, 1AA5 - vancomycin, VITD2 - vitamin D_2, Aa - Amino acid residue):

BL238	P-1	$C_{44}H_{60}N_8Na_4O_4$	Z=4	R=0.12
VITD2	$P2_1$	$C_{28}H_{44}O$	Z=8	R=0.17

P12.02.004 APPLICATION OF THE 'DIRECT METHODS' DIFFERENCE SUM FUNCTION TO THE SOLUTION OF RECONSTRUCTED SURFACE. X. Torrelles, J. Rius, C. Miravitlles [1], S. Ferrer [2], [1] Institut De Ciencia De Materials De Barcelona (C.S.I.C.), [2] E.S.R.F., Bp.-220, F-38043 Grenoble Cedex (France)

The determination of reconstructed surfaces from diffraction data is normally performed in two stages: i) the (x,y) projection of the reconstruction is determined by direct interpretation of the two dimensional partial Patterson map computed with the intensities of the reconstruction in-plane reflections only, and ii) this projection is subsequently expanded to three dimensions by fitting the full data set (in-plane plus out-of-plane data). Unfortunately, interpretation of two dimensional Patterson maps is not a trivial task for reconstructions with large unit cells. Here, an alternative procedure based on the application of the 'direct methods' difference sum function is presented which reduces the two steps to a single highly automated one. This is achieved by simulating an extra periodicity normal to the surface which takes into account all atoms of the reconstruction. In this way a set of reconstruction reflections is generated which can be processed with the same methodology as for superstructure reflections in bulk superstructures. Two known reconstructed surfaces have been selected as test examples: Ge(001) c(4x2) and GaAs(001) p(2x4) [1].

P12.02.005 HALF-INTEGRAL STRUCTURE FACTORS AND THE PHASE PROBLEM. A.Mishnev, Latvian Institute of Organic Synthesis, 21 Aizkraukles St., LV 1006, Riga, Latvia

X-Ray diffraction by a crystal can be described by means of different sets of parameters. Conventional approach employs the formulation in terms of standard index (SI) structure factor (SF) magnitudes and phases. In the present work unknown parameters describing the structure are half-integral (HI) (having half-integral Miller indices) SF's, which are related to the SI SF *via* the discrete Hilbert transforms (DHT) [1-2]:

$$F(n_1,n_2,n_3) = -(i/\pi^3)\sum_{h,k,l} F(h+1/2, k+1/2, l+1/2) \times [(n_1-h-1/2)(n_2-k-1/2)(n_3-l-1/2)]^{-1}. \quad (1)$$

The phase problem is formulated as finding HI SF or HI intensities instead of the phases of SI SF. For this purpose the electron density (2) and the Sayre's equation (3) have been expressed in terms of HI SF:

$$\rho(x,y,z) = (1/7V)\sum\sum\sum F(h/2, k/2, l/2)\exp[-i\pi(hx+ky+lz)] \quad (2)$$

$$\begin{aligned} F(n_1,n_2,n_3) = (\theta/7V)\sum\sum\sum \{&F(h+1/2, k, l)F(n_1-h-1/2, n_2-k, n_3-l) \\ &+ F(h, k+1/2, l)F(n_1-h, n_2-k-1/2, n_3-l) \\ &+ F(h, k, l+1/2)F(n_1-h, n_2-k, n_3-l-1/2) \\ &+ F(h+1/2, k+1/2, l)F(n_1-h-1/2, n_2-k-1/2, n_3-l) \\ &+ F(h, k+1/2, l+1/2)F(n_1-h, n_2-k-1/2, n_3-l-1/2) \\ &+ F(h+1/2, k, l+1/2)F(n_1-h-1/2, n_2-k, n_3-l-1/2) \\ &+ F(h+1/2, k+1/2, l+1/2)F(n_1-h-1/2, n_2-k-1/2, n_3-l-1/2)\} \end{aligned} \quad (3)$$

All experimental SI SF magnitudes and small amount of phased SI SF are used as constraints for HI SF magnitude and phase determination. The HI SF are recovered by minimizing the least squares residuals for DHT (1), HI Sayre's equation (3) and prior phase information by a gradient method.

P12.02.006 UPGRADING THE TWIN VARIABLES ALGORITHM FOR LARGE STRUCTURES. G.Tsoucaris, Laboratoire de Physique, Tour B, Centre Pharmaceutique, Université Paris Sud, 92290 Châtenay-Malabry, FR, P. Tzamalis, K.Bethanis, A.Hountas, Physics and Meteorology Laboratory, Agricultural Univ. of Athens, 75 Iera Odos, 118-55, GR, A.F.Mishnev, Institute of Organic Synthesis, Latvian Academy of Sciences,1006Riga, LV.

Two novelties particularly relevant in the context of Direct Methods, have been applicated in Twin Variables method (Hountas, Tsoucaris,1995)[1].

- The use from the very beginning of a very large set of additional variables defined on reciprocal lattice vectors which can be located beyond the limiting resolution of the observed structure factors. Despite the *extreme dilution* of a very limited initial phase information into this large set of auxiliary variables, the algorithm allows phase refinement and phase extension both within the observed reciprocal sphere and the so called *super-resolution* shell.

- the use of the *crystallographic symmetry as a new figure of merit (FOM) and as a reliable test* for the correctness of the phase extension process.

Tests on real data of protein structures with up to 1000 independent non hydrogen atoms have been performed and considerable refinement and extension in resolution of the phased structure factors from initial 3.5Å to final 1.2Å has been attained.

Preliminary results have been given in two communications (2).

The project is granted by N.A.T.O L.G. 951447

P12.02.007 SAYRE'S EQUATION FOR PHASE DETERMINATION AND ANHARMONIC TEMPERATURE VIBRATION OF ATOMS. Sabita Das and G.B. Mitra ,CSS Department , Indian Association for the Cultivation of Science, Calcutta- 700032, India.

Sayre's equation for phase determination tacitly assumes that all the atoms ,constituting the crystal under study , have the same types of atoms throughout the crystal so that the temperature factors of the atoms will additionally be the same in all directions. In actual cases, there is often atomic heterogeneity and anisotropy and anharmonicity of the temperature factors. The squared atoms assumed in deriving the Sayre's equation can be shown to be due to the averaging process of the products of terms in the crystal structure factors. The average terms will depend to a great extent on the anisotropy and anharmonicity of the atomic scattering factors . Mathematical expression derived shows that the extent of anisotropy and anharmonicity of the vibration of the electrons in the atoms constituting the crystal studies leaves a great stamp on the Sayre's constant studies.

P12.02.008 SIR99, A STEP TOWARDS SIR2001: A TOOL FOR AB INITIO CRYSTAL STRUCTURE SOLUTION OF PROTEINS. M.C. Burla and G. Polidori, Dipartimento di Scienze della Terra, Università di Perugia, 06100 Perugia, Italy, and B. Carrozzini and C. Giacovazzo, Dipartimento Geomineralogico, Università di Bari, 70125 Bari , Italy, and M. Camalli and R. Spagna, Istituto di Strutturistica Chimica "G. Giacomello", CNR, C.P. 10 - Monterotondo Stazione - 00016 Roma, Italy.

Shake-and-Bake [1] and more recently Half-Bake [2] have immoderately enlarged the size of crystal structures solvable by direct methods. These programs repeatedly cycle both in real and in reciprocal space, and structure (or phase) refinement is performed in each space.
A more traditional point of view is at the basis of SIR99. It will be shown how and why traditional programs like SIR97 [3] can evolve to SIR99, a package able to solve macromolecular structures, without repeatedly switching from direct to reciprocal space and viceversa. At the end of the procedure a satisfactory structural model with reasonable bond lengths and angles, and sufficiently low values of the crystallographic residual R are obtained, without any user intervention.
The SIR99 has been successfully applied to several large crystal structures among which we notice the following proteins: Crambin, Rubredoxin, Toxin II, Vancomicin and Gramicidin.

P12.02.009 EXPONENTIAL SHAKE-AND-BAKE: CAN SUCCESS BE GUARANTEED? Hongliang Xu, Herbert A. Hauptman, Charles M. Weeks, and Russ Miller, Hauptman-Woodward Medical Research Institute, Inc., 73 High Street, Buffalo, NY 14203-1196, USA.

Shake-and-Bake is a multitrial direct-methods procedure that automatically and repetitively shuttles trial structures between real and reciprocal space (initial coordinates are chosen at random). Phase refinement depends on using a parameter-shift technique to reduce the value of the cosine minimal function (COS). In recent studies, the cosine minimal function has been replaced by one of exponential type(EXP) [1], resulting in a significantly improved success rate. Applications to three large P1 structures (alpha-1 peptide [471 non-H atoms, 1Cl], vancomycin [547 non-H atoms, 12Cl] and lysozyme [1295 non-H atoms, 10S]) have shown that incompleteness of data is typically a more serious problem than measurement errors. By extending error-free data to sufficiently high resolution, 100% success (convergence of trial structures to solution) could be achieved in all three cases by use of the exponential minimal function under appropriate conditions. In general, parameter shift angles of 120-140° gave the best results

P12.02.010 COMPARATIVE RESULTS OF ESTIMATES IN COMBINED DIRECT METHODS FOR HIGHER INVARIANTS OR NEIGHBORHOODS. Subhasshini Parthasarthy and D.Velmurugan, Department of Crystallography and Biophysics, University of Madras, Guindy Campus, Chennai-600 025, INDIA.

Results are available in literature on the working of (DMAS) and (DMIR)in the case of Triplets and Quartets. While the results are available for Triplets in their first neighborhood both in the case of DMAS and DMIR, new formulae are derived for second neighborhood for the above mentioned cases. The comparative results on the role of neighborhoods in the relative accuracy on the estimation of the invariants will be presented. The applications are made with the error free data of cytochrome c550. Results for Quartets (in DMAS) and Quintets (in DMIR) in their second neighborhood will help us in arriving at the relative advantages or otherwise of higher invariants and higher neighborhoods.

P12.02.011 REAL SPACE AB INITIO PHASING OF PROTEIN CRYSTALS WITH HIGH RESOLUTION DATA. N. Matsugaki & M. Shiono, Faculty of Science, Kyushu University, Fukuoka, Japan.

A simple density modification, low density elimination (LDE) [1,2], has been developed and implemented as a computer program for solving macromolecular crystals *ab initio* with multi-solution strategy. The remarkable feature of the program is that the phase determination is completely carried out in real space. *Ab initio* phase determination was demonstrated for various known protein structures (molecular weight of 4K - 14K Dalton) which give atomic resolution data. In addition, test trials were made using synthetic data at 1.18Å of a known metalloprotein crystal, which consists of about 4600 independent atoms with 4 cobalt atoms (the space group is $P2_1$ and $Z = 4$): we carefully introduced realistic errors into the data. The initial phases were calculated from a structure containing only one atom in an asymmetric unit, whose coordinate was obtained from a peak in the Patterson-Harker section. After multiple trials out of the highest 20 peaks in descending order, one solution was obtained. The data collection of the crystal is in progress.

P12.02.012 COMBINING SHAKE-AND-BAKE WITH MULTIPLE BEAM DIFFRACTION DATA: A SIMULATION. Herbert A. Hauptman1, Charles M. Weeks1, Hongliang Xu1, and Qun Shen2. 1Hauptman-Woodward Medical Research Institute, Inc., 73 High St., Buffalo, NY 14203-1196 USA and 2Cornell High Energy Synchrotron Source (CHESS), 283 Wilson Laboratory, Cornell University, Ithaca, NY 14853 USA.

The minimal principle formulates the phase problem as one in constrained global minimization. The function to be minimized (the objective function) is a measure of the mean-square difference between the triplet cosine invariant and its expected value. One anticipates that, by replacing the objective function by one which measures the mean square difference

between the triplet sine and cosine invariants and their experimentally measured values (rather than their expected values), the power of Shake-and-Bake will be increased. Simulations in which average errors in estimated values of the triplet invariants as large as 50° are permitted show that the expected improvement is in fact realized even at resolutions of 1.5Å or lower. Since the multiple beam diffraction experiment yields estimates of the triplets having average errors of 25° or less, it is expected that the ability to combine Shake-and-Bake with multiple beam diffraction will increase the power of the direct methods. This research was supported by NIH grant GM-46733.

P12.02.013 STRUCTURE DETERMINATION OF A MANNANASE USING THE SAD SIGNAL AT 1.65 Å RESOLUTION. E. Sabini[1], H. Schubert[1], G. Murshudov[1], Matti Siika-Aho[2], Merja Penttila[2] & K.S. Wilson[1] [1]Structural Biology Laboratory, Department of Chemistry, University of York, York, UK. [2]VTT Biotechnology and Food Research, P.O. Box 1501, FIN-02044 VTT Espoo, Finland.

The native structure of a family 5 mannanase from *Tricoderma reesei* has been solved at 1.5 Å resolution using an innovative method based on the Single Anomalous Dispersion signal (SAD) to the resolution of the derivative data, 1.65Å. The success of the procedure used is of especial interest because of the molecular weight of the protein (40kDa).

Glycoside hydrolase family 5 contains many enzymes the majority of which are cellulases whose sequence are only distantly related to the *T. reesei* mannanase. Structures for a number of cellulases from this family are known but none were successful as molecular replacement search models for the *T. reesei* mannanase.

Moreover, since inadequate isomorphous phase information was available, the quality and strength of the anomalous phase information of a non-isomorphous platinum derivative was investigated. The co-ordinates of the two platinum sites were refined using MLPHARE and useful phases were produced using only the anomalous scattering information (SAD).

An atomic model was built in an automated cyclic procedure containing two alternating steps: (1) unrestrained maximum-likelihood refinement in reciprocal space to match properly calculated and observed structure-factor amplitudes and (2) substantial modification of the current atomic model in real space. The procedure produced excellent electron density maps that allowed straightforward building of an essentially complete atomic model.

P12.02.014 DIFFRACTION ANOMALOUS FINE STRUCTURE ON FORBIDDEN AND SUPERLATTICE REFLECTIONS OF $PbZrO_3$, Y.Soejima, T. Toda, T. Nogami and Y. Yamasaki, Department of Physics, Kyushu University, Fukuoka 812-8581, Japan

The characteristics of diffraction anomalous fine structure (DAFS) on forbidden and superlattice reflections have theoretically been discussed on the basis of the symmetry operation in the superstructure of $PbZrO_3$ (ref.). For the forbidden reflections, the site-selectivity of DAFS is well explained in terms of Patterson symmetry of the space group Pbam: since all the Zr atoms occupy 8i site, the environment around the atom is unique. Moreover, all the interatomic vectors connected to Zr atoms are related by mirror symmetry. This results in the fact that the DAFS oscillation vanishes when the polarization of incident X-ray is parallel or normal to the vectors. In contrast, Pb atoms occupy 4g and 4h sites; this means that there are two kinds of circumstances around the Pb atoms. It is found that the DAFS oscillation around the Pb edge vanishes only when the polarization of incident X-rays is parallel or normal to the a- or b-glide plane. For the superlattice reflections, the pattern of DFAS oscillation is affected by the contributions of Pb and Zr atoms to the construction of the superstructure; the detail will be discussed at the presentation. We will also discuss a use of the DAFS for the superstructure determination.

P12.02.015 DIFFRACTION ANOMALOUS FINE STRUCTURE ON SATELLITE REFLECTION IN Rb_2ZnCl_4. S. Nagao, S. Kuwajima and Y. Soejima, Department of Physics, Kyushu University, Fukuoka 812-8581, Japan

To investigate the local structure of the incommensurate phase of Rb_2ZnCl_4, the diffraction anomalous fine structure (DAFS) on satellite reflections around the Zn K absorption edge has been measured in both the incommensurate and commensurate phases. It is found that the structure factor observed is not affected by anomalous dispersion, in the energy region below the absorption edge; this is consistent with the fact that the modulation mainly consists of that of Cl anions. In the energy region above the absorption edge, intensity oscillation due to DAFS has clearly been observed. That is, the DAFS oscillation pattern on satellite reflections remarkably differs from that on fundamental reflections, in particular in the energy region about 150 eV above the absorption edge; for the region with higher energies the difference is not significant. The difference of the DAFS pattern between the incommensurate and commensurate phases gives us detailed information on the local atomic circumstances around the Zn atoms in the modulated structure. The DAFS oscillation observed at Rb K absorption edge will also be discussed at the presentation.

P12.02.016 PHASE DETERMINATION BY THE WAVELENGTH-MODULATED DIFFRACTION METHOD. H. Iwasaki, N. Nakamura, Y. Yoshimura, A. Ishikawa and T. Koganezawa Faculty of Science and Engineering, Ritsumeikan University, Kusatsu, Shiga 525-8577, Japan

Based on a newly developed method of phase determination [1], X-ray diffraction patterns of single crystals of ferrocene derivatives were taken with synchrotron radiation with continually changing wavelength in the vicinity of the K-absorption edge of the Fe atom. Bragg reflections appeared as elongated spots in the patterns and an intensity gradient derived from their intensity profile has yielded, if the positions of the Fe atoms are properly assumed, the phase of the structure factor for the centrosymmetric case. For non-centrosymmetric crystals, the intensity gradients measured at two wavelength regions or the intensity gradients measured for the Bijvoet pair of reflections yield the phase by solving two simultaneous linear equations. The wavelength-modulated diffraction method is free from the problem of intensity scaling often encountered in other methods of phase determination.

P12.02.017 THE STRUCTURE OF $IIA^{MANNITOL}$: ON THE CUTTING EDGE OF MAD. R.L.M. van Montfort, Department of Crystallography, Birkbeck College, London WC1E 7HX, UK, T. Pijning, K.H. Kalk, G.T. Robillard and B.W. Dijkstra, BIOSON Research Institute, University of Groningen, 9747AG Groningen, The Netherlands

The bacterial phosphoenolpyruvate-dependent phosphotransferase system (PTS) catalyses the cellular uptake and subsequent phosphorylation of carbohydrates, and plays a crucial role in the regulation of various metabolic pathways. Its carbohydrate-specific enzymes II (E_{II}s) are usually composed of two cytoplasmic domains, IIA and IIB, and a transmembrane domain IIC. The IIA domains catalyse the transfer of a phosphoryl group from the phosphocarrier protein HPr to IIB, which phosphorylates the transported carbohydrate. We have determined the structure of the *Escherichia coli* mannitol-specific IIA domain, IIA^{mtl}, by a three-wavelength MAD experiment on a selenomethionine variant of IIA^{mtl}. The 16.3 kDa seleno-substituted IIA^{mtl} contained only one selenium atom per molecule. Nevertheless, the four selenium sites in the asymmetric unit could easily be located in both the anomalous and dispersive Patterson maps. An interpretable electron density map was obtained after fourfold averaging. The structure was refined at 1.8 Å resolution to an R-factor of 19.0% (R_{free} 24.2%). The fold of IIA^{mtl} consists of a single five-stranded mixed β-sheet, flanked by helices on both sides. The phosphorylation site of IIA^{mtl} is located in shallow crevice lined with hydrophobic residues. Two residues flanking the phosphorylation site adopt two different conformations in the different IIA^{mtl} molecules. These conformations might represent different states of the active site, required for the different phosphoryl transfer reactions in which IIA^{mtl} is involved.

P12.02.018 DATA TO MAPS: AUTOMATED MAP GENERATION FOR HEAVY ATOM STRUCTURE DETERMINATION. P. Emsley and Neil W. Isaacs, Dept. of Chemistry, University of Glasgow, Glasgow, G12 8QQ, UK.

CHART is a wrapper for SHELXS[1] and the CCP4 Program Suite[2,3,4] that creates (density modified) MIR(AS) or MAD maps suitable for density fitting. The starting point is MIR(AS) data sets. CHART terminates with what it considers to be an optimal density modified map. CHART has a minimalist GUI, which should be suitable for novice crystallographers and hopefully can be easily integrated with the CCP4 GUI. CHART incorporates a ``divide and conquer'' procedure which can optimize many parameters, such as number of molecules in asymmetric unit, resolution limits or best solvent content.

CHART is released under the GNU GPL and can be obtained from http://www.chem.gla.ac.uk/~paule/chart.

P12.02.019 MASC METHOD IN PROTEIN CRYST-ALLOGRAPHY : SEARCH FOR SUITABLE CONTRAST AGENTS. E.Girard, R.Kahn and J.Vicat, Institut de Biologie Structurale, 38027 Grenoble, France.

In MASC experiments a physical contrast variation is obtained by tuning the x-ray wavelength in the absorption edge of an anomalous scatterer present at high concentration and dispersed through the solvent channels of protein crystals. These anomalous scatterers, introduced into the crystal either by soaking or by co-crystallisation, should not bind to the protein.
The ideal compound should (i) contain atom(s) with large anomalous features (white lines), (ii) be neutral to avoid binding to charged regions of the protein and (iii) be water soluble at high concentrations.

Experiments with a brominated non-detergent sulfobetaine, a neutral zwitterion are reported. Hen egg white lysozyme crystals containing up to 0.72M of this compound have been obtained and no binding to the protein was observed.

Experiments with neutral compounds containing stronger anomalous scatterers, such as platinum and rare earth atoms are in progress and will be reported.

P12.02.020 USE OF SIR/SAS DATA TO SOLVE A SE-ATOM SUBSTRUCTURE. C. Lemke and P.L. Howell Structural Biology and Biochemistry, Hospital for Sick Children, Toronto, M5G 1X8 and Department of Biochemistry, University of Toronto, Toronto, M5S 1A8.

Argininosuccinate synthetase (AS) catalyzes the reversible ATP dependent ligation of citrulline and aspartate to produce argininosuccinate, AMP and inorganic pyrophosphate. The primary role of AS is in the urea cycle, which is involved in the arginine biosynthesis of all organisms and in the detoxification of ammonia of ureotelic organisms. AS is rate limiting in this cycle, and also the arginine-citrulline cycle. When activated, the arginine-citrulline cycle provides the cell with a ready supply of arginine for the overproduction of nitric oxide (NO) by iNOS. While overproduction of NO plays a beneficial role in host defense, it is also responsible for the hypotension associated with septic and cytokine induced circularory shock.

