ARTICLE INFO

The authors dedicate this article to the memory of Prof. Alexander A. Kuzubov as he was the one who originally inspired this work but deceased before we could finish it.

Keywords: Transition metal dihalides Monolayers DFT Hubbard correction Band structure

ABSTRACT

Electronic structure and magnetic properties of the family of first-row transition metal dihalides (TMHal₂, TM = V, Cr, Mn, Fe, Co, Ni; H = Br, I) monolayers were studied by means of density functional theory. Strong electron correlations were taken into account by implementing Hubbard U correction in a simplified scheme proposed by Dudarev et al. (U_{eff}). U_{eff} correction essentially affects electronic structure of TMHal₂ widening the band gap and witnessing their highly spin-polarized nature. Two different ligand orientations namely, H and T configurations of monolayers were considered. Unlike others, FeHal₂ monolayers tend to form H structure when U_{eff} correction is included.

1. Introduction

Since the discovery of free-standing graphene [1,2], two-dimensional materials have attracted lots of attention due to their unusual mechanical and electronic properties being rather different from those of the bulk material. In particular, they are being considered as promising materials for spintronics. The use of low-dimensional materials allows decreasing the size of spintronic devices essentially. However, the utilization of graphene in spintronic devices is limited due to its conducting semi-metal nature while contemporary tasks often require a semiconducting or half-metallic material. Along with tuning graphene properties by various methods, new 2D layered materials are developed. Transition metal dichalcogenides (TMD) are of a particular interest because of the wide variety of their electronic properties which enables one to use them in opto- and nanoelectronics [3]. The most studied among all the TMD monolayers are MoX_2 and WX_2 (X = S, Se), or so-called MoWSeS materials [4]. However, to the date, vast majority of TMD family does not possess magnetic ordering. The only exceptions are VS₂ and VSe₂ which appear to be surprisingly intrinsic ferromagnets

[5-7]. It's worth to note that TMD monolayers are actually not atomically thin but represent a three-layered structure with metal ions being sandwiched between two chalcogen's layers. There are, then, two possible configurations of layers mutual arrangement, namely, H (hexagonal, with metal in trigonal prismatic surrounding) and T (trigonal, with metal in octahedral surrounding). It was shown by density functional calculations that quantum confinement effect plays a key role in stabilization of monolayer structure. Even though bulk VS2 has T structure and keeps it when going to the bilayer, H configuration is more favorable for its monolayer [7]. This, in turn, affects monolayer's properties strongly, particularly magnetic ordering. The strain dependence of magnetism in VX_2 (X = S, Se) was explained by Ma et al. as the complex interplay between covalent and ionic bonding [5]. There are several studies aimed to modulate magnetic properties of TMD monolayers by strain, functionalization of the material or their combination [8.9].

Transition metal dihalides (TMHal₂) are substantially less investigated though being structurally analogous to TMD family in terms of the monolayer structure. Up to the date, TMHal₂ monolayers have

not been obtained yet, though there are some reports of PbI₂ monolayer preparation by ion intercalation [10]. Fast development of two-dimensional materials synthesis methods such as liquid exfoliation assisted by surfactants or polymers [11] makes it reasonable to expect TMHal₂ monolayers to be obtained in the nearest future. Along with that, one can expect them to possess challenging magnetic properties due to both larger degree of ionic bonding and expected complex magnetic ordering [12]. However, only a few theoretical studies of their electronic structure can be found [13,14]. Some spin polarization was reported for several compounds, namely, vanadium, cobalt, nickel dihalides [14]. Previously, properties of TMHal₂