The structure of *E. Coli* AS, has been determined to 1.6Å resolution. The selenium atom substructure was determined using both SIR and SAS data and the direct methods program SnBv2. Data were collected on a selenomethionyl AS crystal (Cu Kα radiation) and were used in conjunction with a 1.6Å native (S-Met) data set to calculate isomorphous diffE magnitudes using the DREAR program package. SnBv2 subsequently found 13 of the 16 Se atom positions. These positions were confirmed and the three remaining Se positions located using anomalous diffE magnitudes calculated from the peak data of a 3-wavelength MAD experiment. All 16 Se positions were used to solve the structure by treating the MAD data as a special case of MIR. The structure of the protein, its comparison with other members of the pyrophosphate subfamily (e.g. GMP and NAD+ synthetase) to which AS belongs and the SIR/SAS methods for Se-substructure determination will be presented. Funded by a grant from the Medical Research Council of Canada.

P12.02.022 MAD PHASING WITH TWO DIFFERENT TYPES OF ANOMALOUS SCATERERS. G. Bourenkov and H. D. Bartunik, Max-Planck Research Unit for Structural Molecular Biology, Protein Dynamics group, MPG-ASMB c/o DESY, Notkestrasse 85, 22603 Hamburg, Germany.

The usage of the MAD method in the phasing of protein structures can be considerably extended to applications involving two different types of anomalous scatterers in the same structure. Such MAD experiments, which have not yet become common practice, offer a high potential. Simple statistical considerations prove that even in a two-energy case the phasing power will be approximately twice as high for two types of anomalous scatterers (two different absorption edges) as compared to the case of a single type of scatterer with the same total number of sites. Full advantage of the presence of two types of scatterers can be taken by performing measurements at five energies. Further gain is achieved due to the relative simplicity of locating the reference scatterers and determining the correct enathiomorph.

Recent experience with structure determination by MAD using two types of anomalous scatterers will be summarized. These include structures of a Zn-proteinase incorporating Se-Met [1], heavy-metal derivatives of metalloproteins, and proteins

containing two different metals in their native state. The possibility to use such MAD techniques for the phasing of large molecular weight structures will be discussed.

P12.02.023 DIRECT DETERMINATION OF CRYSTAL STRUCTURE OF HUMAN FERRO-CHELATASE USING [2Fe-2S] ANOMALOUS SCATTERING SIGNAL FROM IN-HOUSE DATA AND SOLVENT FLATTENING. Chia-Kuei Wu[1,2], Amy Burden[1], John P. Rose[1], Joe Ferrara[3], Harry A. Dailey[1], and Bi-Cheng Wang[1], [1]Department of Biochemistry and Molecular Biology, University of Georgia, Athens, GA30602, [2]Department of Crystallography, University of Pittsburgh, Pittsburgh, PA 15260 and [3]Molecular Structure Corporation, 3200 Research Forest Dr., The Woodlands, TX 77381,

The structure of human ferrochelatase has been solved using Fe-SAD (single wavelength anomalous diffraction) data collected in-house on a Cu rotating anode. To the best of our knowledge, this is the first example of a protein structure of this size (86 kDa per asymmetric unit) being solved using only single-wavelength Fe anomalous scattering data collected in-house.

The protein phases were obtained using the ISAS procedure (Wang, *J. Enzymol*. 115: 90, 1985). The sulphur atoms coordinated to the Fe atoms were determined from the Fe-phased Bijvoet difference Fourier and added to the phasing process. The resulting electron density map showed good connectivity, side chain density, the 2Fe-2S cluster, numerous helices and a long beta sheet. In addition, the majority residual peaks in the initial Fe-phased Bijvoet difference Fourier were found to correspond to the sulphur atoms of methionine and cysteine residues and aided in fitting the sequence to the electron density. The structure is now under refinement.

Ferrochelatase is the terminal enzyme in heme biosynthesis and catalyzes the insertion of ferrous iron into protoporphyrin IX to form protoheme IX. The mammalian enzyme is associated with the mitochondrial membrane and contains an 2Fe-2S cluster. The human enzyme has been overexpressed in *E. coli* and crystallized. The crystals, which diffract to 2Å resolution, belong to space group $P2_12_12_1$ with cell constants of a = 93.2 Å, b = 87.6 Å, c = 110.1 Å, and contain two molecules per asymmetric unit.

The initial Bijvoet difference Patterson maps showed a strong signal for the iron atoms and an experiment was then designed to maximize the anomalous signal to investigate if the Fe signal alone is sufficient to solve the structure. Details of the structure determination process will be presented.

P12.02.024 AN EFFICIENT PROBABILISTIC APPROACH FOR MAD PHASING. A. Lebedev, G. P. Bourenkov and H. D. Bartunik, Max-Planck Research Unit for Structural Molecular Biology, MPG-ASMB c/o DESY, Notkestrasse 85, 22603 Hamburg, Germany; G. N. Murshudov, CLRC, Daresbury & Structural Biology Laboratory, University of York, U.K.

A probabilistic model of an X-ray phasing experiment has been built following a Bayesian approach. The model accounts for the main features of the experiment; uncertainties in all parameters of the model are considered during calculation of the moments of structure factors. Due to the specific form of the probability distribution function, it has been possible to develop a fast algorithm for its maximisation. In the theoretical consideration, observable random variables refer to channels of a detector (to the pixels of a 2D-detector), which means that the algorithm could be extended to include the processing of a raw data, scaling and merging of equivalents along with the refinement of reference atom parameters. Experimental data are expressed in the form of the conditional probability distribution function of the observable random variables, given the crystal structure factors. In the algorithm the quadratic approximation of the logarithm of this function is used (which corresponds to the "normal distribution of the experimental intensities"). The consistent treatment of experimental data and model uncertainties and the development of an appropriate algorithm are especially important in MAD experiments, which are characterised by low signal to noise ratio.

P12.02.025 STRUCTURE OF THE UREA+ SUBERIC ACID INCLUSION COMPOUND AT ROOM TEMPERATURE AND BELOW 205K. I. Peral, G. Madariaga, T. Breczewski, Departamentos de Física de la Materia Condensada y Física Aplicada II, Facultad de Ciencias, Universidad del País Vasco, Apdo. 644,48080 Bilbao, Spain.

In urea inclusion compounds guest molecules are located in a structure of linear and parallel tunnels formed by an extensively hydrogen-bonded arrangement of urea molecules (host substructure). Structural compatibility between host and guest components is fundamental to most inclusion phenomena. As a consequence, appropriate guest molecule must be based on a sufficiently long alkane chain with only a limited degree of substitution of this chain allowed [1].

The urea+suberic acid inclusion compound undergoes a structural phase transition at 205K. Our work on this compound has been focused on the resolution of the structure of both phases.

Oscillation photographs show that the c^*_g and c^*_h axis of both subsystems are parallel but mutually incommensurate ($\rho=c^*_g/c^*_h=0.908(1)$). The rotational symmetry and the detected systematic absences of the diffracted intensities allow to assign the superspace group $X3_112(00\rho)$ (a=b=14.163(5) Å, c=10.979(4) Å, $\alpha=\beta=90^o$ $\gamma=120^o$). The superspace group is fairly enough to establish the guest packing in the urea tunnels. Suberic acid molecules are located along the tunnels, with an orientational disorder generated by the 3 fold axis. There exists a correlation of $^1/_3c_g$ between the relative positions along the urea tunnels of guest molecules belonging to adjacent tunnels. Nevertheless, the weakness of the interaction host-guest prevents an accurate determination of the guest molecules positional parameters. X-ray diffraction experiments in the low temperature phase are in progress.

P12.02.026 THREE DIMENSIONAL EXAFS OF PROTEINS USING CRYSTALLOGRAPHIC DATA. Richard W. Strange, Kan C. Cheung & S. Samar Hasnain, Synchrotron Radiation Department, CCLRC Daresbury Laboratory, Warrington, Cheshire WA4 4AD, UK.

We describe a new approach to EXAFS data analysis which uses high resolution crystallographic information combined with full inter-ligand multiple scattering theory. This approach can yield 3D EXAFS information at atomic resolution at metal centres in proteins and the method can be extended to provide a similar model of the metal centre where no crystallographic data is yet available. We illustrate this by application to the type-1 and type-2 Cu centres of the nitrite reductase from *Alcaligenes xylosoxidans* for which crystallographic data at 2.1Å resolution is available.

P12.02.027 THE D.A.F.S. SPECTROSCOPY : TECHNIQUES AND APPLICATIONS. J.L. Hodeau, H. Renevier, M.G. Proietti*, J. Garcia*, J.F. Berar, S. Bos, V. Favre-Nicolin, P. Wolfers, Lab. de Cristallographie-CNRS, BP 166, 38042 Grenoble 9, France, (*) ICMA-CSIC, Univ de Zaragoza, 50009 Zaragoza, Spain

The DAFS (Diffraction Anomalous Fine Structure) spectroscopy is an atomic and site selective probe which gives XAFS-like information on the electronic structure and the local atomic environment as well as on the long range ordered crystallographic structure. A DAFS experiment consists in measuring the Bragg peak intensities as a function of the energy of the incoming X-ray beam. Much efforts are being made at the French CRG (Collaborative Research Group) beamline BM2-D2AM at the ESRF (European Synchrotron Radiation Facility) to develop the data acquisition and the data analysis.

After an introduction to the DAFS spectroscopy, we will show the experimental requirements for such studies. We will present the analysis of the EDAFS oscillations (Extended DAFS) and point out the interest of using the DAFS spectra to recover quantitative information about the crystallographic structure and particularly to the positions and Debye Waller factors of the anomalous atoms.

Several applications will illustrate the spatial and site selectivity of the DAFS spectroscopy. For the study of powdered catalytic samples containing diluted particles, we can separate the absorption spectra of the particles from those of the support. On superlattices we can extract the EDAFS information of the interface layers, corresponding to 6% of the multilayer. On thin films such as strained III-V semiconductors, we could obtain quantitative information by using both a single first shell analysis and a multishell analysis on the raw data using theoretical phase shifts and amplitudes [1], and we found that Ga-P and GaAs bond distances in the Ga(As1-xPx) single epilayer remain very close to their respective bulk values, independent of the residual strain. In conclusion we will discuss the strengths and limitations of DAFS method.

P12.02.028 XANES-SPECTRA AND THE CONDUCTION BAND OF SEMICONDUCTORS $AgGaS_2$, $CdGa_2S_4$, and $InPS_4$. A.A.Lavrenryev, B.V.Gabrelian, I.Ya.Nikiforov, V.A.Dubeyko, Don State Technical University, 344007, Rostov-on-Don, Gagarin sq.1, Russia.

The semiconductor compounds $AgGaS_2$, $CdGa_2S_4$, and $InPS_4$ are of interest because their crystal structures form the row: chalcopyrite - defective chalcopyrite - twice defective chalcopyrite. In this row the atom of sulphur in $AgGaS_2$ has 4, in $CdGa_2S_4$ - 3, and in $InPS_4$ - 2 the nearest neighbours. For all these compounds the XANES K-spectrum of sulphur and K-absorption spectrum of phosphorus in $InPS_4$ with the X-ray spectrograph DRS-2 have been obtained with the resolution about 0.2 eV. Using FEFF7 code [1] in the approximation of the multiple scattering theory of high order the K-absorption spectra of S and P in the compounds investigated have been calculated. The obtained theoretical curves reflect satisfactorily all the particularities of the experimental spectra. The local partial density of states of all components in these compounds have been calculated in the frame of the full multiple scattering theory in the approximation of the local coherent potential [2]. The same crystal potential calculated according to FEFF7 code, has been applied. In this case the curves of DOS show all features of the fine structure of the experimental spectra. It was found, that the transition from "pure" chalcopyrite to the defective and twice defective one results in the change of the fine structure of XANES-spectra. The investigation of the influence of the core vacancy on the partial unoccupied p-DOS has been carried out. This influence is shown to be rather strong for p-states of phosphorus, and it can not be neglected when one calculates the form of XANES of K-spectra of P in the sulphides.

P12.02.029 THE FEATURES OF THE CONDUCTION BAND OF SEMICONDUCTORS GaN and BN IN DIFFERENT CRYSTALLOGRAPHIC MODIFICATIONS. B.V.Gabrelian, A.A.Lavrentyev, I.Ya.Nikiforov, T.P.Zhdanova, Don State Technical University, 344007, Rostov-on-Don, Gagarin sq.1, Russia.

The compounds GaN and BN are the wide-gap semiconductors. Being of high hardness BN is applied as superhard material as well as light-emitting diod in different optoelectronic devices. Using the FEFF7 code [1] the XANES K-absorption stectra of Ga, N, and B in semiconductors GaN and BN have been calculated. The calculations have been carried out for the cubic (zinc-blend) and hexagonal (wurtzit) modifications of GaN and BN. For BN the graphite modification has been also investigated. The satisfactory agreement between the calculated and experimental XANES K-spectra has been achieved. Using the same crystal potential the local partial densities of electron states of B, N, and Ga have been calculated in the approximation of the local coherent potential (full multiple scattering). The distributions of the partial densities of electron states of the compounds investigated have the rich fine structure that depends on the type of the crystallographic modification. It can be seen at the experimental X-ray spectra too.

P12.02.031 USE OF POWDER X-RAY DIFFRACTION IN DETERMINATION OF TUNNEL STRUCTURE TYPE ION EXCHANGERS. A. Clearfield, X. Ouyang, D.M. Poojary, Department of Chemistry, Texas A&M University, College Station, Texas 77842-3012 USA

A group of inorganic ion exchangers has recently been synthesized and their structures determined “ab initio” from in house powder X-ray data. These compounds have framework structures enclosing tunnels or cavities in which are sited exchangeable cations. The phase changes and structures of these compounds brought about by exchange of protons, alkali and alkaline earth cations will be described. Powder neutron diffraction was utilized to locate acid H atoms (in collaboration with Santiago Garcia-Granda, University of Oviedo). This structural information revealed details of the exchange mechanism.

P12.02.032 CRYSTAL STRUCTURE OF A NEW BINARY RHENIUM-OXIDE. T. Hartmann, G. Miehe, G. Wltschek, H. Fuess, Materials Science, Darmstadt University of Technology, Petersenstr. 23, D-64287 Darmstadt, Germany, H. Ehrenberg, Interdisciplinary Research Centre in Superconductivity, University of Cambridge, Madingley Road, Cambridge, CB3 0HE, United Kingdom, T. Buhrmester, Institute for Physical Chemistry, Darmstadt University of Technology, Petersenstr. 20, D-64287 Darmstadt, Germany, J. Galy, CEMES/CNRS, 29 Rue J. Marvig, F-31055 Toulouse Cedex 4, France

The crystal structures of ReO_2 [1,2], ReO_3 [3] and Re_2O_7 [4] have already been reported, but, except for attempted indexing in a tetragonal [5] and a monoclinic [6] setting, the structure solution

of Re_2O_5 is still missing. Therefore a pellet containing ReO_2 and ReO_3 in ratio 1:1, which gave the theoretical composition Re_2O_5, was heated in an arc melting furnace under argon atmosphere. The very hygroscopic, royal blue product has been investigated by X-Ray powder diffraction using a STOE STADI-P with germanium-monochromatized Cu-Kα-radiation and a position-sensitive detector with 6° aperture in transmission mode. The diffraction pattern could be indexed on the basis of a tetragonal cell, the structure solution from powder data revealed space group $I\bar{4}$ m2. The structure refinement by the Rietveld method lead to a = 5.1716(4) Å and c = 13.356(2) Å with Re(1)-atoms on the 4f-site (0, ½, 0.0199(3)) and Re(2)-atoms on the 2d-site (0, ½, ¾). Oxygen-atoms with O(1) on the 8g- (0.25, 0.25, 0) and O(2) on the 4f-site (0, ½, -0.85(4)) forming layers of tetragonal pyramides with shared corners give a five-fold coordination of the Re(1)-atoms. The Re(2)-atoms should be coordi-nated by four oxygen-atoms either on the 8i- or half occupying the 16j-site forming isolated tetrahedra, but because of very high isotropic temperature factors, the oxygen-positions could not be determined precisely. This structure model yields to the stoichiometry Re_3O_{10} for the studied compound.

P12.02.033 STRUCTURE DETERMINATION OF Nd_2CuO_4 FROM ELECTRON DIFFRACTION DATA. C. Bougerol-Chaillout, D. Tranqui, Laboratoire de Cristallographie CNRS, BP166, 38042 Grenoble cedex 9, France; M. Gemmi, A. Migliori, CNR-LAMEL, Via Gobetti, 101, I-40129 Bologna, Italy; G. Calestani, Dip. Chimica Generale ed Inorganica, Universitˆ di Parma, Viale delle Scienze, I-43100 Parma, Italy.

Nd_2CuO_4 is tetragonal (I4/mmm, a = 3.945(2) Å, c= 12.176(4) Å, space group I 4/mcm) and remains the same down to 4K. Above room temperature, $SrBiO_3$ keeps the same structure until decomposition around 700°C, whereas the K-doped phases decompose around 300°C. Electron diffraction data corresponding to the [100], [110], [210], [111], and [311] zone axes were recorded on crystallites of a powder sample. Two different procedures were used : the microdiffraction mode with a condensor aperture of 15µm and a spot size of 7nm, and the SAED mode over an area of 300nm in diameter. In the former case, data were recorded on photographic films, which were digitised using a CCD Kodak Megaplus camera; the IDL software was used for integration; in the latter case data were directly recorded on a Gatan Slow Scan CCD camera and intensities were extracted using the QED v1.0 package [1]. Two approaches were used to solve the structure. From a Patterson type analysis, which was successfully used previously in the case of a complex oxide [2], two sets of Nd-Nd and Nd-Cu vectors on the Patterson projection map along [110] were identified and thus Nd and Cu atoms were located. By direct methods, tested using SIR97 [3] with a 3-D data set of intensities obtained by merging (R=0.28) the ED patterns using common rows of reflections, the Nd, Cu and one O atoms could be identified in the E-map of the first solution. The remainder of the structure was completed by difference-Fourier technique and by symmetry considerations and refined using electron data. In spite of a high final R-factor, obviously due to dynamical effects, the refinement gave reasonable isotropic temperature factor and led to a model in close agreement with neutron data.

P12.02.034 Ta_2P, A CASE STUDY OF COMBINING THE ADVANTAGES OF ELECTRON DIFFRACTION AND X-RAY POWDER DIFFRACTION. M. Boström, Stockholm University, Structural Chemistry, 106 91 Stockholm, Sweden, magnusb@struc.su.se and Th. E. Weirich, Darmstadt University of Technology, Materials Science, Petersenstrasse 23, 64287 Darmstadt, Germany, weirich@hrzpub.tu-darmstadt.de

The feasibility of solving inorganic heavy atom crystal structures by direct methods with electron diffraction intensity data was investigated in a recent study with Ta_2P as an example [1]. All the 24 Ta positions in the unit cell could be located from the ED data using the direct methods program SIR97 [2]. However, none of the phosphorus atoms in the cell could be detected in that study. In the present study we show the powerful possibilities given by combining electron crystallography with x-ray powder methods for solving inorganic crystal structures from powders. X-ray powder diffraction data was collected on a STOE diffractometer. A Rietveld refinement was done with the Ta positions determined from the ED data as a starting model. After refining the Ta positions with the X-ray powder data the 12 P atoms in the unit cell could be located by difference Fourier synthesis. Also is shown that the heavy atom structure could be solved directly by image processing of high resolution electron micrographs.

P12.02.035 STRUCTURAL INVESTIGATIONS OF CLUSTER COMPOUNDS IN THE SYSTEM $BA_4NB_2O_9$ - NB/NB_2O_5 - TIO_2. G. Nilsson, Dept. of Inorganic Chemistry, and G. Svensson, Dept. of Structural Chemistry, Arrhenius Laboratory, Stockholm University ,S-106 91 Stockholm

Several syntheses were made in the system $Ba_4Nb_2O_9$ - Nb/Nb_2O_5 - TiO_2 , varying the Nb/Nb_2O_5 ratio in order to obtain different oxidation states of Nb (+2 → +4). The samples prepared were not found to be single phase, but several yielded single crystals. Single crystals, all identified as new phases, were taken from three different samples and single crystal *X*-ray diffraction data was collected for each on a STOE image plate system. Three types of compounds where found with different degrees of cluster condensation. One structure, isostructural with the compound $Ba_4Nb_{14}O_{23}$, containing triple chains of corner sharing Nb_6 octahedra, was refined, showing partial or replacement of Nb by Ti at specific Nb positions. The composition of the compound was found to be approximately $Ba_4Nb_{13}TiO_{23}$, as determined by the structural refinement, which is in good agreement with findings in electron dispersive spectroscopy (EDS) investigation. A second phase, with two dimensional condensed Nb_6O_{12} clusters, is believed to be related to the compound $Ba_2Nb_5O_9$, with partial replacement of Nb for Ti. The third, new phase, was structurally solved (R_w=2.68%, R_{obs}=2.68%) and found to be monoclinic with the space group Cm and the cell parameters *a*=8.9373, *b*=15.4798, *c*=9.4145 Å and γ=90°. It is a close packed pseudohexagonal structure with merohedral multiple twinning, containing three different types of metal clusters, Nb_6O_{12}, Ti_3O_{13} and Ti_3O_{10}. More over, high resolution transmission electron investigations and electron diffraction showed the occurence of defects and disorder. The composition was refined to $BaNb_{5.915}Ti_{4.185}O_{16}$ which is in good agreement with what was found in EDS analysis. This compound will be further discussed.

P12.02.036 CRYSTAL STRUCTURE OF $Nd_5W_{11}O_{39}$. C. Grenthe[1], M. Sundberg[1], A. Guagliardi[2] and P.-E. Werner[1], [1]Department of Inorganic and Structural Chemistry, Arrhenius laboratory, Stockholm University, S-106 91 Stockholm, Sweden, and [2]C.N.R.-IRMEC c/o Dip. Geomineralogico Campus Universitario, Via Orabona, 4, 70125 Bari, Italy.

The crystal structure of $Nd_5W_{11}O_{39}$ has been determined by a combination of X-ray powder diffraction, high-resolution transmission electron microscopy (HRTEM) and electron crystallography methods. The unit cell dimensions are *a*= 3.862, *b*=35.951 *c*=21.897 Å, space group *Pbcm* (No.57).

HRTEM images (JEOL 3010, 300kV) taken along the *a*-axis showed all the projected neodymium and tungsten positions. EDS-analysis of individual crystals indicated an Nd-content of about 30-33 at%.

The direct method program system EXPO (1) was used to determine the three dimensional distribution of the cations. All metal atom positions were found in approximately two planes perpendicular to *a*. The oxygen atoms were then introduced into the model by consideration of interatomic (W-O), (Nd-O) and (O-O) distances. The final R_F value obtained by Rietveld refinement was 12.9%.

The structure is built up of pentagonal columns (PC - a WO_7 pentagonal bipyramid sharing its equatorial edges with five WO_6 octahedra, stacked by cornersharing) connected to ReO_3-type fragments consisting of three octahedra. These units form ´pillars´ along *c*. These ´pillars´ are joined by pairs of tilted octahedra (W_2O_{11} groups) to form corrugated layers perpendicular to *b*. The Nd atoms (7- or 8-coordinated) are located in the space between these layers, and form the only link between them. $Nd_5W_{11}O_{39}$ thus represents an entirely new type of PC structure.

The unit cell parameters of $Nd_5W_{11}O_{39}$ are similar to those previously reported for $Nd_{10}W_{22}O_{81}$ (2). No structure model of the latter compound has been published, however.

P13.02.001 NANOSECOND TIME-RESOLVED X-RAY CRYSTALLOGRAPHY: EARLY STRUCTURAL EVENTS IN THE PHOTOCYCLE OF A XANT. Perman, Ben [1], Srajer, Vukica [2], Ren, Zhong [2], Teng, Tsu-yi [2], Anderson, Spencer [1], Pradervand, Claude [2], Ursby, Thomas [3], Bourgeois, Dominique [4], Schotte , Friederich [4], Wulff, Michael [4], Kort, Remco [5], Hellingwerf, Klaas [5], Moffat, Keith [2], [1] Department of Biochemistry and Molecular Biology, and the [2] Consortium for Advanced Radiation Sources, University of Chicago, Chicago IL 60637, USA; [3] Molecular Biophysics, Chemical Center, Lund University, P.O.B 124, S-221 00 Lund, Sweden; [4] European Synchrotron Radiation Facility, 38043 Grenoble Cedex, France; 5Laboratory for Microbiology, E.C. Slater Institute, 1018 WS Amsterdam, The Netherlands

Photoactive yellow protein (PYP) is a member of the xanthopsin family of eubacterial blue light photoreceptors. On absorption of light, PYP enters a photocycle that ultimately transduces the energy contained in a light signal into an biological response. Time-resolved X-ray crystallography was used to analyze a series of thermal intermediates in the relaxation of the protein after photoelectronic excitation of the chromophore. Laue data with nanosecond time resolution was collected at white beam station ID-9 at the ESRF at several time points between 1ns and 10ms. Trends in the data were interpreted through |F1ns| - |Fdark| difference Fourier maps. One intermediate structure has been refined against differences in the observed structure factors. This structure reveals regions of flexibility that comprise the chromophore binding pocket. Specific regions of flexibility lower the activation energy barrier between the dark state, denoted pG, and [pR], and help initiate entrance into the photocycle. The combination of new H-bonds and steric hinderance serve to explain why the chromophore does not simply undergo immediate thermal relaxation to the pG state and why PYP has a high quantum yield of entrance into the photocycle. This study provides direct structural results on the initial processes of transduction of light energy and evidence for the rapid evolution of an important physiological signal.

P13.02.002 TIME-RESOLVED PROTEIN CRYSTALLOGRAPHY BASED ON LIMITED-BANDWIDTH LAUE DATA COLLECTION WITH A CCD. H. D. Bartunik, G. Bourenkov, D. Kosciesca, Max-Planck Research Unit for Structural Molecular Biology, Protein Dynamics group, MPG-ASMB c/o DESY, Notkestrasse 85, 22603 Hamburg, Germany, A. N. Popov, European Molecular Biology Laboratory (EMBL) Hamburg Outstation, Notkestrasse 85, 22603 Hamburg, Germany.

The use of the limited-bandwidth Laue diffraction technique and a CCD detector with rapid readout permits measurements of a complete set of structure factors to high resolution within at total of about 100 sec. This is demonstrated by a number of applications using bandwidth $\Delta E/E \approx 5\text{-}10$ % on the wiggler beamline BW6 at DORIS and a MAR CCD detector system. The bandwidth has been defined by a graphite double-crystal monochromator and by a multilayer monochromator, respectively. The readout time of the MAR CCD detector was about 5 sec. Highly complete sets of structure factors have been obtained from series of still exposures at different angles of crystal rotation. The quality of the data proved to be comparable to the case of the conventional monochromatic rotation method. The new diffraction method offer a number of potential advantages over fine-angular interval white-beam Laue methods [1]. These include a) a higher signal-to-noise ratio, b) the absence of harmonic overlaps, c) strongly reduced effects of radiation damage, d) the possibility to use crystals of much higher mosaicity.

The method is also of interest for Laue diffraction experiments using (tapered) undulator radiaton with similar bandwidth. The limited-bandwidth Laue diffraction technique may be applied on even shorter time scales when pixel detectors [2] or other area detectors with extremely short read-out times become available.

P13.02.003 A WAVE FIELD OF PROBABILITY AND THE FORM OF CRYSTALS. G.P. Shpenkov, Institute of Mathematics and Physics, Technical University, 85-796 Bydgoszcz, Poland, and L.G. Kreidik, Department of Physics, Technical University, 220027 Minsk, Belarus.

The relation between the form and contents is vital to the understanding of the structure and geometry of crystal substances. The roentgenographic method has greatly enhanced the understanding of this relation. At the same time, in some degree, the study of the structure has diverted attention from the investigation of crystal forms. However, an analysis of the characteristic angles of crystals, determining their form, was and still is an important scientific problem.

We offer such an analysis for the first time on the basis of the abstract wave theory of probabilistic processes. The notion of the density of phase probability Ψ is introduced.

Discrete elements of the wave probabilistic field are considered as "atoms" of such an abstract discrete-wave field. The correspondence of the mass numbers of the abstract atoms of the probabilistic wave field with the atoms of real physical space is demonstrated here.

The application of a theory of the wave phase probability for material spaces in the solid state is presented. The material realization of the superposition of elementary solutions, obtained from the equation for the wave field of probability, is shown in concrete examples of the crystal structure of natural minerals. The characteristic angles of the minerals are compared with the corresponding angles of the polar function of the wave phase probability.

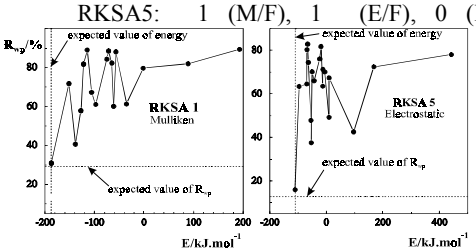
The theoretical data presented confirm that the directions of the chemical bonds are determined by the superposition of elementary solutions of the equations for the wave field of probability. These results can be used for the prediction of the molecular and crystalline structures.

P13.02.004 PREDICTION OF CRYSTAL STRUCTURES OF TWO RARE SUGARS - INFLUENCE OF ATOMIC CHARGE TYPES. Ďurík, M., Smrčok, L, Tunega, D., Institute of Inorganic Chemistry, Slovak Academy of Sciences, SK-842 36 Bratislava, Slovak Republic.

Crystal structures of two sugars RKSA1 ($P2_1$) and RKSA5 ($P6_2$) (40 atoms per molecule) were predicted by potential energy minimization method. Two types of atomic charges - Mulliken (M) and those derived from molecular electrostatic potential (E) were used in calculations together with Williams force field. For each type of atomic charges 20 trial crystal structures were generated either with cell parameters optimized (O) or fixed (F). Each generated crystal structure was compared to the corresponding experimental powder pattern collected on STOE diffractometer by means of Rietveld refinement. A scale factor, zero-point, *W* and *Q* were the only refined parameters.The numbers of correct crystal structures were as follows:

RKSA1: 2 (M/F), 3 (E/F), 1 (M/O), 1 (E/O);

RKSA5: 1 (M/F), 1 (E/F), 0 (M/O), 0 (E/O).



All successful predicted structures corresponded to the expected minimum of potential energy.

Conclusion: the force field we used was not very sensitive to the choice of atomic charges, though they differed a lot for some atoms within the molecules.

P13.02.005 INTERATOMIC POTENTIAL FITTING FOR STRUCTURE MODELING OF ALKALINE EARTH CUPRATES. N.N.Eremin, L.I.Leonyuk, V.S.Urusov, Geological Faculty of Moscow State University, Moscow, Russia.

The main aim of this study was to carry out pair potential model, which was able to predict and describe satisfactorily the crystal structure and some physical properties of alkaline-earth cuprates. All calculations were performed using GULP [1] program package. As it was found, the conventional procedure of Cu-O pair potential parameters fitting failed to find an optimal set, available to reproduce crystal structure of any alkaline-earth cuprate. That is why the purely ionic pair potential model was modified in the following way: Firstly, for the correct modeling of CuO_4 group planar geometry the O-Cu-O three body harmonic potential was taken into account. Secondly, it was found that some Morse potential contribution to the simple Buckingham Cu-O potential enables to improve essentially the cuprates crystal structure modeling.

The developed pair potential set seems to be well transferable for different cuprates, in spite of the variety in CuO_4 groups linking. This pair potential model was applied in this work for Ca_2CuO_3, $CaCuO_2$, $SrCuO_3$ and $(Sr_{1.19}Ca_{0.73})Cu_2O_4$ crystal structure modeling. It was shown, that for all tested compounds the differences between experimental [2-4] and calculated unit cell parameters are no more then 2%, and the largest atomic shifts are less then 0.012 fractional units. Some physical (elastic) and energetic properties of compounds were predicted. A few further recommendations for structure modeling of related compounds were given.

P13.02.006 COMPUTER SIMULATION TO PREDICT STEROID POLYMORPHS. Paul Verwer, CAOS/CAMM Center

The completeness of polymorph predictions, as well as the expected accuracy of the calculated lattice energies was investigated, by comparing the results of crystal packing predictions on steroids with the polymorphs known from the CSD [1], and by comparing the calculated energies of pairs (or triples) of steroid polymorphs that are experimentally known to exist. In all calculations, the Cerius2 [2] software was used, in combination with the Dreiding-2.21 force field [3]. Steroids were used in these calculations because they represent a class of molecules which are not too small, not very flexible but neither fully rigid, of moderate polarity and also of industrial relevance.

It was found that calculated energy differences between experimentally observed polymorphs are usually less than 4 kcal/mol, indicating that this is a reasonable energy window to use in polymorph predictions. Due to the Monte Carlo based search algorithm, the set of predicted polymorphs will differ between runs. Because all structures in the 4 kcal/mol energy window are not always found, repeating the prediction runs is necessary not to miss any structures.

Finally an automated procedure has been tested to find crystal structures of stereoids containing hydroxyl groups, irrespective of the initial orientation of those groups, which can be a problem if the energy barrier between the rotamers is high. This eliminates the need to carry out separate prediction runs for every single rotamer.

P13.02.007 EXPO: THE LAST ADVANCES. A.G.G. Moliterni, C. Giacovazzo, A. Altomare, A. Guagliardi, and R. Rizzi, Istituto di Ricerca per lo Sviluppo di Metodologie Cristallografiche, CNR, 70125 Bari, Italy, and G. Polidori, Dipartimento di Scienze della Terra, Universita', 06100 Perugia, Italy

The package EXPO [1] is devoted to solve crystal structures from powder data. The program first estimates the intensity values of each reflection *via* a pattern decomposition, then finds a structural model *via* Direct Methods. The main features of EXPO including the new ones, are the following: Automatic peak-search and preliminary FWHM refinement; Automatic integrated intensities extraction;Automatic structure solution by Direct Methods; Optimisation of extraction process by exploiting several kinds of prior information; Preliminary automatic Rietveld refinement ; A powerful graphic interface both for profile analysis and structure interpretation; A combined use of neutron and X-ray data, or electron and X-ray data to improve the quality of the structural model. By courtesy of Prof. P. E. Werner , we have integrated the program TREOR [2], in the version of EXPO under development. Several modifications into TREOR are in progress to increase the effectiveness of the indexing process; a friendly graphical interface has also been added.

P13.02.008 CRYSTAL STRUCTURE DETERMINATION WITH THE PIMM FORCE FIELD. H. J. Lindner and T. Goerdten Institute of Organic Chemistry, Technical University of Darmstadt, 64287 Darmstadt, Germany

As our PIMM force field programme shows to be a promising tool to model crystal packings of organic compounds[1], a basic new feature has been added to simplify the determination of crystal structures of organic compounds starting from powder data alone. The global optimization of energy-based fitness values hase proven to be applicable for this purpose, but the success of this method is bound to the quality of the used potential functions and shows to be a time-consuming method. In addition, in the case of compounds whose crystal structures depend highly on electrostatic interactions even more complicated model functions than now implemented in the PIMM force field have to be used to locate local minima properly. A more effective way for the practical need of obtaining an unknown crystal structure is to directly optimize crystallographic figures of merit as the goodness-of-fit χ^2 or the residual value *R* with the implemented simulated annealing based algorithm. The possibility to check out a large amount of trial structures eases the treatment of high dimensional problems such as the calculation of flexible molecules.

T. Goerdten, H. J. Lindner, ECM-18, Eighteenth European Crystallographic Meeting, Book of Abstracts C6-P1, Praha 1998

P13.02.010 THE CATION-ORDERED SUPERSTRUCTURE OF NA_6 SODIUM SODALITE BY POWDER DIFFRACTION AND COMPUTER SIMULATION. *Branton J. Campbell, †‡Bo B. Iversen, *Jose M. Delgado, †Nick P. Blake, †Scott R. Shannon, †Susan Latturner, *†Galen D. Stucky and *†Anthony K. Cheetham. *UCSB Materials Research Lab, Santa Barbara, CA 93106, US, †UCSB Dept. of Chemistry, Santa Barbara, CA 93106, US, ‡Presently at the U. of Aarhus Dept. of Chemistry, DK-8000 Aarhus C, Denmark.

The combination of computer simulation and powder diffraction methods can greatly facilitate the characterization of complex structures when powder diffraction data alone is inadequate. We have investigated the structure of $Na_6Al_6Si_6O_{24}$ sodalite below its phase transition near 500 K, using both variable temperature synchrotron X-ray powder diffraction and lattice-energy minimization calculations. The low-temperature pseudo-tetragonal supercell was indexed using both the superlattice reflection positions and the splittings of the ordinary reflections. The average cation location was then determined, by constrained Rietveld refinement, to be near the center of the six-ring window. Possible cation configurations within the supercell were first enumerated, and then evaluated by employing both classical force-field energy and density functional theory calculations, and by comparing calculated and experimental diffraction data. Particular attention was paid to the structural features and Bragg reflections associated with the formation of the superstructure. We finally obtained a cation-ordered superstructure that both minimizes the lattice energy and adequately models the diffraction data.

P13.02.011 DEVELOPMENTS IN POWDER INDEXING: FROM CRYS2RUN TO THE INDEXER'S WORKBENCH. R.Shirley, School of Human Sciences, University of Surrey, Guildford, Surrey GU2 5XH, UK.

"The powder-indexing problem is history - just use a synchrotron..."

Data quality is certainly crucial for indexing a powder diffraction pattern when the unit cell is unknown, but indexing's solution space tends to be hostile, and limitations of specimen quality often mean that even synchrotron data cannot assure success, especially for the products of phase transitions and other specimens with poor texture and doubtful purity. With the growth in Rietveld method studies, the need for reliable indexing has never been greater, but the three classic programs in general use (ITO, TREOR and DICVOL) are each at least 20 years old, and again an IUCr Congress has come round which seems to lack any clear programme category for powder-indexing software.

The "Indexer's WorkBench" is a proposed co-operative project to integrate 32-bit versions of the available mature indexing programs into a single system running from a common graphical front end, to be implemented in parallel versions for 32-bit Windows and for LINUX. The implementers will form a virtual project team communicating over the internet. Apart from the classic programs, it is hoped that newer methods such genetic algorithms will be included, and both line-position and profile data supported. Those interested in taking part are invited to contact the author at R.Shirley@surrey.ac.uk.

CRYS2RUN will also be demonstrated. This is a simple script-based system for non-specialists that runs under MSDOS and calls the major indexing programs using CRYS as a front end, feeding data automatically to the indexing programs via the format-translator QDAT. CRYS is now at v9.28. Through CRYS2RUN, it supports ITO v12, TREOR90 and DICVOL91, and also now LZON and LOSHFZRF (new PC versions of the combined Shirley, Louër & Visser zone-finding/heuristic/dichotomy programs). CRYS2RUN, CRYS, QDAT, etc., are available free for non-commercial use via the CCP14 web site (see http://www.ccp14.ac.uk/tutorial/crys/index.html).

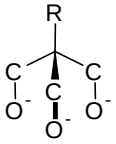
03. COMPUTERS IN ANALYSIS, MOLECULAR MODELLING AND MOLECULAR DESIGN

P07.03.001 SIMULATION OF DIAMOND (100) AND (110) SURFACE STRUCTURE AND SURFACE ENERGY. Chongmu Lee, Department of Metallurgical Engineering, Inha University, 253 Yonghyeon-dong, Inchon 402-751, Korea

The structures and energies of diamond (100) and (110) surfaces have been calculated by the computer simulation employing the lattice statics technique based on Tersoff potential. The simulation results suggest that the reconstruction patterns of the (100) and (110) surfaces are (1×1) and (2×1) respectively and that the surface energies of the two surfaces are 6,671.3 and 4,032.0 erg/cm2, respectively. According to the simulation results the surface reconstruction of the (100) surface mainly consists of the reduction of the interlayer spacing between the first and second atomic layers, whereas that of the (110) surface consists of the contraction of the interplanar spacing between the neighboring atoms in the first atomic layer as well as the contraction of the interlayer spacing between the first and second atomic layers. Besides them the stress components of the first four atomic layers of the surfaces were obtained and their effects on the surface adsorption were discussed.

P07.03.002 HIGH FASHION IN EDINBURGH: USING CSD DATA TO MODEL METAL OXIDE SURFACE INTERACTIONS. Andrew Parkin, Steven Harris, David Henderson, Simon Parsons and Peter Tasker, Edinburgh Centre for Surface Coordination Chemistry, Department of Chemistry, University of Edinburgh.

Our approach to modelling the interactions of metal surfaces with various donor groups involves the use of predetermined crystal data, in particular from the CSD and the ICSD. As most metals are lightly oxidised in air we use known crystal structures of the appropriate metal oxide or hydroxide to identify the most prominent growth faces, taking into account classical morphological theory. Then, by studying single-crystal forms of ligands both free and bound to various metal clusters or single metal atoms, we can use a pattern-matching approach to constructing a model for the interaction of a ligand with the correct surface of our metal oxide.



Most of the work to date has been performed on aluminium oxide and the theories developed from the above approach have been tested using surface adsorption studies. Our initial aim is to try to explain how a surface-active ligand binds and we hope to develop this remit towards ligand design. The modelling has also been used to predict likely interactions of carboxylate, phosphate, and the so-called “tripodal ligands” (shown in the diagram) with aluminium, and to explain the successes (and failures!) of our attempts to make these complexes.

P08.03.001 A COMPARATIVE STUDY OF SOME ABSORPTION CORRECTION PROGRAMS. J. F. Van der Maelen Uría, M. Pérez-Priede, and S. García-Granda, Dpto. Química Física y Analítica, Facultad de Química, Universidad de Oviedo, E-33006 Oviedo, SPAIN.

A comparative study of different empirical and semiempirical absorption correction methods widely used for structure determination in single-crystal X-ray diffraction procedures is made in order to shed some light on the controversy about their utility and the meaning of the parameters used by them. A new version of the local data reduction program called REFLEX [1] has been used to accomplish this work. This version of the program performs the calculation of the direction cosines for the data by using two different but equivalent algorithms, which allows us the use of such empirical absorption correction methods as SHELXA and the new version of DIFABS running over F^2 included in the EUCLID program package. Both these methods, together with the empirical XABS2 method and the semiempirical EMPABS method, are used to make a comparative study of the absorption correction for some mono-, bi-, and trinuclear Ru compounds as well as other organometallic compounds containing W [2].

Calculations show that both SHELXA and DIFABS give quite the same results for every compound studied, whereas XABS2 has to be used in conjunction with EMPABS in order to take into account the dependence of the absorption correction in other variables apart from θ. On the whole, the preferred method for applying absorption correction (when an accurate description of the sample shape and size is very difficult, if not impossible, to obtain) has found to be the semiempirical EMPABS method (given a ψ-scan properly made) followed by the empirical XABS2 method.

P08.03.002 POWDERX - A WINDOWS95-BASED PROGRAM FOR POWDER X-RAY DIFFRACTION DATA PROCESSING. Cheng Dong, National Laboratory for Superconductivity, Center for Condensed Matter Physics & Institute of Physics, Chinese Academy of Science, P. O. Box 603, Beijing 100080, China.

A Windows95-based program (PowderX) has been written for powder x-ray data processing and analysis. PowderX takes full advantage of the graphical interfaces of the Windows95. It uses pull-down menus and mouse to control the program executions. PowderX provides the convenient tools for processing powder x-ray diffraction data. It can be used for plotting x-ray patterns, data smoothing, background subtraction, α2 elimination, peak search, indexing and correcting zero-angle errors. PowderX has many useful features:

A new and accurate Cu $K\alpha_2$ elimination algorithm is used.

Zero-angle shift can be corrected automatically after peak search and no internal standard material is required.

Read data in more than 10 different format, including data obtained by diffractometer from several well-known makers (Mac Science, Philips, Rigaku, Siemens, etc.).

PowderX can also be used for data format conversions and prepared data for ab-initio crystal structure determination, whole-pattern fitting and Rietveld refinement programs such as DBWS, EXPO, FULLPROF, GSAS, RIETAN, SIMPRO and XFIT.

It is very easy to use. It can produce the input file for Treor90 after peak search automatically too. Only minor editing is needed.

It can perform both automatic and manual peak search and background subtraction.

Index of crystal plane can be automatically labeled in the plot if you know the lattice parameters.

It is freely available for academic and non-commercial use. The present version of PowderX can be obtained by mailing the author, Cheng Dong at chengdon@aphy.iphy.ac.cn.

P08.03.003 DIRECT-SEARCHER AUTOMATIC SYSTEM (Ver. 4) FOR SOME ORGANIC COMPOUNDS RUNNING ON PCs. K. Okada, Ricoh Research and Development Center, Yokohama, Japan, and S. Okada, Science University of Tokyo, Tokyo, Japan.

The DIRECT-SEARCHER system version 4 (DS*SYSTEM4) has been developed and consists of more than twenty main programs and subroutine libraries. The main new features are: (1) development of a new phase solver ShakePSD (Shake Patterson, Search and Direct methods), (2) update of a least-squares program LSBF for refining on $|F_o(h)|$ or $F_o(h)^2$ considering anomalous dispersion terms, (3) adaptation of the interface to/from other program systems (DIRDIF, *Shake and Bake*, Shelex, PLATON/PLUTON, Cerius2 and CSD), and (4) preparation of Postscript and HP-GL files with CRT display for graphical output on MS-Windows 95/98 and NT 3.x/4.0/5.0 operating systems.

ShakePSD becomes an automatic phase solver being able to handle both heavy-atom methods (Patterson function and search for all remaining atoms) and direct methods (tangent formula and/or minimal function[1]) within one program. The input data are cell constants, space group, number of atoms with atomic kinds and observed structure factors $|F_o(h)|$. The outputs are 2D-projection diagrams of the molecules in a unit cell. The ShakePSD program succeeds over previous capabilities[2], adopts the minimal function for power up of the traditional direct methods, and determines with certainty molecule fragments.

The revised LSBF program refines atomic parameters by the least-squares method with the block-diagonal or the full-matrix approximations which treats anomalous dispersions, refining on $|F_o(h)|$ and $F_o(h)^2$.

P08.03.004 ANISOTROPIC CRYSTAL STRUCTURE VALIDATION STATISTICS: THE *R*-TENSOR. Sean Parkin, Biochemistry Department, Duke University Medical Centre, Durham, N.C., 27710, USA. sean@xray.duke.edu

An expansion of global validation statistics to include important spatial information is presented.

Assessment of quality at various stages of crystal structure determination invariably entails comparison of a variety of global indicators. At the data reduction stage, quality is assessed using R_{merge} and $I/\sigma(I)$. Later, progress in structure solution and refinement is checked by the goodness-of-fit, variants of the *R*-index, R_{cryst}, and its cross-validation counterpart, R_{free}. While such statistics are important and provide a convenient means of comparison, as scalar quantities they are quite inadequate. Any truly representative validation statistic should at the very least reflect the three-dimensional nature of the diffraction pattern and molecular model. The need for better measures of crystal structure quality has been stressed in recent years [1].

The proposed method obtains the elements of a (3x3) matrix, the *R*-tensor, via a least-squares scheme. An effective value of the particular statistic in question can then be obtained for any point or region of reciprocal space. Variation amongst effective *R*-indices (for example) for different classes of reflection can provide a wealth of additional information that can help to steer refinement strategy and to assess the final product.

Details of the algorithm and some results are given. A FORTRAN77 program 'RT' is also available from the author at the e-mail address above.

P08.03.005 SQUIDGY ELECTRONS, SHAKING THE ATOMS AND DUST IN THE STRUCTURE. D.J.Watkin, R.Cooper, Chemical Crystallography Laboratory, 9, Parks Road, OXFORD OX1 3PD L.Schroeder, A. Cousson, Laboratoire Leon Brillouin (CEA a CNRS), CE Saclay, Batiment 563, 91191 GIF-SUR-YVETTE Cedex (France), W.Paulus, RWTH Aachen, Institut fur Kristallographie, Jõgerstrasse 17-19, 52056 AACHEN (Allemagne)

Development of the CRYSTALS program continues in two major directions - the provision of a safe environment for routine work (see CRYSTALLOGRAPHIC TOOLS FOR CHEMISTS, ms 12FF), and the incorporation of useful facilities previously only found in stand-alone programs. Amongst recent introductions are:

1 Modified distributions to permit the modelling of electron density distributed uniformly along a line or over an annulus or spherical shell. These can be mixed with conventional thermal parameters to produce 'peaky' distributions.

2 Controlled perturbation of structures. Sophisticated refinement of difficult structures can lead to false minima. The stability of the solutions can be probed by perturbing and re-refining the structure.

3 Voids and loose packing in a structure have been modelled by filling the voids with dust-like pseudo-atoms. These can be operated on just like normal atoms, providing a useful tool for the understanding of packing.

4 Groups of atoms (or molecules) can be replaced by the enveloping ellipsoid of inertia, and these ellipsoids used to represent the molecules in packing diagrams. The ellipsoids can be mixed with conventional atoms to high light packing features.

P08.03.006 NEW FEATURES OF THE PROGRAM FULLPROF. J. Rodríguez-Carvajal, T. Roisnel, A. Daoud-Aladine and A. Bouvet, Laboratoire Léon Brillouin (CEA-CNRS), CEA/Saclay, 91191 Gif sur Yvette Cedex, FRANCE.

We present an analysis of the new features included in the last beta-version of the program FullProf. Extensive changes have been made in the source code of the program in order to increase its capabilities and to conform to the new Fortran standard. The program is written in a subset of Fortran 90 and can be compiled with ELF90 [1]. The new features include:

Multi-pattern capabilities. Three executable versions of the program exist: single pattern, fixed multi-pattern, and multi-pattern with dynamic memory allocation: the number of patterns to be treated is fixed at run time by a setting file. The user may combine different X-ray and neutron (CW and/or TOF) diffraction patterns in order to refine crystal and magnetic structures with a total control of their relative weight.

Refinement of incommensurate crystal structures. Incommensurate structures can now be refined either from a powder profile or from single crystal data. This part of the program is still being testing. The formulation is based on Fourier components of atomic displacements in 3D space. The symmetry constraints between Fourier components should be provided by the user and may be obtained from group representation theory.

The Windows 9x/NT version of FullProf can be run through the program WinPLOTR [2] that is a complete graphic interface to FullProf.

The complexity of the input control file (of extension "pcr" and called PCR-file) for non-experienced users may be overcome by using the new Java interface that allows the full preparation of this file. The interface is independent of the platform and contains full graphics features.

P08.03.007 PEAK PROFILE FUNCTION FOR POWDER DIFFRACTOMETRY WITH BRAGG-BRENTANO GEOMETRY. T. Ida and K. Kimura, Department of Material Science, Faculty of Science, Himeji Institute of Technology, Kamigori-cho, Hyogo 678-1297, JAPAN.

Experimental diffraction peaks in powder diffractometry with Bragg-Brentano geometry are generally shifted and become asymmetric due to the effects of (1) vertical (axial) divergence of the incident and diffracted beams, (2) flat-specimen, and (3) sample transparency. The above effects are mathematically treated as convolutions with asymmetric window functions. Recently, we have found analytical formulas for the vertical divergence in Bragg-Brentano geometry [1], and also an efficient method for numerical calculation of the convolution [2].

In this study, we have constructed an advanced model for the peak profile by triple convolution of the pseudo-Voigt function with the above three effects, the shape of which is determined by well-defined instrumental parameters and the linear absorption coefficient and thickness of the specimen. The validity of the model is examined by least-squares fitting to the experimental diffraction peak profiles of diluted lanthanum hexaboride (LaB_6) samples, the transparency of which are varied by mixing with different amount of starch. It has been found that the model function fairly well reproduces the experimental profiles (typically less than several % in R-factor) only by adjusting the parameters for the location and intensity of the peak, even in the case of heavily distorted profiles of the highly transparent sample with the linear absorption coefficient of 1 mm^{-1}.

P08.03.008 A NEW IDEA ON THE MOLECULAR REPLACEMENT METHOD FOR PROTEIN CRYSTALLOGRAPHY Nobuo Tanaka [1], Masami Kusunoki [2], [1] Faculty of Bioscience and Biotechnology, Tokyo Institute of Technology, [2] Institute for Protein research, Osaka University

The recent development of the computer has made it possible to search vectors from all atoms of the model quite cheaply. The present idea is to fix copies of molecules in the unit cell by calculating the observed Patterson function and the vector map calculated from the model with varied orientations. The fitting between the observed Patterson map and calculated vector map of the model which is rotated by the Euler angles is calculated quickly with the fast Fourier transform. The biggest FIT for each is collected to construct the map from which the prominent peaks are picked up as the plausible orientations. The obtained Euler angles are dedicated to the rotation of the model for the successive conventional translation search. The degree of the overlap among molecules is estimated from the volume occupied by all molecules. The unit volume is calculated to put one molecule arbitrarily in the unit cell. The present research has been undertaken as one of research and development applying advanced computational science and technology.

P08.03.009 A FORTRAN PROGRAM FOR CHOOSING REFLECTION-SETS IN AN OPTIMUM WAY FOR CROSS-VALIDATION CALCULATION. S. Parthasarathy and A. Abdul Ajees, Department of Crystallography and Biophysics, University of Madras, Guindy Campus, Chennai – 600 025, India, and H. Schenk, Laboratory for Crystallography, University of Amsterdam, Nieuwe Achtergracht 166, 1018 WV Amsterdam, The Netherlands.

Validation and cross-validation are methods of assessing the predictive ability of a statistical model and choosing between alternative models. They are based on the idea that models should be judged by their ability to predict new data, rather than the degree to which they fit the data from which their parameters were estimated. Cross-validation is an extension of validation and it aims to use the data more efficiently. Cross-validation method for choosing between two models consists of the following steps : (i) Dividing the data into k subsets (S_i , i = 1 to k, say) whose sizes are as nearly equal as possible, (ii) estimating the model parameters of one model by the validation method by using one of the subsets as the test set and calculating the free R-value for the reflections of the work set constituted by the union of the remaining k-1 subsets, (iii) repeating step(ii) k times, each time using a different subset as the work set and the union of the remaining k-1 subsets as the corresponding test set, (iv) finding the mean value of the k free R-values thus obtained, (v) repeating steps (ii) - (iv) for the other model, and (vi) selecting the model for which the mean free R-value is smaller.

An optimum way of partitioning the given set of reflections taking into account the probability distribution law of the intensities is proposed. The algorithm of the method is implemented in a Fortran porgram called CROSSVAL.

P08.03.010 TOWARDS IMPROVED REFINEMENT WITH AN ENSEMBLE-AVERAGED POTENTIAL. Rob Grothe, Molecular Biology Institute, University of California at Los Angeles

A refinement program must address two issues: selecting a quantity to maximize and deciding how to find its maximum over possible protein structure models. There is a consensus that probability is the right quantity to maximize. Maximizing a model's probability (or likelihood) density is equivalent to minimizing its energy. When Bayes' Law is used to construct the probability density of a model given observed data, the energy function is the sum of a prior energy, based upon interatomic interactions, and a data likelihood energy. These terms are often denoted by E_chem and E_xray. The formulation of E_xray has received much attention. This work focuses upon improving E_chem, the assignment of energy to a model, prior to consideration of diffraction data. A crystallographic model of a protein is an ensemble of states specified by a centroid state, which gives the average position for each atom, and atomic displacement parameter values. Until now, the prior energy assigned to a model has been the energy of the model's centroid state, neglecting the variations about the centroid. The energy of the centroid state only approximates the desired quantity: the average energy over an ensemble of states consistent with the model. This ensemble is a special case of the canonical ensemble of statistical mechanics, in which the most frequently occurring states have low energy. Since we are only interested in those states consistent with a given model, the most likely states also lie close to the model's centroid relative to its atomic displacement parameter values. Rapid, accurate estimates of this ensemble-average energy and its gradient are computed by sampling neighborhood-average energies. The ensemble-average energy has much less curvature than the conventional (static centroid) energy function. It is believed that the limited radius of convergence of conventional refinement programs results from

inappropriately sharp priors which fail to consider the uncertainty or variation in atom positions.

P08.03.011 QUANTITATIVE ANALYSIS OF ANOMALOUS ATOMIC THERMAL MOTION IN AN ORGANIC NON-LINEAR OPTICAL MATERIAL. J. M. Cole, School of Physical Sciences, University of Kent, Canterbury, Kent, CT2 7NR, UK, C. C. Wilson, ISIS Facility, CLRC Rutherford Appleton Laboratory, Chilton, Didcot, Oxon, OX11 0QX, UK, and J. A. K. Howard, Chemistry Department, University of Durham, South Road, Durham, DH1 3LE, UK.

A single-crystal neutron and X-ray diffraction study of the organic non-linear optical material, 3-(1,1-dicyanoethenyl)-1-phenyl-4,5-dihydro-1H-pyrazole (hereafter DCNP) is presented. The study was conducted in order to relate the structural characteristics of the compound to its physical properties [1-3]. The neutron study shows that some unusual atomic thermal motion is present in part of the molecule. Subsequent variable-temperature (90K, 100K, 200K, 290K) single-crystal X-ray diffraction experiments on DCNP were carried out in order elucidate the cause of the atypical thermal motion and to rule out the possibility of disorder, a looming phase-transition or some subtle form of twinning. These results show that libration is the cause of this anomalous motion. Three regions of the molecule appear to librate in an independent but concerted manner: predominantly in the molecular plane about the phenyl group, secondly in the nitrile group branch and slightly in the pyrazole group. The libration is fully characterized using THMA11 algorithms [4]. As a result, suitable corrections to the bond geometry and anisotropic displacement parameters of DCNP are made. The libration is also shown to enhance the non-linear optical effect.

P08.03.012 STRUCTURE DETERMINATION FROM POWDER DIFFRACTION DATA BY USE OF A SWARM ALGORITHM. T. Csoka and W.I.F. David, ISIS Facility, Rutherford Appleton Laboratory, Chilton, Didcot, Oxon. OX11 0QX, UK.

Recent years have shown an increase in the use and success of global optimisation search methods, specifically Genetic Algorithms [1,2] and Simulated Annealing [3], in structure determination from powder diffraction data. The Swarm algorithm [4] can be used as a viable alternative to both these methods. As in a GA, the Swarm algorithm uses a population of solution vectors, which change over time, mimicking the behaviour of a swarm of insects or a flock of birds. Accordingly, the Swarm uses co-operative adaptation techniques rather than the competitive techniques employed by GAs.

The algorithm will be illustrated with the crystal structure solutions of a range of drug substances, including salt forms.

P08.03.013 A PARALLEL COMPUTER FOR A GENETIC ALGORITHM BASED CRYSTAL STRUCTURE SOLUTION PROGRAM. K. Shankland and T. Csoka, Rutherford Appleton Laboratory, Chilton, Didcot, Oxon. OX11 0QX, U.K.

Genetic algorithm based programs typically possess intrinsic coarse grained parallelism. This is certainly the case for 'the GAP', a program designed to solve crystal structures from powder diffraction data [1].

Within 'the GAP', hundreds of potential structure solutions are evaluated for a particular generation, each evaluation consisting of generating trial diffraction data and comparing it with measured diffraction data via the method of correlated integrated intensities. As each evaluation is independent of the others, the system lends itself to a parallel implementation, particularly if an 'island model' is used.

One straightforward design for a parallel computer is based on the 'pile of PCs' concept. We constructed a cluster of four diskless dual Pentium Pro 166Mhz PCs using commodity components, and enabled communications via a matrix of 100Mb ethernet connections. A parallel version of 'the GAP', written in C and using the MPICH library, was implemented on the cluster under the control of the Linux operating system.

The benefits and difficulties encountered whilst implementing this parallel version of 'the GAP' will be fully discussed.

P08.03.014 GRAPHICAL REPRESENTATION OF ALTERNATE CONFORMERS. F. C. Bernstein, H. J. Bernstein : Bernstein + Sons, Bellport, NY 11713, USA

It is challenging to display alternate conformers, microheterogeneity and multiple NMR models in ways which convey a clear understanding of correlated and uncorrelated conformations. Assigning a color to each conformer and massing the bulk of the molecule under a background color works for broad-scale representations of molecular surfaces and secondary structure, but can become confusing when atom-by-atom representations are used with stick bonds, especially when each element is also to be assigned a distinct color. We suggest a banded-bond/dotted-atom representation, with illustrations from a new version of RasMol able to accept mmCIF and PDB data for macromolecules and core CIF data for small molecules. The impact of similar changes and CIF adaptation for other popular graphics programs are discussed.

P08.03.015 SOFTWARE FOR ANALYSIS AND MANIPULATION OF CRYSTAL STRUCTURES. David J. Duchamp, Kalamazoo, MI 49009-9159

CrystMol, a personal computer software package, provides for display, analysis, and manipulation of crystal and molecular structures of varying complexity, ranging from one-atom structures to macromolecules. CrystMol was designed as both a teaching and research tool with crystallography and crystal structures as the focus. The current released version provides interactive rotation, translation, zooming, and clipping of structures drawn in a variety of display styles including: line, stick, ball, ball & stick, thermal ellipsoid, space filling, and various combinations of these. Space group symmetry is built in, and symmetry-related units may be easily added and deleted, facilitating the study of symmetry and crystal packing. Other facilities include an electronic notebook, user libraries of structures, support for disordered structures, and three-dimensional building and editing of structures. Standard metrics

with standard deviations are available, including: bond distances, bond angles, torsion angles, non-bonded distances, hydrogen bonds, and best planes. CrystMol supports structure input by several means, including both small molecule and macromolecular versions of the Crystallographic Information File (CIF), Cambridge Data Base files, and Protein Data Bank (PDB) format files. The current released version requires a PowerPC Macintosh computer, but porting to Windows 98 is contemplated.

The next version of CrystMol is under active development, and ideas and suggestions are being solicited. The current version and current plans have been influenced significantly by discussions at the 1998 ACA Meeting and feedback from those who tested the initial version. Along with numerous other features, the next version will provide for interactive linking to background calculation applications, and a background molecular mechanics application is currently under development. One of the main challenges in design of CrystMol has been the handling of disorder (microheterogeneity) in structures, both small molecule and macromolecular. The current version makes a try at this, but new ideas from the crystallographic community would be very welcome. The author would welcome any and all suggestions on how to make CrystMol more useful in research and teaching.

To facilitate such discussions, the status of the current and development versions of CrystMol will be discussed, along with current plans. The author will be available to demonstrate CrystMol on a laptop Macintosh if suitable arrangements can be made.

P08.03.016 A MODELING SYSTEM OF MOLECULAR USED ON MICROCOMPUTER. T. Shao Fan Lin, Yomng Bing Peng Ron Chen, Lian Hu Wei, W. D. Zhang [1], Yu.Hua.Xu [2], [1] Central Laboratory, Nankai University, Tianjin 300071, P.R.China, [2] Guangdong Part Time University of Science and Technology Guangzhou 510090 P.R.China

A modeling system of molecular and crystal structure used on IBM/586 is reported in this paper. The programming language is C++ and it can be run in WINDOWS-95 or WINDOWS-98. The modeling of the molecular and the crystal structures can be completed conveniently using those 3D-dimension coordinates of atoms and the parameters of unite cell. It is very useful for crystallographers. The system has following functions: 1. Model building: The system provides powerful and convenient functions to building the 2D or 3D structural formula of an organic compound on screen: A. Drawing on screen using mouse-pointing. B. Choosing the fragments from fragment library then modify them C. Linking between sub-structures and fragments. D. Above functions can be done in 2D or 3D dimension. Then program stores those structural messages into computer 2. Modeling of molecular structure. Three kinds of molecule models can be displayed, which are stick, stick-ball and full space. Those models can be enlarged, reduced, moved and rotated. 3. Modeling of unite-cell crystal structure including the edges, atoms and bonds between atoms in the unit-cell. The model of unit-cell can be enlarged, reduced, moved and rotated too. 4. The 3D-dimension coordinate of any atom, the distance between any two atoms, the angel between the three atoms, and the angel of two planes, which are fixed by four atoms and the length of the sides of unit-cell can be measured on the screen. The system can be connected with PCPDFWIN database of ICDD and single crystal databank of Cambridge, read the data of organic compound in the databanks and display it.

P08.03.017 DINO, A VISUALIZATION SYSTEM FOR STRUCTURAL DATA. A. Philippsen Biozentrum, University of Basel, Basel 4055, Switzerland

DINO allows the visualization of different structural data types obtained by X-ray crystallography, NMR, electron microscopy, AFM and theoretical calculations, namely structures, surfaces, trajectories, scalar fields (such as electron densities or electrostatic potentials), height-grids and geometric primitives.

Using realtime 3D graphics through the OpenGL (TM) library, DINO offers both schematic and high quality graphics, transparency, depthcueing and perspective corrected stereo (crystal eye stereo on equipped machines), ready for direct output in TIFF, RGB, PostScript or Raster3D format.

At the time of writing supported formats include: PDB (coordinates), XPLOR/CNS (coordinates and maps), CCP4(maps), UHBD (potentials), MSMS (molecular surfaces), CHARMM (coordinates and trajectories) and TIFF (greyscale height-grids).

Supported architectures: SGI, DEC, Linux

DINO is freely available on the WWW: http://www.bioz.unibas.ch/~xray/dino

P08.03.020 COMPARISON OF MOLECULAR STRUCTURES DETERMINED BY X-RAY METHODS WITH THE RESULTS QUANTUM CHEMICAL CALCULATIONS. G. Raabe, Institut für Organische Chemie, Rheinisch-Westfälische Technische Hochschule Aachen, Prof.-Pirlet Straße 1, D-52056 Aachen, Germany.

Interactions between molecules in the solid state might stabilize molecular structures which would be considered unusual for the isolated molecule in the gas phase.

Such crystal- or lattice effects can be detected and explained using the solid state structure of a molecule as starting geometry in quantum chemical geometry optimizations for the free molecule. Most of the available computational methods either belong to the group of the strongly parameterized semiempirical procedures, the non-empirical *ab initio* methods, or to those schemes derived from density functional theory. Due to the size of most of the molecules under consideration, semiempirical methods are still frequently used in this field. However, some of these procedures might fail if the molecule contains structural elements which were not considered in the set of compounds used to derive the set of the underlying semiempirical parameters. Usually *ab initio* methods yield correct results in such cases. These non-empirical computational methods, however, might also lead to misinterpretations of the experimentally observed structure if, for example, the geometry optimizations are carried out at the *Hartree-Fock* level and thus correlation effects are omitted from the calculation of the gradients.

In general, knowledge of the limitations of the computational methods mentioned above is not only of utmost importance if one attempts to detect and to interpret lattice effects but also if it is the point to generate molecular structures to be used in the modelling of crystal lattices.

In this paper the author reports on possible pitfalls in the application of some quantum chemical methods in order to detect lattice effects and to obtain molecular geometries to be used in calculations carried out in order to predict hitherto unknown crystal structures.

P08.03.021 ANALYSIS OF WEIGHTING SCHEMES. R. Spagna and M. Camalli, Istituto di Strutturistica Chimica CNR, C.P.10, 00016 Monterotondo Stazione, Roma, Italy.

16 weighting schemes, taken from the more common used in literature, and a wrong and an unrealistic scheme for comparison were implemented in the program CAOS. We run refinements using data of 13 known structures of medium size complexity. The starting model was composed by the atomic coordinates refined with unitary weights and isotropic thermal parameters. Then the full-matrix refinement (on $|F|$) was repeated using each of the 18 weighting schemes until convergence was reached with anisotropic thermal parameters for

non-hydrogen atoms. After convergence, some additional cycles were added with two procedures of weight-modification designed to lessen the effects of outliers.

For each weighting scheme, we calculated the distribution of $<\Delta^2>$, $<1/w>$ and $<w\Delta^2>$ against $\sin\theta/\lambda$ and $|F|$. To compare the results, we calculated the mean value, M, and the standard deviation , $\sigma(M)$, from the distribution of $<w\Delta^2>$ and we took into account the value of $\sigma(M)$ to evaluate how much the distribution of $<w\Delta^2>$ was constant.

In order to understand by how much the refined versions differ for each structure, we calculated three indices

$IND1 = 100.0* [R\%_{(highest)}-R\%_{(lowest)}]/ R\%_{(lowest)}$

$IND2_j = <\Delta x/u_x+\Delta y/u_y +\Delta z/u_z >$

$IND3_j = (<\Delta r^2>)^{½} = (<\Delta x^2>+<\Delta y^2>+<\Delta z^2>)^{½}$

where Δx, Δy, Δz were the coordinate differences between the atoms of the version having the lowest R% and the atoms of the *j*th version, and the u_x, u_y and u_z were the e.s.u.'s of the atomic coordinate.

To try to answer the question, which is the best weighting scheme, we calculated indices of confidence obtained by calculating the averages for each weighting scheme:

$index_j=\sum_{i=1,13}(R_{lowest,i}/R_{j,i})/13$

where $R_{i,j}$ is the R factor of *i*th structure using the *j*th weighting scheme and $R_{lowest,i}$ is the lowest R obtained for the *i*th structure.

P11.03.001 A MODEL THAT CORRELATES SIDE-CHAIN CONFORMATIONS OF FF-MAS RELATED COMPOUNDS AND THEIR ACTIVITIES. D.R. Boer, H. Kooijman and J. Kroon, Department of Crystal and Structural Chemistry, Bijvoet Center for Biomolecular Research, Utrecht University, The Netherlands.

A recent discovery has shown that the final stage of the development of a human egg cell (called meiosis) is triggered by an intermediate in the post-squalene biosynthesis of cholesterol. The compound was found in the follicle fluid, where the egg cell is maturing before ovulation, and was subsequently called follicle fluid-meiosis activating sterol (FF-MAS). It is evident that the hypothetical receptor mediating this trigger could be an interesting target for development of contraceptive and fertility-increasing drugs. We are currently trying to derive structure-activity relationships for FF-MAS and related compounds.

The structure of FF-MAS resembles that of cholesterol: it consists of a rigid steroid skeleton framework of 4 fused rings, with a stretched side-chain attached to it. By varying the side-chain structure, while retaining the skeleton of FF-MAS, the influence of side-chain conformation on activity can be assessed. This poster describes the correlation between activities and side-chain conformations that are present in the crystal structures of a number of FF-MAS derived compounds.

The conformational space of the side-chain was searched using crystal structure data from the Cambridge Structural Database (CSD). Principle Component Analysis (PCA) was applied to analyse the data. The conformations found were clustered in 3 areas. To correlate conformation with activity, the PCA results were applied to the appropriate parameters found in five crystal structures of the FF-MAS related compounds, the activities of which had been determined. Conformations of side-chains of active compounds were found to occur within one cluster, whereas side-chain conformations of inactive molecules were occurring in a different one. The PCA results can therefore be used as a pharmacophore model for the side-chain moieties of the FF-MAS related compound series.

P11.03.002 AN EFFICIENT FLEXIBLE SEARCH METHOD TO DISCOVER NEW LIGANDS FROM 3D DATABASE BASED ON AUTOMATIC DOCKING. M. Y. Mizutani and A. Itai, Institute of Medicinal Molecular Design (Key Molecular Inc.), 5-24-5 Hongo, Bunkyo-ku, Tokyo 113-0033, JAPAN.

On a target macromolecule, easily finding novel lead compounds with various core structures will greatly contribute to rational drug design. We have developed an efficient method for finding ligand candidates from among a number of flexible compounds included in 3D database when the receptor structure is known. The method, named ADAM&EVE, makes use of our automatic docking method ADAM [1], and is able to select ligand candidates based on the stability of interaction energy of the most stable docking structure of each small compound and receptor. As same as ADAM method, ADAM&EVE can fully explore the conformational space for each compound to construct the stable docking models.

Our method has been applied to several test cases, and all the cases were successful. In the case of acetylcholinesterase (AChE), 25 hit compounds that have different core structures to known ligands were found to have moderate potent activities ($IC50 = 10^{-6} \sim 10^{-7}$ M). Also in other test cases, new active compounds were discovered by our method.

P11.03.003 STRUCTURAL INFORMATION DATA-BASE AND MODEL BUILDING USING KINK PARA-METERS OF NUCLEIC ACID STRUCTURES. S. Fujii, School of Pharmaceutical Sciences, University of Shizuoka, 52-1 Yada, Shizuoka-Shi 422-8526, Japan

The conformational flexibility of torsion angles in nucleic acid is very diverse and the number of torsional angle combination would be virtually infinity. The current structural description is the helicoidal parameters of the base moiety aspect to helical axis. However, for curved or kink fragments, the definition of helix axis is much more complicated. The kink parameters would provide the tolerant aspect for irregular structure. The program BIOCON calculates the kink parameters using the coordinates in PDB format. The algorithm of the normalized base calculation and the kink parameter definition accord to Lavery and Sklenar method. The calculated kink parameters are written in mmCIF format using data description language. The model building program, HLX5 has been also developed. In stead of torsion angle, the helical and/or kink parameters are elected as the input information to generate the starting global structure. The building performance is threefold. (i) Generation of structure and coarse connectivity check: Input terms are basic geometrical information such as base pairing scheme and also helical and/or kink parameters, such as tip, inclination and twist angles, and displacements. The glycosyl torsion angle and sugar puckering mode also are treated as independent values. The structural generation is accomplished in accordance with allowed helical parameters. The resulting O3'-C4' distance, of which O3' and C4' atoms are belonged to 3'-link and 5'-link moieties, respectively, is used as selection determinant. (ii) Fine connectivity check: The further conformer space search is carried with fine step among the above selected domain of variable values. Besides the same distance indicator O3'-C4', the short contacts not only between strands but also between the adjacent linked nucleotides are checked. Algorithm Metropolis is constructed to reduce computer time in this procedure. (iii) Energy minimization: Program package X-PLOR affords the convenient calculation to manipulate the structure maturation.

P11.03.004 STRUCTURE OF APO *T.cruzi* GLYCERALDEHYDE-3-PHOSPHATE DEHYDROGENASE: IMPLICATIONS FOR DRUG DESIGN. Oliva, B.G. Guimaraes, L.F. Delboni, M.C. Nonato, M.T. Pupo, Instituto de Física de São Carlos, USP, Cx.P.369, 13560, São Carlos, SP, Brazil, F. Pavao, Instituto de Química de São Carlos, USP, J. Mafezolli, P.C. Vieira, Departamento de Química, Universidade Federal de São Carlos

Aiming at the design of specific inhibitors of the enzyme GAPDH from the parasite *Trypanosoma cruzi*, causative agent of Chagas' disease, the crystallization and structure determination of this enzyme was undertaken. We report here the structures of the apo-form of the enzyme. Crystals were obtained in microgravity at 22ºC (VDA2) by vapor diffusion, with protein solution at 8 mg/ml, 5 mM of chalepin (coumarin derivative), 0.1 M sodium cacodilate at pH 7.1, 0.1 M calcium acetate and 16% PEG 8000. The crystals have grown to a size of 0.2x0.3x0.5 mm after the 9 days, and belong to the space group $P2_1$ with unit cell dimensions a=82.2 Å, b=85.1 Å, c=105.4 Å, β=96.4º and one tetramer per asymmetric unit. Diffraction intensities were collected at 100 K to 1.95 Å resolution and 78% completeness with an R_{merge} of 10.7%. The structure was determined by molecular replacement with a search model of *T. cruzi* glycosomal holo-GAPDH cryo-crystal structure refined in our laboratory at 2.15 Å. Initial refinement aimed at the possible identification of the binding of the inhibitor chalepin was conducted without NCS symmetry using REFMAC to final R=20.5% and R_{free}=30.0%, with a model containing 359 aminoacids per monomer and 848 water molecules in the asymmetric unit. The apo enzyme shows extensive conformational changes when compared with the NAD bound structure. The catalytic domain remains essentially unchanged whereas the NAD binding domain shows a global rotation of 2.8°, followed by internal changes that lead to an opened NAD binding site, with modifications at the hydrophobic pocket adjacent to the adenine moeity originally observed in the holo-form.

P11.03.005 ENZYME SPECIFICITY AS MODELLED BY A SERIES OF SIX METHYLASES IN THE VITAMIN B_{12} BIOSYNTHETIC PATHWAY. K.S. Wilson and H.L. Schubert Protein Structure Group, Department of Chemistry University of York, Heslington, York, England YO10 5DD and E. Raux, J. Roper and M.J. Warren Department of molecular Genetics, Institute of Ophthalmology, University College London, London EC1V 9EL

Many aspects of rational drug design and enzyme engineering rely of a limited set of information regarding the way and enzyme dictates its specificity for its particular substrate. These aspects are not well understood, though individual cases have been investigated using enzyme mutagenesis and extensive drug screening. Mutagenesis can probe the aspects of a structure that are essential for substrate binding or for maintaining the overall structure, while extensive drug screens test the flexibility of an active site to accommodate a range of compounds. Rarely does nature present a series of enzymes within a genome that possess a similar three dimensional structures and similar though distinct substrates.

Over thirty enzymatic steps are required to synthesise vitamin B_{12} including 8 single-carbon methylations carried out by six independent methylases. The structure of one such methylase from *Bacillus megaterium* was recently solved to 2.4 Å resolution[1]. Based on this structure the other five methylases encoded in the *B. megaterium* pathway have been modelled and their substrate binding sites compared to identify residues that may impart particular aspects of substrate specificity, while retaining the same overall structure and relative catalytic activity.

P11.03.006 MODEL OF MACROPHAGE STIMULATING PROTEIN β CHAIN, A DOMAIN RESPONSIBLE FOR RECEPTOR BINDING. Maria Miller[1], Alla Danilkovitch[2] and Edward J. Leonard[2]. [1] Macromolecular Structure Laboratory, ABL-BRP, and [2]Laboratory of Immunobiology, NCI-Frederick Cancer Research and Development Center; Frederick, MD 21702, USA

Macrophage stimulating protein (MSP) activates the RON receptor protein-tyrosine kinase. MSP and its close homologue, hepatocyte growth factor (HGF) form a distinct family of growth factors that evolved from plasminogen. They are produced as single chain precursors and are converted to their mature form by cleavage to disulfide-linked α,β-chain heterodimers. Their β-chain serine protease-like domains are devoid of enzymatic activity due to mutations in the catalytic triad. Despite structural similarities, the high affinity receptor binding regions are different α chain for HGF [1] and β chain for MSP [2]. We carried out modeling and site-directed mutagenesis studies of the MSP β chain serine protease domain and showed that the region corresponding to the S1 specificity pocket is critical for the receptor binding ability of MSP. MSP is able to bind RON with high affinity only after proteolytic cleavage, which in zymogens causes conformational changes leading to formation of a mature binding site. The residues critical for zymogen activation are conserved in MSP and HGF, suggesting that the structural basis for conversion to the biologically active growth factors is the same as for zymogen activation. Based on the comparison with HGF we proposed that both HGF and MSP have two receptor binding sites of different affinity, one on the α chain and one on the β chain, and a monomeric ligand induces receptor dimerization.

P11.03.007 ROLES OF THE SHORT-RANGE AND LONG-RANGE INTERACTIONS ON PROTEIN LOOP CONFORMATION. Yuzhen Han, Zhijie Liu, Weizhong Li, Luhua Lai, Institute of Physical Chemistry & College of Chemistry, Peking University, Beijing 100871, China

Short peptides in proteins can be classified into two groups according to whether they will always take a conserved conformation: conserved peptides are those that will always take the same conformation independent of protein environment; variable peptides are those that will change conformation under different protein environment. Structurally conserved peptides may act as nucleation site in protein folding.

P12.03.002 *AB INITIO* CRYSTAL SOLUTION OF A PROTEIN WITH 132 AMINO-ACID RESIDUES BY LDE METHOD. M. Shiono and N. Matsugaki, Faculty of Science, Kyushu University, Fukuoka, Japan, and G. Kurisu, Institute for Protein Research, Osaka University, Osaka, Japan and S. Harada, Graduate School of Pharmaceutical Sciences, The University of Tokyo, Tokyo, Japan and Y. Kai, Faculty of Engineering, Osaka University, Osaka, Japan.

The X-ray crystal structure of the zinc endoprotease produced by *Streptomyces caespitosus* (ScNP)[1] has been solved *ab initio* at 1.05 Å resolution by Low Density Elimination (LDE) method[2],[3] refining completely random phase sets. The protein consists of 132 amino-acid residues and the molecular weight is approximately 14 KDa. Multi-solution strategy is employed and 6 solutions out of 10 trials were obtained. An initial structural model with 677 atoms out of 1017 belonging to the protein was built by analysing the resultant map. The complete structure was obtained by least squares refinement and Fourier analysis. Although the crystal structure of ScNP was already solved at 1.6 Å resolution, the analysis was carried out by Kyushu University group who did not know any information for the protein structure except the amino-acids sequence.

P12.03.003 AUTOMATIC MAP INTERPRETATION. Thomas J Oldfield, Molecular Simulations Inc., Department of Chemistry University of York Heslington York YO10 5DD UK

Recent developments in recombinant DNA techniques, crystallisation protocols, X-ray data collection techniques and devices, and computing have led to a substantial increase in the speed and number of protein structure determinations in modern crystallographic laboratories. However, there still remains a number of key stages in the crystallographic process which limit the rate of structure determination. One of these is fitting electron density maps, either in the initial stages of tracing a chain to a new map, or in the manual rebuilding during refinement. This is a particularly onerous task, requiring many days and often weeks of working at a graphics terminal with maps and model. The presentation will show how methods developed within the program QUANTA can be used to automate the interpretation of electron density maps of proteins, both in the denovo tracing stage and in the model building stage. The level of automation provided by the presented methods is defined by the quality of the data, but this is significant even where the resolution is moderate (3Å) and initial phase error is high (75 degrees). At higher resolution the map tracing and model building is almost entirely carried out by the software. Examples of the use of the application using real data will show that a 10-100 fold reduction in the interpretation time is possible regardless of the data quality where data is useful. The electron density applications available within of QUANTA represent novel and effective tools for speeding up all aspects of map interpretation. The various modules (X-AUTOFIT, X-LIGAND, X-SOLVATE, X-BUILD and X-POWERFIT) have been developed in close collaboration with the large number of crystallographers working on projects in the Protein Group at York. These tools provide the crystallographer with map skeletonisation, map masks, CA-tracing, fuzzy logic sequence assignment, real space torsion angle refinement using grid/gradient/Monte Carlo protcols, interactive regularisation, model building recording, validation, ligand conformational searching and water fitting all in a single application.

04. CRYSTALLOGRAPHY OF BIOLOGICAL MACROMOLECULES

P05.04.001 THE ACTIN-BINDING REGION OF UTROPHIN CRYSTALLISES AS A HEAD-TO-TAIL DIMER. Nicholas H. Keep [1], Andrew Sutherland-Smith[2], Carolyn A. Moores[2], Fiona L.M. Norwood[2], Steven J. Winder[3] and John Kendrick-Jones[2], [1]. Department of Crystallography, Birkbeck College, University of London, Malet St London WC1E 7HX [2]. MRC Laboratory of Molecular Biology, Hills Road, Cambridge CB2 2QH [3]. Institute of Cell and Molecular Biology, University of Edinburgh, Mayfield Road, Edinburgh EH9 3JR

The structure of the actin-binding region from the dystrophin homologue, utrophin has been solved at 3.0 Å. This region belongs to a superfamily of actin-binding proteins that includes spectrin, α-actinin and fimbrin. All these actin-binding regions consist of two calponin homology domains, CH1 and CH2. The individual domains are similar to other structures of calponin homology domains. They are about 100 amino acids long. The structure is all α-helical with four main helices, three roughly parallel and the fourth roughly perpendicular to these.

In the utrophin structure there are two actin-binding regions in the asymmetric unit such that CH1 of one region makes extensive contacts with CH2 of the second region and so makes a head-to-tail dimer. This is in contrast to the structure of the equivalent region of fimbrin, where the two CH domains come from the same protein chain. The possible implications for models of the actin binding in this family of proteins are discussed.

P05.04.002 DISSECTING THE OVERALL STRUCTURE OF THE GIANT MUSCLE PROTEIN TITIN INTO ITS DOMAINS BY X-RAY CRYSTALLOGRAPHY. Olga Mayans, Jochen Wuerges and Matthias Wilmanns, EMBL c/o DESY, Notkestrasse 85, D-22603 Hamburg, Germany and Mathias Gautel, EMBL Heidelberg, Meyerhofstrasse 1, 69117 Heidelberg, Germany.

Two domains of the giant muscle protein titin have been determined by X-ray crystallography, this allowing modelling of numerous related domains from the same protein. Because of its size and its flexibility the three-dimensional structure of titin cannot be determined by diffraction methods. Therefore, we are aiming to assemble an atomic picture of this giant protein by solving X-ray structures of various domains or segments and fit them into low resolution EM images of titin.

The giant muscle protein titin forms the third filament system in striated muscles of vertebrates. It has a molecular weight of about 3 MDa (26926 aas) and a length of about 1 μm, spanning half of the sarcomeric unit from the Z disk to the M line. During development, titin contributes to the muscle ultrastructure by acting as a template for the assembly of sarcomeric proteins whilst in mature muscle it is responsible for elasticity and resting tension. The sequence of titin reveals a modular architecture, with 248 copies of immunoglobulin-like (IG) domains and fibronectin type-III domains arranged in a specific pattern. One single catalytic domain is comprised in the molecule, a serine kinase, referred to as titin kinase (TK) near the C-terminus of the titin molecule.

We have started our investigations by determining the high resolution X-ray structure of TK in its auto-inhibited form [1]. The structure demonstrated that the active site is blocked by a tyrosine from the P+1 loop. Subsequent studies revealed an unprecedented activation mechanism of this kinase by binding of calcium/calmodulin and tyrosine phosphorylation by a so far unknown up-stream kinase. More recently, we have solved a crystal structure of the first IG-like domain in the I band, called I1, using another IG-like structure, the telokin domain from myosin light chain kinase [2], as structural template. The I1 structure serves as a template to model numerous other immunoglobulin-like domains in titin and will provide insight into the molecular basis of titin elasticity.

P05.04.004 STRUCTURAL STUDIES OF THE MOTILE PROTEIN IN NEMATODE SPERM, THE MAJOR SPERM PROTEIN (MSP). A. M. E. Baker and A. J. McCoy, MRC Laboratory of Molecular Biology, Hills Road, Cambridge, CB2 2QH, UK, H. E. Smith and S. D. Ward, Department of Molecular and Cell Biology, University of Arizona, Tucson, AZ 85721, USA, T. M. Roberts, Department of Biological Science, Florida State University, Tallahassee, FL 32306, USA, and M. Stewart, MRC Laboratory of Molecular Biology, Hills Road, Cambridge, CB2 2QH, UK.

The simplicity and specialisation of nematode sperm cells makes them an ideal system for investigating the fundamental mechanism of amoeboid cell motility. Locomotion in nematode sperm is generated by vectorial assembly and bundling of filaments of the major sperm protein (MSP). The structure of the MSP filaments and bundles is central to understanding these processes at the molecular level. To investigate this we have generated a number of different crystal types in which the MSP chains are arranged in helical assemblies. *Ascaris* MSP forms both tetragonal and orthorhombic crystals whereas *C. elegans* MSP-142 generates a different tetragonal form. X-ray crystallography has shown that in tetragonal *Ascaris* crystals the helices have 16 chains arranged as dimers in 5 turns [1], and similar helices were found in the tetragonal *C. elegans* crystals. The helices are apolar and therefore it is unlikely that motor proteins play a significant role in generating the protrusive force in nematode sperm motility. In each of the tetragonal crystal structures, we have found 2 types of interface involved in subfilament formation, and have identified the residues at each interface. The fact that the tetragonal structures are different and yet the packing interactions are preserved suggests that these interactions are important in filament formation and bundling. Supported in part by the MRC, NIH, USDA and the Royal Society.

P05.04.006 ANCHORING ACTIN - THE STRUCTURE OF THE ACTIN BINDING DOMAIN OF ALPHA-ACTININ. F. Ekström [1], G. Stier [2], U.H. Sauer [1], [1] Umeå Center for Molecular Pathogenesis, Umeå University, S901 87 Umeå, Sweden, [2] EMBL-Heidelberg, Meyerhofstr. 1, D-69012 Heidelberg, Germany

We will present the structure of the Actin-Binding-Domain (ABD) of α-Actinin, the first example of a Calponin-Homology (CH) domain involved in muscle architecture.

α-Actinin anchors Actin and the giant protein Titin within the Z-disc of striated muscle. The ABD is located at the N-terminus of α-Actinin and comprises two CH domains in tandem. The C-terminus of the protein interacts with Titin via Calmodulin like EF hands.

The structure of the N-terminal 268 residues containing two CH domains is under determination. The model will be refined against synchrotron data extending to 1.8 Å resolution. Ananlysis of the features of the α-Actinin ABD will be with respect to related proteins such as β-Spectrin [1,2], Fimbrin [3] and Utrophin [4].

P05.04.007 RABBIT MUSCLE CREATINE KINASE - CRYSTAL STRUCTURE AND ITS IMPLICATIONS. J. K. Mohana Rao and Alexander Wlodawer, Macromolecular Structure Laboratory, NCI-FCRDC, ABL - Basic Research Program, P. O. Box B, Frederick, MD 21702, USA.

The crystal structure of homodimeric rabbit muscle creatine kinase (rMCK) was solved to a resolution of 2.35 A recently [Rao, Bujacz and Wlodawer: FEBS Letters (1998) 439, 133-137]. This structure was compared to those of the octameric chicken mitochondrial (Mt) CK and the related monomeric arginine kinase (AK). The sulfates in rMCK (crystals of which were grown from ammonium sulfate) occupy the phosphate positions of ATP or ADP in MtCK and AK. The dimer interfacein CK is stabilized by a small number of hydrogen bonds that remain invariant in the muscle (M), brain (B) and Mt enzymes. These interactions are not facilitated in AK because of the substitution of Asp54 by Leu, of Arg148 by Ala and of Asp210 by Tyr. This may be the reason why only monomers occur in AK. Since the residues involved in these interactions are identical in the M and B enzymes, MB heterodimers can and do occur. There is a distinct difference in the active site region depending upon whether ATP or ADP is present. Models of the BB and MB dimers are also being developed based on the present structural data. These and other structural results will be presented.

Research sponsored by the National Cancer Institute, DHHS, under contract with ABL.

P05.04.009 TRPRS: THREE-STATE BEHAVIOR, INDUCED FIT, CONFORMATIONAL COUPLING, AND FREE-ENERGY TRANSDUCTION, C. W. Carter, Jr., V. A. Ilyin, X. Huang, Y. Yin, P. Retailleau, P. Vachette[¶], A. Longo, and M. Hu, Biochemistry and Biophysics, Univ North Carolina, Chapel Hill, NC. [¶]LURE, Orsay, France

Tryptophanyl-tRNA synthetase (TrpRS) appears to assume three distinct conformations during tryptophan activation. Ca coordinates for ground-state, activated pre-transition state, and product complexes differ by at least five times the r.m.s. deviation within each family. The following new aspects of this three-state behavior obtained from crystal structures, in parallel with solution X-ray scattering, suggest that conformational forces are poised to favor transfer of the a-phosphoryl high-energy bond from pyrophosphate to the amino acid and then from the activated amino acid to the cognate tRNA:

The ATP binding site is structurally fragmented in ligand-free TrpRS.

An open, ternary AMP:tryptophan:TrpRS complex isomorphous with ligand-free TrpRS implies that either an intact nucleoside triphosphate or an aminoacyl-adenylate analog is necessary to induce active site-closure.

Solution scattering and a TrpRS:$[ATP]_2$ complex isomorphous to the closed, pre-transition state show that ATP binding is sufficient to close the active site, driving the first step of the "induced-fit" catalytic cycle.

A product-analog:pyrophosphate:TrpRS complex mimics the Michaelis complex for the pyrophosphate-exchange reaction, the reverse of aminoacylation. Adding pyrophosphate to the product complex does not reverse the second conformational change if the adenosyl-tryptophan bond is stabilized. Thus, transfer of the high-energy AMP-PPi bond to the tryptophan carboxylate stabilizes the product-complex conformation, which binds the activated amino acid before its transfer to cognate tRNA.

A high-quality nonpolar core linking the helical domain and its $tRNA^{Trp}$ anticodon binding determinants to the highly conserved isoleucine in the active-site T**I**GN signature couples active-site chemistry to tRNA binding.

The TrpRS structures confirm in detail conclusions from pre-steady state kinetics of TyrRS active-site mutants. Specifically, residues interacting with the nucleotide ribose are separated in the ligand-free enzyme, consistent with the observation that mutations exert their effect only in the transition state. By implication, other and perhaps all class I aminoacyl-tRNA synthetases may have similar conformational states. The "three-state" cycle: triphosphate => phosphorolysis-products => unliganded => triphospate strongly resembles the conformational cycles of energy-transducing and signaling enzymes like myosin and F1 ATPase,. (Supported by NIH GM48519-02)

P05.04.010 IMPROVING THE RESOLUTION BY REVERSIBLE FREEZING COMBINED WITH SOLVENT CONCENTRATION SCREENING. A.N. Popov and V.S. Lamzin, EMBL Hamburg Outstation, c/o DESY, Notkestasse 85, Hamburg 22603, Germany, and V.R. Samygina, The Institute of Crystallography, Russian Academy of Sciences, Leninsky pr. 59, Moscow 117333, Russia.

A new method of improving the diffraction limit for macromolecular crystals is proposed. The method is based on reversible multiple refreezing combined with searching for the solvent concentration providing the best crystal ordering. Using this method for E.Coli inorganic pyrophosphatase complexed with calcium and with calcium and pyrophosphate allowed us to improve resolution limit and collect data sets up to atomic resolution.

The pyrophosphatase crystals grown from 1.8M sodium chloride and 200mM sodium acetate pH 5.0 diffracted to 1.8 Å. The crystal was first flash frozen from a cryosolution containing the mother liquor and 27% glycerol. Then the crystal was transferred back to cryosolution with increased by 0.05M concentration of sodium chloride. The procedure was repeated several times. On every cycle the diffraction was checked. The highest resolution (1.2 Å) was attained when the concentration of sodium chloride reached 2.2M. The effect was reproducible. The same results have been obtained using other crystals of phyrophosphatase. This simple technique may be useful to improve the diffraction quality of protein crystals generally.

P05.04.011 AN OPEN FLOW HELIUM CRYOSTAT FOR MACROMOLECULES. B. Leif Hanson*, Anthony Martin#, Joel M. Harp*, Damon A. Parrish#, Christopher G. Bunick+, Kristin Kirschbaum#, A. Alan Pinkerton#, and Gerard J. Bunick*+; *University of Tennessee/Oak Ridge Graduate Program in Genome Sciences and Technology, #Chemistry Department, University of Toledo, Toledo, OH, 43606, and +Life Sciences Division, Oak Ridge National Laboratory, Oak Ridge, TN 37831-8080

A helium cryostat developed at the University of Toledo was recently described in the *Journal of Applied Crystallography*. The liquid He consumption of the device is sufficiently low to allow the acquisition of complete diffraction data from a protein crystal on a single 250 L tank of liquid He. This helium cooling system has been tested on macromolecules, using crystals of chicken egg lysozyme, sperm whale myoglobin, concanavalin A, and the nucleosome core particle. Phase changes in terbium vanadate crystals indicate that temperatures delivered by the cryostat were < 33 K at the crystal position. The observed unit cell dimensions in the macromolecular crystals were consistent with temperatures < 77K.

Large crystals approaching suitability for neutron diffraction studies were successfully flash-cooled and a large crystal of lysozyme was rescued for data collection after undergoing a cycle of macromolecular crystal annealing (MCA) following poor flash-cooling. The results of these studies show that this device might be an especially useful adjunct both for neutron diffraction studies and at high intensity synchrotron X-ray sources, in addition to its use in the standard macromolecular repertoire.

P05.04.012 STUDIES OF THE LIGANDS OF C-ABL SH3 DOMAIN. A. Douangamath[*], G. Superti-Furga[f], M. Wilmanns[*].[*] EMBL-Hamburg, c/o DESY, Notkerstraße 85, 22603 Hamburg, Germany. [f] EMBL-Heidelberg, Meyerhofstraße 1, 69012 Heidelberg, Germany

C-Abl, a non-receptor tyrosine kinase located in the nucleus and in the cytoplasm, is the cellular homolog of v-Abl, an oncogene of the transforming retrovirus A-MuLV (Abelson Murine Leukemia Virus). This protein of 150 kDa contains a SH2 and a SH3 domain, known to mediate protein-protein interactions with specific tyrosine phosphorylated sequences and proline-rich motifs, respectively. Some evidences from the last few years show the involvement of c-Abl in the cell growth regulation, in the response to DNA damage and in the cytoskeleton regulation [1]. In the cells, the activity of c-Abl is negatively and tightly regulated by the association of the SH3 domain with extracellular factors [2] In order to understand the regulation mechanism of c-Abl involving the SH3 domain, we would like to get the crystal structure of the complex SH3 domain and its partner. Among the possible ligands of c-Abl, we chose Pag, the product of the Proliferation Association Gene [3]. It is an antioxidant protein of 22 kDa localised also in the nucleus and in the cytoplasm. Although the binding of Pag to the SH3 domain still remains to be clarified, the role of Pag in the inhibition of c-Abl tyrosine kinase activity has been defined to be SH3-domain-dependant. We have established the protocols for the expression and the purification of Pag and the optimisation of the crystallisation conditions is in progress.

P05.04.013 DRUG ACTION ON CALMODULIN - COMPLEXES WITH ANTAGONISTS OF DIFFERENT TYPES. V. Harmat, G. Bunkóczy, J. Debreceni, Zs. Böcskei, G. Náray-Szabó [1], B. G. Vértessy, J. Ovádi [2], [1] Dept. of Theoretical Chemistry, Eötvös Loránd Univeristy, H-1518 Budapest 112. POB 32, Hungary, [2] Institut of Enzymology, Biological Research Center of the HAS, H-1518 Budapest POB 7, Hungary.

Calmodulin (CaM), being one of the most important intracellular mediators of Ca(2+)-dependent signalling in eucariotic cells, plays an important role in the modulation of several biochemical processes. Upon Ca(2+) binding CaM changes its conformation facilitating its binding to its target proteins and influencing their action. Modulation of CaM activity is achieved by several antagonists which differ in both chemical structure and mechanism of action. Structural details of antagonist binding are known only for a phenotiazine drug (trifluoperazine [1,2,3]), and an arylalkylamine type molecule [4], two competitive antagonists which occupy the very same binding pockets as the side chains of the CaM recognising peptides of several target enzymes.

Preliminary experiments suggest that the above arylalkylamine type molecule binds in a different way in complexes of different CaM-ligand ratios. Crystallization of an 1:1 Ca-CaM - arylalkylamine is in progress. Biochemical tests indicated that vinblastine derivatives have different binding sites and can also bind to apo-CaM. Crystallisation trials are in progress with quaterner complexes Ca-CaM, target peptides and noncompetitive antagonists. Crystals with vinblastine type compounds have been produced both in presence and in absence of Ca(2+). The analysis of the complex structures can help to better understand the mechanism of CaM antagonism of these molecules.

P05.04.014 SEX AT THE MOLECULAR LEVEL: THE CRYSTAL STRUCTURE OF A FERTILISATION PROTEIN. N. Kresge and C. D. Stout, The Scripps Research Institute, 10550 N. Torrey Pines Rd., La Jolla, California 92037, and V. D. Vacquier, The Scripps Institution of Oceanography, University of California, San Diego, La Jolla, Calilfornia 92093.

The structures of a gamete recognition protein (lysin) from two species of abalone have been determined, which has lead to insights on how lysin interacts with an egg receptor protein and the role it plays in acting as a barrier to cross-species fertilisation.

At the molecular level, fertilisation begins with the penetration of the egg's outer coat by the sperm. Abalone sperm accomplish this task by releasing a 16kDa protein (lysin) onto the surface of the egg's Vitelline Envelope (VE). Lysin then binds to the Vitelline Envelope Receptor for Lysin (VERL) and creates a hole in the VE by a non-enzymatic mechanism. Percent identity of lysins from different species ranges from 63% to 90%, and lysins exhibit species specificity - they will not easily bind to or dissolve VEs from other abalone species.

As part of an effort to understand, at atomic resolution, lysin's interaction with VERL and its role in species-specificity, we have solved the crystal structures of lysin from Haliotis rufescens (red abalone) and Haliotis fulgens (green abalone) to 1.35Å and 1.7Å respectively. Both molecules consist of an amphipathic 5 helix bundle with two tracks of basic residues running the length of one side, and a solvent-exposed hydrophobic patch on the other side. Neither lysin has obvious binding pockets or active sites suggesting the whole surface of lysin is its "active site". The overall folds of the two proteins are remarkably similar with a c-alpha rms deviation of 1.0Å, indicating that its species-specificity lies in the locations of non-conserved residues and in subtle side-chain rearrangements.

P05.04.016 STRUCTURE OF THE PH DOMAIN FROM BRUTON'S TYROSINE KINASE IN COMPLEX WITH IP4 K. Djinovic Carugo, E. Baraldi [1], M. Hyvönen [2], P. Lo Surdo [1], A. M. Riley, B.V.L. Potter [3], R. O'Brien, J. E. Ladbury [4], M. Saraste [1], [1] European Molecular Biology Laboratory, Meyerhofstrasse 1, D-69012, Heidelberg, Germany, [2] Department of Biochemistry, University of Cambridge, 80 Tennis Court Road, CB2 1GA Cambridge, UK, [3] Wolfson Laboratory of Medicinal Chemistry, Department of Pharmacy and Pharmacology, University of Bath, Claverton Down, Bath, BA2 7AY, UK, [4] Department of Biochemistry and Molecular Biology, University College London, Gower Street, London WC1E 6BT, UK

The activity of Bruton's tyrosine kinase (Btk) is important for the maturation of B cells. A variety of point mutations in this enzyme results in a severe human immunodeficiency known as X-linked agammaglobulinemia (XLA). Btk contains a PH domain which specifically binds phosphatidylinositol 3,4,5-trisphosphate and hence responds to signalling via phosphatidylinositol 3-kinase. Point mutations in the PH domain may abolish membrane binding, preventing signalling via Btk.

We have determined crystal structures of the wild type PH domain and a gain-of-function mutant E41K in complex with inositol 1,3,4,5-tetra-kisphosphate. It binds to a site that is similar to the Ins(1,4,5)P3 binding site in the PH domain of phospholipase C-delta. A second Ins(1,3,4,5)P4 molecule is associated with the domain of the E41K mutant, suggesting a mechanism for its constitutive interaction with membrane.

Our data provide an explanation for the specificity and high affinity of the interaction with PtdIns(3,4,5)P3 and lead to a classification of the XLA mutations that reside in the Btk PH domain. Missense mutations which do not simply destabilize the PH fold either directly affect the interaction with the phosphates of the lipid head group or change electrostatic properties of the lipid binding site. One point mutation (Q127H) cannot be explained by these facts, suggesting that the PH domain of Btk carries an additional function such as interaction with a G-alpha protein.

P05.04.017 STRUCTURAL AND BIOCHEMICAL STUDIES ON RCC1 THE GUANINE EXCHANGE FACTOR FOR THE SMALL GTP-BINDING PROTEIN RAN. L. Renault[#], Y. Azuma[+], J.A. Garcia-Ranea*, A. Valencia*, T. Nishimoto[+] and A. Wittinghofer[#], [#]Max-Planck-Institut für molekulare Physiologie, Rheinlanddamm 201, 44139 Dortmund, Germany, [+]Department of molecular Biology, Graduate School of Medical Science, Kyushu University, Maidashi, Fukuoka 812, Japan, *Protein Design Group, CNB-CSIC, Campus U. Autonoma, Cantoblanco, Madrid M-28049, Spain.

The protein RCC1, for Regulator of Chromosome Condensation, has been originally identified as a control element of the cell cycle [1]. Biochemically, RCC1 is the guanine nucleotide exchange factor (GEF) of the small regulatory GTP-binding protein Ran (Ras-like nuclear GTP-binding protein). This GEF activity makes RCC1 an essential element in the GTPase cycle of Ran as it controls the timing of molecular processes that are regulated by the transition of Ran to the GTP-bound form. The molecular switch Ran regulates two important biological pathways: nucleo-cytoplasmic transport and cell cycle progression [1].

The structure of human RCC1, solved to 1.7 Å resolution by X-ray crystallography, reveals a seven-bladed β-propeller, formed by internal repeats of 51-68 residues per blade [2]. These repeats are also found in more than 20 different proteins, not related to RCC1. The structure is very similar to the seven-bladed β-propellers found in the β-subunit of heterotrimeric G proteins, and explains the consequences of a wide range of known mutations, which affect the radial arrangement of the repeated units. Based on site-directed mutagenesis [3], one face of the β-propeller has been proposed as the interacting face with the GTPase Ran, whereas the opposite face is thought to be involved in chromatin interaction. A model of the Ran-RCC1 interaction using biochemical and structural docking experiments has been obtained recently and it allows us to gain further insight into the guanine exchange release mechanism induced by RCC1 on Ran [4].

P05.04.019 CRYSTAL STRUCTURE OF THE CALMODULINS IN COMPLEX WITH ANTIPSYCHOTIC PHENOTHIAZINE-TYPE DRUGS. M. Senda, T. Senda, Department of BioEngineering, Nagaoka University of Technology, Nagaoka, Niigata 940-2188, JAPAN. H. Kasai, Tokyo Metropolitan University of Health Siences Arakawa-ku, Tokyo 116, JAPAN, and Y. Mitsui, Department of BioEngineering, Nagaoka University of Technology, Nagaoka, Niigata 940-2188, JAPAN.

Calmodulin (CaM) is a ubiquitous Ca^{2+}-binding protein of 148 amino acid residues present in all eukaryotic cells. It has been known that the CaM molecule can bind such small compounds as trifluoperazine (TFP) and chlorpromazine (CHL) as well as a variety of target peptides (or proteins). To date two groups have reported on the crystal structures of CaM in complex with TFP. These analyses showed that CaM in complex with TFP assumed a the compact shape, which is similar to that of CaM complex with a target peptide. However, the number of the TFP molecule bound to CaM, and the location of bound TFP molecules vary in each crystallographic analysis. To gain a precise insight into the three-dimensional structure of CaM in complex with small compounds such as TFP and CHL, we undertook reexamination of the crystal structure analyses on CaM in complex with the small compounds.

Crystal structure of CaM in complex with TFP was solved using a multiple isomorphous replacement procedure. Using this structure as a search model, the crystal structure of the CaM-CHL complex was then solved by a molecular replacement method. The overall structures of CaM were almost identical to each other and to that found in the previously reported CaM-TFP complex structure. In the present TFP complex, one TFP bound to the hydrophobic pocket of the N-terminal domain of CaM, the other TFP binding to the C-terminal domain. In the CHL complex, the C-terminal binding site was equivalent while the other binding site appeared unique.

P05.04.021 CRYSTAL STRUCTURE OF HUMAN RHOA^{V14} COMPLEXED WITH GDP. Kentaro Ihara, Toshiyuki Shimizu, Shinya Kuroda, Kozo Kaibuchi, and Toshio Hakoshima, Faculty of Bioscience, Nara Institute of Science and Technology, 8916-5 Takayama, Ikoma, Nara 630-0101, Japan.

The crystal structure of RhoA^{V14} complexed with a GDP and a Mg^{2+} ion was determined at 2.2 ≈ resolution by the molecular replacement technique. Compared with RhoA^{N25}-GDP (1), the switch I (27-46) region shows significantly large structural displacements that are also dissimilar to those of RhoA^{V14}-GTPγS (2). In the switch I, some residues displaced more than 20 ≈ from the corresponding main-chain C_α carbon atoms of RhoA^{N25}-GDP. It seems to be unlikely that these structural changes due to the difference in the mutated residues. In RhoA^{V14}-GDP, the switch II can be traced with no interruption, although three residues are missing in RhoA^{N25}-GDP. This stabilization of the switch II in RhoA^{V14}-GDP seems to be due to the contacts with the side-chain of Val14. In spite of the large displacements, the conformational changes between the GDP- and GTP-bound forms were occurred only in the switch regions. It is known that the switch II regions of the Ras family members display various conformations especially in the GDP-bound form (3). These results may suggest the existence of multiple quasi-stable states in the switch regions of RhoA bound to GDP. Similar observations are reported in the

solution strucutres of H-Ras (4), although they are in the GTP-bound forms.

P05.04.022 STRUCTURAL STUDIES OF NEUROTROPHINS AND THEIR RECEPTORS. M.J. Butte, Graduate Group in Biophysics, University of California San Francisco, Box 0448, 513 Parnassus, San Francisco, CA 94143 USA; W.C. Mobley, Department of Neurology, Stanford University, Stanford CA 94305 USA; and R.J. Fletterick, Dept. of Biochemistry and Biophysics, University of California San Francisco, San Francisco CA 94143 USA.

The neurotrophins are cystine-knot growth factors that control the survival, proliferation, differentiation, and programmed cell death of developing neurons and are potential therapeutics for neurodegenerative diseases. Two classes of cell-surface receptors have been found for these secreted proteins: the Trk family, which are receptor tyrosine kinases that show selectivity for each neurotrophin and are essential for neuronal development; and $p75^{NTR}$, a member of the tumor necrosis factor receptor (TNFR) superfamily that binds all the neurotrophins with equal affinity and plays a role in neuronal apoptosis. To clarify the open issues of the structural basis of receptor specificity and the mixed roles of the Trk receptors and p75 in neurotrophin signaling, we have undertaken biochemical and x-ray crystallographic studies of the neurotrophins and their receptors. So far, we have solved the structure of human neurotrophin-3 (NT-3) homodimer, which reveals structural clues to NT-3 specificity with TrkC. Co-crystallization studies of the neurotrophin BDNF with its partner TrkB are underway to expand our structural understanding of neurotrophin/Trk interaction. Using limited proteolysis, mass spectrometry, and surface plasmon resonance interaction analysis, we are determining the domains of p75 that are most important for neurotrophin binding. Co-crystallographic analysis of these fragments is underway. We will report on our progress to date on these structural and biochemical experiments, including the structure of NT-3.

P05.04.023 THE CRYSTAL STRUCTURE OF D-GLUCARATE DEHYDRATASE, A MEMBER OF THE ENOLASE SUPERFAMILY Andrew M. Gulick [1], David R. J. Palmer [2], Brian Hubbard [2], John A. Gerlt [2], and Ivan Rayment [1]. [1] The Institute for Enzyme Research and Department of Biochemistry, University of Wisconsin, Madison, USA. [2] Department of Biochemistry, University of Illinois, Urbana, USA

The Enolase superfamily of enzymes represents several enzymes with limited sequence homology that exhibit a conserved structural fold and catalyze similar chemistry. The enzymes contain an N-terminal domain composed of helices and sheets, followed by a C-terminal barrel domain. The barrel consists of alternating helices and strands in which the 8 parallel strands form a closed sheet in the form of a barrel. The active site of these enzymes is located at the cavity formed at the C-terminus of the strands in the barrel. This architecture allows residues from all of the barrel strands to interact with the substrate.

Glucarate dehydratase (GlucD) catalyzes the elimination of water from (D)-glucarate to form 5-keto-4-deoxy-(D)-glucarate. We have determined the structure of this enzyme from two sources, E. coli and P. putida. The E. coli GlucD structure was determined in the absence of any bound substrate, in the presence of the product, and also two inhibitors, 4-deoxy-(D)-glucarate and the hydroxamate of glucarate. The structures demonstrate the conservation of important residues for specific catalytic roles, as well as the recruitment of additional residues involved in the binding of the substrate. Specifically, a large loop from the N-terminal domain, which is disordered in the unliganded form, and an extended C-terminal domain form important interactions with the product and inhibitor molecules.

P06.04.001 THE STRUCTURAL MECHANISM FOR HALF-THE-SITES REACTIVITY IN THYMIDYLATE SYNTHASE. Amy C. Anderson, Robert H. O'Neil and Robert M. Stroud. Department of Biochemistry and Biophysics, University of California at San Francisco, San Francisco, CA 94143-0448.

We have determined the first structural mechanism for the basis of half-the-sites reactivity, an extreme form of negative cooperativity, in an enzyme. The co-crystal structure of thymidylate synthase from *Pneumocystis carinii* (PcTS) with its substrate, dUMP, and a cofactor mimic, CB3717, at 2.6 Å resolution shows an asymmetric dimer with two molecules of substrate bound, yet only one molecule of the cofactor analog bound. The structural evidence reveals the mechanism by which binding of the cofactor or an antifolate inhibitor to one monomer renders the opposite monomer catalytically inactive and incapable of binding a second molecule of cofactor.

A structural analysis program was used to create a three-dimensional movie of the conformational changes. This structural comparison shows that covalent bond formation between the catalytic cysteine and dUMP in one monomer is accompanied by conformational changes that translate to residues across the molecular two-fold axis at the dimer interface, generating the asymmetry seen between the two active sites. The asymmetry prevents a covalent bond, and hence, catalysis, in the second active site. Additionally, the conformational changes break hydrogen bonds between a key asparagine residue and dUMP in the second monomer, allowing a misorientation of the substrate and a rise in the K_M for cofactor since the orientation of the cofactor is directly dependent on the orientation of the pyrimidine base.

P06.04.002 STRUCTURAL STUDIES INVESTIGATING THE CATALYTIC INTERMEDIATES OF GALACTOSE OXIDASE. Susan J. Firbank, Elinor Vinecombe, Carrie M. Wilmot, Michael J. McPherson, Peter F. Knowles & Simon E.V. Phillips. School of Biochemistry and Molecular Biology, University of Leeds, Leeds LS2 9JT, U.K.

Galactose oxidase is the simplest known copper containing oxidase. It is an extracellular enzyme produced by *Fusarium spp.* which catalyses the stereo-selective oxidation of specific primary alcohols ranging from small molecules to polysaccharides. The two electron redox reaction follows the general scheme:

$$RCH_2OH + O_2 \rightarrow RCHO + H_2O_2$$

The crystal structure has been determined to 1.7Å revealing a novel thioether bond between tyrosine 272 and cysteine 228, with tryptophan 290 stacking over this thioether bond. Insight into the reaction mechanism has been gained using spectroscopic, kinetic and mutagenesis studies in conjunction with the structure.

Recently a different crystal form has been identified which allows the catalytic turnover of D-galactose. We are hoping to use this crystal form to investigate the spectrally distinct intermediate structures of galactose oxidase produced during the reaction, by monitoring the timecourse of the reaction using a microspectrophotometer, and flash freezing the crystals at the various stages. This technique has recently been used to characterise intermediates in the catalytic cycle of *E. coli* amine oxidase.

P06.04.003 MUTANTS OF ASPARTATE SEMIALDEHYDE DEHYDROGENASE: ESSENTIAL BACTERIAL BIOSYNTHETIC ENZYME. C.N.Y.A. Shammas, J. Axcell, A.T. Hadfield, Dept. Biochemistry, Bristol University, University Walk, Bristol BS8 1TD; C. James, R.E. Viola, University of Akron, Ohio.

Aspartate β-semialdehyde dehydrogenase lies at a branch point in the biosynthetic pathway through which bacteria, fungi and the higher plants synthesize diaminopimelate and lysine from aspartate. Blocks in this biosynthetic pathway are lethal, making ASADH an attractive target for anti-bacterial, fungicidal, or herbicidal agents. The enzyme, which is active in *E. coli* as a dimer, catalyses the reductive phosphorylation of β-aspartyl phosphate, with a mechanism similar to glyceraldehyde-3-phosphate dehydrogenase. The structure of the apo-enzyme and of a ternary complex with NADP, phosphate and the substrate-mimicking inhibitor S-methyl cysteine sulfoxide has been solved [1].

The crystal structures above suggest a role in the mechanism of the enzyme for a conserved histidine. Mutation of this histidine results in greatly reduced activity. We currently have crystals of the enzyme in complex with NADP alone and also that of site directed mutants including His274Gln.

[1] A.T. Hadfield, *et al.* 1999 IUCr abstracts (0235).

P06.04.004 UNRAVELLING THE RIBONUCLEOLYTIC MECHANISM OF ANGIOGENIN : AN ATYPICAL RIBONUCLEASE IMPLICATED IN NEOVASCULARIZATION. G.V. Subbarao and D.D. Leonidas, University of Bath, UK and R. Shapiro, Harvard Medical School, Boston, USA, and K.R. Acharya, University of Bath, UK.

Angiogenin (Ang), a member of the RNase superfamily having a 33.1% sequence homology is a 14.1 kDa protein (123 AA), is implicated in the onset of vasculature, both in human health and disease. Although Ang has approximately 10^5-10^6 times lower ribonucleolytic activity than RNase A, it is observed that this diminished ribonucleolytic activity is an obligatory prelude to its angiogenic potency. The structure of human Met(-1) Ang demonstrated that Gln-117 hinders active site acess, partly accounting for it's diminished ribonucleolytic. It has been suggested that the residues from the C-terminus also contribute to the impediment of the active site.

The focus of our work is to gain structural insights into the ribonucleolytic activity of Ang by characterisation of the C-terminus and the active site. Subsequently, high-resolution X-ray crystallographic structures of Ang variants D116H, Des121-123, H13A and I119A-F120A Ang were determined. Ang differs from RNase A in substrate specificity and appears to be modulated by the 'B_1' subsite, having a strong (12- to 20- fold) preference for cytosine vs. uracil nucleotides. In order to understand the structural role of the 'B_1' subsite, variants T44D and T80A Ang have been overexpressed and purified. The structure of a variant from a peripheral subsite of Ang, H8A Ang has also been determined. A detailed analysis of the structure-function relationships of all the mentioned variants and their implications for inhibitor design will also be presented.

P06.04.005 A TRANSITION STATE ANALOG COMPLEX OF *ESCHERICHIA COLI* PHOSPHOENOLPYRUVATE CARBOXYKINASE-AlF_3-ADP-Mg^{2+}. Athena M. Sudom, J. Wilson Quail, Hughes Goldie and Louis T. J. Delbaere, Departments of Chemistry, Biochemistry and Microbiology, 107 Wiggins Road, University of Saskatchewan, Saskatoon, Saskatchewan, S7N 5E5 Canada.

The mechanism of reversible transfer of the γ-phosphate of ATP by phosphoenolpyruvate carboxykinase (PCK) onto its substrate is of great interest. It is known that metallofluorides are accurate analogs of the transition state in the context of kinase mechanisms, and so AlF_3 and ADP were crystallized in complex with PCK. AlF_3 forms a trigonal bipyramid that mimics the transition state of phosphoryl transfer, allowing investigation into the catalytic mechanism of this kinase. PCK is indispensable in gluconeogenesis for its role in decarboxylation and phosphorylation of oxaloacetate to form phosphoenolpyruvate, ADP, and CO_2.

Initially, crystals of *E. coli* PCK were grown in complex with AlF_3, magnesium and ADP via hanging drop vapour diffusion at 21°C. The components of the hanging drop protein solution were as follows: 6 mg ml^{-1} PCK, 0.8 mM $Al(NO_3)_3$, 4 mM NaF, 5 mM $MgCl_2$, 2 mM ADP, 0.1 mM EDTA, 200 mM ammonium acetate, 100 mM sodium acetate buffer (pH 5.0), 0.1 mM dithiothreitol (DTT) and 12% polyethylene glycol 4000 (PEG). The reservoir solution contained 30% PEG 4000, 100 mM sodium acetate buffer (pH 5.0) and 200 mM ammonium acetate.

Diffraction data were collected to the maximum resolution of 2.0 Å at the Photon Factory in Tsukuba, Japan. The monoclinic unit cell dimensions were a = 126.0, b = 95.8, c = 46.6Å, β = 95.6° with space group C2. The initial round of refinement gave an R factor of 25.5%. Further analysis is ensuing.

This research is funded by the Medical Research Council of Canada.

P06.04.006 CRYSTAL STRUCTURE OF PHOSPHOGLUCOSE ISOMERASE / AUTOCRINE MOTILITY FACTOR / NEUROLEUKIN. Yuh-Ju Sun, Chia-Cheng Chou and Chwan-Deng Hsiao, Institute of Molecular Biology, Academia Sinica, Taipei, Taiwan 11529, ROC, Wei-Shone Chen, Veterans General Hospital, Taipei, Taiwan, 11217, ROC, Rong-Tsun Wu, Graduate Institute of Biopharmaceutical Science, National Yang-Ming University, Taipei, Taiwan, ROC and Menghsiao Meng, Graduate Institute of Agricultural Biotechnology, National Chung Hsing University, Taichung, Taiwan 40227, ROC.

Phosphoglucose isomerase (PGI), a glycolytic enzyme, was recently described to exhibit the equivalent function as neuroleukin (NLK) as well as autocrine motility factor (AMF) of tumor cells. Here we present the first complete crystal structure of phosphoglucose isomerase cell from *Bacillus stearothermophilus* at 2.3 Å resolution. The structure of PGI is a open twist α/β structure. The functional form of PGI is a dimer, each subunit consists of two globular domains and two protruding loops. The subunits associate in an arm-to-arm hug fashion. The proposed substrate binding-site is in both the domain interface and the subunit interface. A mechanism for enzymatic specificity and activity is postulated. We also demonstrate that PGI exhibits cell motility-stimulating activity on CT-26 mouse colon cancer similar to that of endogenous AMF, and that PGI enhances neurite outgrowth in terms of length and density on neuronal progenitor cells observed in NLK.

P06.04.007 CRYSTAL STRUCTURE OF A BIOSYNTHETIC THIOLASE IN COMPLEX WITH ACETOACETYL-COA. Y. Modis, European Molecular Biology Laboratory, Postfach 10.2201, D-69012, Heidelberg, Germany and R.K. Wierenga, Department of Biochemistry, University of Oulu, FIN-90570, Oulu, Finland.

The crystal structure of biosynthetic thiolase from the bacterium Zoogloea ramigera in complex with its substrate, acetoacetyl-CoA, was solved at 2.35 Å resolution.

Thiolases can function either degradatively in the β-oxidation pathway of fatty acids, or biosynthetically in the synthesis of various fuel molecules, cholesterol and steroid hormones.

The tetrameric biosynthetic thiolase from Zoogloea ramigera [1] has the same subunit structure as the dimeric yeast degradative thiolase whose structure was solved previously [2], but the biosynthetic thiolase contains a striking and novel cage-like tetramerisation motif. A molecule of acetoacetyl-CoA, which is a thiolase substrate, is visible in two of the four active sites in the tetramer. The mode of binding of the substrate shows in molecular detail how the substrate is activated for nucleophilic attack by the catalytic cysteine residue, Cys89, leading to the formation of a covalent substrate-enzyme reaction intermediate. Finally, the shape of the active site pocket of biosynthetic thiolase reveals the basis for the short-chain substrate specificity of the enzyme [3].

P06.04.008 PRELIMINARY X-RAY STUDIES OF 12S FORM OF PHOSPHOFRUCTOKINASE 1 FROM SACCHAROMYCES CEREVISIAE. I. Mechin[a], G. Kopperschläger[b], W. R. Rypniewski[a] at [a]European Molecular Biology Laboratory (EMBL) c/o DESY, Germany, [b]Institute of Biochemistry, Medical Faculty, University of Leipzig, Germany.

Extensive crystallographic studies have been carried out on bacterial phosphofructokinase1 but until now no eukaryotic PFK1 has been crystallised in a form suitable for X-ray analysis. PFK1 catalyses the conversion of fructose 6-phosphate into fructose 1,6-bisphosphate in the presence of MgATP. It is an allosteric key enzyme in glycolysis, with various effectors, both activators and inhibitors. In baker's yeast PFK1 is a hetero-octamer ($\alpha_4\beta_4$) of molecular weight approximately 800 kDa (21S). As a result of an early gene duplication each eukaryotic subunit consists of two homologous parts, each repeat similar to one prokaryotic subunit. One of them is thought to have lost catalytic function and acquired a regulatory role. In yeast a second gene duplication event is supposed, forming two different types of subunits called α and β. Yeast PFK1 octamer consists of 16 prokaryotic like units with heterogeneous terminal regions responsible for subunit association.

The 12S form of yeast PFK1 is obtained by limited proteolytic cleavage of the native enzyme by chymotrypsin in the presence of ATP, leading to the truncation of C- and N- terminal parts. As a consequence the 21S octamer dissociates to form two 12S tetramers of identical size composed of partially degraded α" and β' subunits. This truncated form is catalytically active, possesses similar kinetic properties to the native enzyme and shows no micro-heterogeneity.

The size of yeast PFK1 makes the crystallography a challenge but structure solution feasible. The 12S PFK1 enzyme was crystallised under a variety of conditions. The crystals have been characterised. Diffraction data have been collected to 2.9Å under cryogenic conditions, on the EMBL beamline at the DORIS storage ring in Hamburg. Work is in progress to solve the structure by molecular replacement using the bacterial subunit as the research model. Preliminary results will be presented.

P06.04.009 ATP BINDING TO THE N-TERMINAL DOMAIN OF HUMAN HEXOKINASE TYPE I REVEALED BY X-RAY CRYSTALLOGRAPHY. C. Rosano, M. Bolognesi [1], E. Sabini [2], M. Bianchi, G. Serafini, E. Bartolucci M. Magnani [3], [1] Advanced Biotechnology Center-IST and Dept. of Physics, University of Genova, Largo R. Benzi 10 16132 Genova (I), [2] Department of Chemistry, University of York, Heslington, York (UK), [3] Institute of Biological Chemistry, University of Urbino, Via Saffi 2, 61029 Urbino (I)

Human Hexokinase type I (HKI) is the enzyme starting glucolysis in the brain through the ATP-based glucose → glucose-6-phosphate (G6P) phosphorylation reaction.

HKI, which plays a key role in normal but also in malignant cancer cells, can be found bound to the mitochondrial membrane as well as in a cytoplasmic soluble form.

The enzyme associated with the membrane is dimeric or tetrameric; release from the membrane is favoured by nucleotides such as ATP, GDP, UDP.

Crystals of HKI belong to the monoclinic space group P21 with unit cell constants a=82.42 Å, b=174.35 Å, c=86.28 Å, beta=90.54º. Diffraction data were collected at 100 K at the EMBL/DESY synchrotron radiation facility in Hamburgh (D), beamline X11.

A total of 68,573 unique reflections up to 2.67 Å resolution were measured for a completeness of 87%, Rmerge=4.8%.

The structure of HKI was solved by molecular replacement methods using a previously determined human hexokinase model (PDB code 1HKB).

The HKI structure was refined through cycles of simulated annealing/slowcooling first, followed by maximum likelihood refinement with conjugate gradients. The final R factor is 0.208.

The electron density is continuos all over the dimeric protein, clearly showing the binding of glucose and G6P at both domains of each subunit.

Remarkably, an unexpected AMP-PNP molecule is found in a surface cleft next to the N-terminal part of the protein.

Based on their strategic location next to the membrane anchoris segments, it is proposed that the two nucleotide binding sites are involved in the control of HKI membrane association-dissociation processes.

P06.04.010 X-RAY STUDIES OF TWO GLYCOLYTIC ENZYMES FROM THE ARCHAEON SULFOLOBUS SOLFATARICUS. Crowhurst, G., Isupov, M. N. and Littlechild, J. A., Schools of Chemistry and Biological Sciences, University of Exeter, Exeter, UK.

Two glycolytic enzymes phosphoglycerate kinase (PGK) and glyceraldehyde-3-phosphate dehydrogenase (GAPDH) from the thermostable archaeon *Sulfolobus solfataricus* (which grows optimally at pH 3.5 and at 87°C) have been cloned into a pET expression system and overexpressed in *Escherichia coli*. Crystals of GAPDH were grown in space group $P42_12_12$ with unit cell dimensions a=b=102.3Å, c=181.6Å in PIPES pH 6.5, in the presence of cofactors NAD^+ and $NADP^+$ using 33% ammonium sulfate as the precipitant. The X-ray structure of apo GAPDH has been solved using isomorphous replacement method. The overall fold of this archaeal GAPDH is similar to that of eukaryotic and prokaryotic counterparts with which the enzyme shares low sequence identity (under 22 %), although there are additional, mainly α-helical, secondary structure elements. The long additional α-helix and following additional β-strand of catalytic domain β-sheet at the C-terminus of the enzyme create an

additional link between the catalytic and NADP+ binding domains. A conserved Asp at the end of the second β strand is replaced by Lys as the enzyme has a preference for $NADP^+$. Although the enzyme was originally reported to catalyse the reaction on glyceraldehyde the sulphate ions bound at the inorganic phosphate and the substrate phosphate binding sites suggest a preference for glyceraldehyde-3-phosphate. Although this archaeal GAPDH active site resembles that of the prokaryotic enzymes the residues of the catalytic domain are all shifted one β-strand across its β-sheet. Several ion pair clusters of up to 15 charged residues and a disulfide bond rarely found in intracellular proteins contribute to the marked enzyme thermostability (an activity half life of 17h at 80°C).

Small needle crystals of *S. solfataricus* PGK have been obtained from polyethylene glycol at a concentration of 24% w/v and 0.1M Tris-HCl buffer pH 8.5, using the hanging drop method.

P06.04.011 CRYSTALLOGRAPHIC STUDIES ON TRANSITION STATE MIMIC COMPLEXES IN THE XYLANASE/CELLULASE CEX. Valerie Notenboom and David Rose, Department of Medical Biophysics, University of Toronto, Toronto M5G 2M9, Canada, and Stephen G. Withers, Department of Chemistry, University of British Columbia, Vancouver V6T 1Z1, Canada.

The reaction mechanism employed by retaining β-1,4-glycanases has long thought to be a double displacement mechanism involving a covalent reaction intermediate. Significant evidence has been accumulating over the years supporting the existence of such an intermediate. Recently, crystallographic studies have shown the direct observation of the covalent reaction intermediate in the family 10 glycosidase Cex from using mechanism based 2-fluoro inhibitors [Notenboom *et al.,*1998, *Biochemistry* **37**:4751; White *et al.*, 1996, *Nat. Struct. Biol.* **3**:149], as well as trapping the intermediate in a mutated enzyme [Notenboom *et al.*,1998, *Nat. Struct. Biol.* **5**:812] . Details of the reaction driving forces are not well understood, in particular the enzyme-substrate interactions stabilizing the transition states that are flanking the covalent reaction intermediate are as yet unclear. Several residues surrounding the disaccharide during catalysis have been implicated in the reaction mechanism, as well as a possibly significant stabilizing force involving the 2'-hydroxy group of the proximal saccharide itself. As one approach to deconvolute these interactions present during different stages of catalysis we are looking at the crystal structures of several enzyme substrate complexes in which the substrate is a mimic of the proposed transition states. The main characteristics of these transition states are a partial positive charge carried by the cyclic oxygen and the C-1 carbon, and a planar conformation around this anomeric carbon. The compounds xylobiosyl imidazole and xylobiosyl lactam oxime exhibit these characteristics and have been shown to be good inhibitors of Cex (K_i 150 nM and 370 nM respectively). The crystal structures of Cex in complex with these compounds will be presented.

P06.04.012 CRYSTAL STRUCTURE OF DEOXYCYTIDYLATE HYDROXYMETHYLASE FROM BACTERIOPHAGE T4. S. W. Suh, H. K. Song, and S. H. Sohn, Department of Chemistry, College of Natural Sciences, Seoul National University, Seoul 151-742, Korea.

Bacteriophage T4 deoxycytidylate hydroxymethylase (EC 2.1.2.8), a homodimer of 246-residue subunits, catalyzes hydroxymethylation of the cytosine base in deoxycytidylate (dCMP) to produce 5-hydroxymethyl-dCMP. It forms part of a phage DNA protection system and appears to function *in vivo* as a component of a multienzyme complex called deoxyribonucleoside triphosphate (dNTP) synthetase. We have determined its crystal structure in the presence of the substrate dCMP at 1.6 Å resolution. The structure reveals a subunit fold and a dimerization pattern in common with thymidylate synthases despite low (~20 %) sequence identity. Among the residues that form the dCMP binding site, those interacting with the sugar and phosphate are arranged in a similar configuration as in the deoxyuridylate binding site of thymidylate synthases. However, the residues interacting directly or indirectly with the cytosine base show a more divergent structure and the presumed folate cofactor binding site is more open. Our structure reveals a water molecule properly positioned near C-6 of cytosine to add to C-7 methylene intermediate during the last step of hydroxymethylation. On the basis of sequence comparison and crystal packing analysis, a hypothetical model for the interaction between T4 deoxycytidylate hydroxymethylase and T4 thymidylate synthase in the dNTP-synthesizing complex has been built.

P06.04.013 X-RAY STUDIES OF TRYPTOPHANASE. M. N. Isupov[1], A.A. Lebedev[2], E.H. Harutyunyan[2], F.A. Antson[3], K.S. Wilson[3], G.G. Dodson[3], L.N. Zakomirdina[4], J. A. Littlechild[1] and I.S. Dementieva[4], 1 Schools of Chemistry and Biological Sciences, University of Exeter, Exeter, UK. 2 Institute of Crystallography, Leninsky pr. 59, Moscow, Russia 3 Department of Chemistry, University of York, York, UK 4 Institute of Molecular Biology, Vavilov Street 32, Moscow, Russia.

Tryptophanase is a bacterial PLP-dependent enzyme that catalyses *in vivo* degradation of L-tryptophan to yield indole, pyruvate and ammonia. Indole produced by enteric bacteria is metabolised into the neurological poison oxindole during the course of acute hepatic failure while the indole formation from tryptophan, catalysed by tryptophanase is a limiting step in oxindole synthesis. Tryptophanase is also a possible virulence determinant in meningitis, otitis and a number of other severe diseases caused by *Haemophilus influenzae*[1]. There is therefore a possible medical interest for structure-based development of tryptohanase inhibitors. The structure of the holotryptophanase from *Proteus vulgaris* [2] have been determined by molecular replacement using the related PLP-dependent enzyme tyrosine phenol lyase model [3]. A structure of *E.coli* tryptophanase which is over 80 % identical to *H. influenzae* tryptophanase is currently being refined at 2.7 Å, as is a 3.0 Å complex of *P.vuglaris* tryptophanase with a competitive inhibitor oxindolyl-L-alanine which traps the tryptophanase reaction at a quinonoid intermediate stage.

P06.04.014 CRYSTALLOGRAPHIC STUDIES OF E.COLI MHPC. F. Mohammed, G. Dunn, J.B. Cooper, D. Thompson S.P. Wood [1], T.D.H. Bugg, T.Robertson [2], [1] School of Biological Sciences, University of Southampton, Southampton SO16 7PX, UK, [2] Department of Chemistry, University of Southampton, Highfield, Southampton SO17 1BJ, UK

The E.coli MhpC (2-hydroxy-6-keto-nona-2,4 diene-1,9-dioic acid-5,6-hydrolase) is a C-C hydrolase (Mr 29000) involved in the catabolic pathway for the degradation of the aromatic compound, phenylpropionic acid. MhpC catalyses the hydrolytic cleavage of a C-C bond from 2,3 dihydroxyphenylpropionic acid to give succinic acid and 2-hydroxy-penta-2,4-dienoic acid.

The cleavage reaction occurs via an enzyme activated nucleophile which could be an activated water molecule or an amino acid side chain. By determining the three dimensional structure of the native enzyme we will gain further understanding of the catalytic mechanism.

The MhpC crystals were grown using the hanging drop vapour diffusion method. This enzyme crystallizes in the orthorhombic space group P21212 with cell dimensions a=144.60Å b=144.15Å c=62.23Å. A 2.9Å native data set has been collected with in-house equipment under cryogenic conditions.

Phase determination by isomorphous replacement is in progress.

P06.04.015 HIGH RESOLUTION COMPLEXES OF TYPE II DEHYDROQUINASES. A. W. Roszak, J. R. Coggins and A. J. Lapthorn, Dept's of Chemistry and Biochemistry, University of Glasgow, Glasgow, G12 8QQ, Scotland, U.K.

Dehydroquinate dehydratase [dehydroquinase or DHQase, EC 4.2.1.10] catalyses the dehydration of 3-dehydroquinate [DHQ] to 3-dehydroshikimate, a reaction common to two metabolic pathways, (i) the biosynthetic shikimate pathway [present in microorganisms and plants but absent in animals] and (ii) the catabolic quinate pathway in fungi (1). DHQase has been found to fall into two unrelated classes of enzyme, type I and type II (2). The existence of two distinct types of DHQase in microorganisms [e.g., *Escherichia coli* has a type I enzyme whereas *Streptomyces coelicolor, Helicobacter pylori* and *Mycobacterium tuberculosis* possess type II enzymes] offers a unique opportunity to inhibit selectively pathogenic microorganisms using the type II enzyme as a drug target.

Structures of several inhibitor complexes of the enzyme from *Streptomyces coelicolor* and *Mycobacterium tuberculosis* have been determined to better than 1.8Å resolution. We can compare these complexes with 1.6Å structure of a mutant DHQase (R23A) complexed with the reaction product, 3-dehydroshikimate. These structures provide a detailed picture of the enzyme active site [14 residues have been identified lining the active site] and have allowed us to develop a model of the enzyme mechanism. The proposed reaction mechanism requires abstraction of an axial proton from C2 of the substrate by a tyrosine residue. Site-directed mutagenesis of this key residue and other residues are now underway in order to confirm the model and to aid in assigning the relative contributions of residues to substrate binding and catalysis.

P06.04.016 THE S2 SUBSITE OF CYSTEINE PROTEASES: TWO CRYSTAL STRUCTURES OF PAPAIN WITH BOUND DIAZOMETHYLKETONE INHIBITORS. M.Kozak, R. Janowski, Dept of Crystallography, A.Mickiewicz Univ, Poznan, Poland, E.Jankowska, Z.Grzonka, Faculty of Chemistry, Univ of Gdansk, Poland, M.Jaskólski,Center for Biocrystallographic Res, Pol Acad Sci, Poznan, Poland.

Papain from the latex of Carica papaya is the best studied representative of a superfamily of cysteine proteases. Cysteine proteases are a major component of lysosomal proteolytic systems and play a significant role in intracellular proteolysis. In abnormal cases, uncontrolled activity of cysteine proteases may lead to serious tissue-degenerative disorders, such as muscular dystrophy, osteoporosis, pulmonary emphysema, and tumors. Our previous crystallographic studies of papain inhibited by chemically reacting the enzyme's thiol nucleophile with an oxirane ring attached to a peptidic fragment (ZRLVψ[CH_2-NH]-CO-) showed that the inhibitor's P2 site (Val) does not occupy the S2 pocket of the enzyme, in contrast to earlier conclusions that P2-S2 complementarity is essential for productive inhibition and for enzyme specificity. Our observation has been confirmed by careful analysis of other complexes based on the same chemical principle (reactive oxirane function) in which no significant P2-S2 association could be found. In the next step, we have synthesized another inhibitor, with similar amino acid sequence, ZRLVG-, but with a different, diazomethyl (DAM), reactive group attached. A covalent complex between papain and this inhibitor has been formed and crystallized. The structure has been solved by molecular replacement and refined to R=0.168 for X-ray data extending to 1.78 Å resolution. The structure demonstrates again no specific association between the S2 pocket and the inhibitor's P2 site. This persistent lack of P2-S2 interactions in our ZRLV-type inhibitors is in contrast to the early findings by Drenth that covalent, methylketone- type, inhibitors containing the peptidic sequence -FX-CH_2- had invariably the side chain of the phenylalanine P2 subsite located in the enzyme's S2 pocket. As a step towards understanding these differences we have synthesized a new inhibitor, ZLFG-DAM, containing phenylalanine at the P2 site, and reacted it with the active site of papain. Single crystals of the complex have been grown and diffraction data to 2.0 Å resolution have been collected. The structure of the complex has been solved by molecular replacement and refined to R=0.170. It unambiguously reveals that the P2 phenylalanine side chain is located in the S2 pocket of the enzyme. We therefore conclude that in covalent complexes, hydrophobicity of the P2 residue is not sufficient for productive binding of the inhibitor in the S2 pocket of papain and that the bulkiness of this residue is equally important. This does not preclude, however, that even smaller residues, like Val, may be effective during recognition and docking prior to the formation of the covalent link

Research supported by grant 279/P04/97/13 from KBN (Poland).

P06.04.017 CRYSTAL STRUCTURE OF A HETERODIMERIC PLA_2 COMPLEX FROM TWAIWAN VIPER: STRUCTURAL ANALOGUE OF VIPOXIN. Ch. Betzel[1], N. Genov[2], Inn-Ho Tsai[3] and K.R. Rajashankar[1] [1]Institute of Physiological Chemistry, UKE, c/o DESY, Building 22a, Notkestrasse 85, 22603, Hamburg, Germany [2]Institute of Organic Chemistry, Bulgarian Academy of Sciences, Sofia 1113, Bulgaria, [3]Institute of Biological Chemistry, Academia Sinica, P.O. Box 23-106, Taipei, Taiwan, R.O.C

The heterodimeric complex from Taiwan viper (*Vipera russelli formosensis*) (F4/F7 complex), a 28 kDa molecule, is composed of a neurotoxic Phospholipase A_2 (designated F4) and a non-toxic PLA_2 like component (F7). Despite a high sequence identity of 65%, the biological and pharmacological activities of F4 and F7 are contrasting. While F4 shows PLA_2 enzymatic activity, F7 is very weak in this. F4 is neurotoxic while F7 is not. Interestingly, F7 potentiates the lethal potency and neurotoxicity of F4. F4/F7 complex can be considered as the first structural analogue of Vipoxin. - a heterodimeric complex of a highly toxic PLA_2 (Vp) and a catalytically inactive PLA_2 like natural inhibitor (Inh) - found in Bulgarian viper (*Vipera ammodytes meridionalis*). The primary structure of F4 and F7 are 92% identical to those of Vp and Inh, respectively. Despite this similarity, there are marked difference in the biochemical and pharmacological properties of F4/F7 complex and Vipoxin. Hence F4/F7 complex appears like a natural mutant of Vipoxin complex with altered biochemical and pharmacological properties. The 3-D structure of F4/F7 complex will provide structural basis for these differences and augment the knowledge on modulation of PLA_2 activity and toxicity.

F4/F7 complex was crystallized using hanging-drop vapour diffusion and macroseeding techniques. The space group is monoclinic $P2_1$ (a=74.92, b=85.13, c=78.16 Å and β=95.12º) with four molecules of F4/F7 complex in the asymmetric unit. The structure was determined using molecular replacement method. We will present a comparative analysis of the structural features of

the complexes F4/F7 and Vipoxin. Both structures were analysed with synchrotron radiation to 2.0 Å resolution and are so far the only known heterodimeric PLA_2 complexes.

P06.04.018 THREE POLYMORPHIC FORMS OF E. COLI ASPARAGINASE II D90E MUTANT. D.Borek, M.Kozak, Dept of Crystallography, A.Mickiewicz Univ, Poznan, Poland, M.Jaskólski, Center for Biocrystallographic Res, Pol Acad Sci, Poznan, Poland.

Asparaginases convert asparagine to aspartic acid and ammonia. There is a group of these enzymes, found in the periplasm of some bacteria, which have high asparaginase affinity ($K_m \sim 10^{-5}$ M) and variable degree of glutaminase activity. Some of them, from *E. coli* (EcAII) and from *Erwinia chrysanthemi* (ErA), are valuable drugs in the treatment of certain kinds of leukemia. The crystal structure of EcAII revealed a triad of catalytic residues (T89-K162-D90) in the active center and the oligomeric nature of the enzyme. All known bacterial asparaginases are 222-(pseudo)symmetric ABCD homotetramers with four active sites created within pairs of monomers (AC and BD). In order to elucidate the role of the catalytic residues in the enzymatic process and substrate specificity, we have characterized crystallographically a D90E mutant of EcAII (kindly provided by Prof. K.Röhm, Philipps Univ., Marburg) in which the catalytic-triad aspartic acid has been replaced by a similar but bigger Glu residue. The mutant protein has been obtained in three different crystal forms. One of them (I), grown from a solution containing 2M sodium citrate and Hepes, pH 7.5, is trigonal ($P3_121$) and contains the active-site-competent AC dimer in the asymmetric unit. Forms II ($P2_12_12$) and III ($P2_12_12_1$, $P2_12_12$ or $P222_1$) are orthorhombic, but have different contents of the asymmetric unit. Form II (grown at pH 9.0 using PEG-MME 500 as precipitant) has one complete tetramer plus the AC dimer in the asymmetric unit. Form III (grown analogously to form I) has one tetramer in the asymmetric unit. Complete diffraction data have been collected for forms I (2.6 A) and II (2.3 A). For form III, which is very unstable in the X-ray beam, only incomplete (60%) data are available (2.3 A). The crystal structures of forms I and II have been solved and refined to the crystallographic R factor of 0.21 and 0.24, respectively. Electron density maps unambiguously confirm the mutation and illustrate the reduction of the size of the active site cavity upon D90 $\rightarrow$ E90 substitution. In spite of the different crystallisation conditions (pH) for forms I and II, none of the eight independent active sites seems to be occupied, in contrast to the EcAII structures reported earlier which invariably have the reaction product, aspartate, bound in the active site.

P06.04.019 STRUCTURES IN THE VITAMIN B_{12} BIOSYNTHETIC PATHWAY. H.L. Schubert and K.S. Wilson Protein Structure Group, Department of Chemistry University of York, Heslington, York, England YO10 5DD E. Raux, J. Roper, M.J. Warren Department of molecular Genetics, Institute of Ophthalmology, University College London, London EC1V 9EL.

Vitamin B_{12} is an essential mammalian dietary factor synthesised by various microorganisms. The thirty enzymes are required for its synthesis that can utilize up to 1% of a bacterial proteome. In addition to a lengthy and intricate biosynthesis, alternate aerobic and anaerobic synthetic routes exist, and encompass such diverse chemistry as single-carbon methylation, ring contraction, side chain amidation, and metal ion chelation. The X-ray structures of two individual enzymes have recently been solved, the precorrin-4 methylase from *Bacillus megaterium*, CbiF, and the anaerobic cobalt chelatase from *Salmonella typhymurium*, CbiK.

Though the initial steps in tetrapyrrole cofactor biosynthesis are identical, beyond the intermediate uroporphobilinogen III the pathways diverge and share no common enzymatic steps other than metal ion insertion. Two general classes of chelatases can been identified. The heterotrimeric, ATP dependent chelatases encompass the aerobic cobalamin biosynthetic pathway, the magnesium chelatase from chlorophyll biosynthesis and the nickel chelatase involved in F_{430} production. Monomeric ATP-independent chelation occurs in anaerobic cobalamin, haem and sirohaem production. The structure of two monomeric chelatases have now been solved, protoporphyrin IX ferrochelatase and the anaerobic cobalt chelatase. Though these two enzymes were though to be non-homologous, the structures have turned out to be remarkably similar and aspects of both reactions can be understood more clearly through a comparison of the two structures.

P06.04.020 X-RAY CRYSTAL STRUCTURE ANALYSIS OF A MUSHROOM RIBONUCLEASE FROM LENTINUS EDODES. Y.Kitagawa, A.Komaki, K.T.Nakamura [1], H.Kobayashi, N.Inokuchi, T.Koyama [2], K.Ohgi, M.Irie [3], [1] School of Pharmaceutical Sciences, Showa University, Tokyo 142-8555, Japan, [2] College of Pharmacy, Nihon University, Chiba 274-8555, Japan, [3] Hoshi College of Pharmacy, Tokyo 142-8501, Japan

A T2 type ribonuclease was isolated and purified from an edible mushroom, lentinus edodes (RNase LE2). It does not have strict base specificity but is preferable in the order of A>G>C>U. The RNase LE2 consists of 239 amino acid residues and shows approximately 30% sequence identity to the other T2 type ribonucleases (such as T2 and Rh).

We obtained two types of crystal. One is from the solution with the precipitant of PEG8000 (Form I) and the other is with ammonium sulfate (Form II). Both crystals belonged to the same space group $P2_12_12_1$, with unit cell dimensions of a=71.38, b=87.28, c=33.46 Å for the Form I crystal, and of a=71.23, b=90.88, c=31.43 Å for the Form II crystal. The crystal structure of RNase LE2 was solved by the molecular replacement methods using the AMoRe program package, with the structure of ribonuclease Rh as the search model (1).

The structure has been refined with an overall R factor of 23% and a free R factor of 29% up to 2.34 Å resolution. Water molecules have not included in the refinement yet. The further refinement is under way. The basic structure is composed of 4 β-strands and 6 α-helices. The detailed structure of RNase LE2 and its implications to the catalytic mechanism of ribonucleases will be discussed.

P06.04.021 CRYSTAL STRUCTURES OF RIBONUCLEASE LE COMPLEXED WITH RNA FRAGMENT SHOW THE ADDITIVITY OF SUBSTRATE FRAGMENT. N. Tanaka, J. Arai and K.T. Nakamura, School of Pharmaceutical Sciences, Showa University, Tokyo 142-8555, Japan, and N. Inokuchi and T. Koyama, College of Pharmacy, Nihon University, Funabashi 274-0063, Japan, and K. Ohgi and M. Irie, Hoshi College of Pharmacy, Tokyo 142-8501, Japan.

Ribonuclease LE (RNase LE) from cultured tomato (*Lycopersicon esculentum*) cell is a member of the RNase T_2 family showing broad base specificity. RNase LE consists of 205 amino acid residues and has a molecular mass of 22,666 Da. As basis for further studies on the chemistry and molecular biology of T_2 family ribonucleases, here we report on the first example of three-dimensional structure of a plant ribonuclease, RNase LE.

Crystals of RNase LE belong to an orthorhombic space group $P2_12_12_1$with cell dimensions of a = 74.02 Å, b = 78.79 Å and c = 32.93 Å. There is one molecule per asymmetric unit. The structure has been solved by the multiple isomorphous

replacement method using five derivatives and refined to an R value of 0.205 (free R value of 0.283) at 1.65 Å resolution.

The structure consists of seven α-helices and seven β-strands, belonging to α+β type structure. Comparison of the structure of RNase LE with that of RNase Rh, a microbial RNase belonging to the RNase T_2 family, shows that, while the overall folding topology are similar to each other, insertion and deletion are found at the N-terminal regions.

The substrate-fragment complex crystals were obtained by transferreing the native crystals into a series of substrate-fragment solutions containing guanosine 2'-monophosphate (2'-GMP: inhibitor), guanosine 3'-monophosphate (3'-GMP: substrate fragment), guanosine 5'-monophosphate (5'-GMP: substrate fragment), or deoxyguanylyl-3,5-deoxyguanosine (d(GpG): substrate analogue). The structures of these four complexes have been solved by the difference Fourier method and refined to R values below 0.20 at 1.8 Å resolution.

These complexes reveal interesting features: the substrate fragments and substrate analogue bound in the productive binding mode while inhibitor bounds non-productive binding mode; and the binding mode of 3'-GMP at B_1 subsite and that of 5'-GMP at B_2 subsite are similar to that of d(GpG) bound at both B_1 and B_2 subsite. These observations show that the binding of substrate fragments may conform to the principles of additivity.

P06.04.022 STRUCTURE OF THE CHITINASE FROM JACK BEAN M. Hahn [(1)], M. Hennig [(2)], B. Schlesier [(3)] and W. Höhne [(1)], (1) Institut für Biochemie der Charité, Humboldt-Universität, Monbijoustr.2, 10117 Berlin, Germany. (2) F. Hoffmann-LaRoche AG Pharma Research 65/308 CH-4070 Basel, Switzerland. (3) IPK Gatersleben, Corrensstr. 3, 06466 Gatersleben, Germany

Chitinases hydrolyze the β-1,4-glycosidic bond between N-Acetylglucosamins in chitin, one of the most abundant biomolecules. Chitinases in plants function as defense proteins against fungi. The structure of barley chitinase was solved previously [1,2]. It is a α-helical protein with three disulfide bridges and a putative substrate-binding groove along the molecule. The chitinase from jack bean was purified from seeds and crystallized in space group $P6_1$. The monomeric enzyme consists of 243 amino acids and is 66% identical in sequence to the chitinase from barley. It could be solved with molecular replacement using the barley enzyme as a search model. The refined structure has a R-factor of 18.7% (R_{free}= 22.2%) at a resolution of 1.8 Å. R.m.s. deviations from standard bond lengths/bond angles are 0.008 Å/1.43°, respectively. The overall fold and the secondary structures are the same as in the barley enzyme. The superposition of all C_α-positions of the two enzymes gives a r.m.s. deviation of 0.98 Å. The conserved amino acids are located in the interior of the protein and in the binding groove, whereas mutated positions are mostly found on the protein surface. A cleavage mechanism with inversion of configuration at the anomeric carbon was proposed for the barley chitinase [3]. In our structure a water molecule was found, that binds to the proposed residues in the active site. It could act as the nucleophil in substrate cleavage and supports the idea of a single rather than a two-step mechanism for this type of enzyme.

P06.04.023 BENZYLALCOHOL DEHYDROGENASE - A HIGH-PERFORMANCE ADH FOR SPECIALISED SUBSTRATES. Jeremy Beauchamp[†], David Gillooly[‡], Charles Fewson[‡] and Adrian Lapthorn[†], [†]Dept. of Chemistry & [‡]IBLS, University of Glasgow, Glasgow G12 8QQ. UK.

The structure of benzyl alcohol dehydrogenase (BADH) from *Acinetobacter calcoaceticus* has been determined at 2.2Å resolution. The enzyme is an anomalously efficient member of the zinc-dependant type II alcohol dehydrogenase family that enables *A. calcoaceticus* to use benzyl alcohol and similar molecules as its sole energy source.

Crystals were grown using an initial sparse-matrix screen followed by refinement of the most promising conditions. Careful control of the reducing environment, precipitant concentration and additives were critical for the production of high quality crystals. Despite this, the crystals were short-lived and diffracted poorly after more than a week in the mother liquor. Data were collected, however, at Daresbury SRS (9.5) and the structure was solved by molecular replacement using AMoRe with subsequent refinement using Refmac.

The structure implies an enzyme mechanism that is extremely well characterised in the horse-liver alcohol dehydrogenase system. However, there are highly significant adaptations for the substrates peculiar to BADH. The implications for enzyme engineering, molecular evolution and the reaction mechanisms of the alcohol dehydrogenase family will be discussed.

P06.04.024 CRYSTAL STRUCTURE OF CYTOSOLIC CREATINE KINASE: PROPOSED CATALYTIC MECHANISM. Dominic Tisi[1],Ben Bax[2] and Andreas Loew[3], Biophysics Section, Blackett Laboratory, Imperial College, Prince Consort Road, London SW7 2BZ, Uk, Department of Crystallography, Birkbeck College, Malet Street, London WC1E 7HX, UK and University of Illinois at Chicago, Department of Biochemistry and Molecular Biology, College of Medicine West, 1819 West Polk Street, Chicago, USA

Creatine kinase (E.C.2.7.3.2) (CK) belongs to the family of ATP:guanidino phosphotransferases and plays an essential role in energy metabolism. CK catalyses the reversible transfer of the phosphate moiety from phosphocreatine (PCr) to ADP, generating creatine and ATP.
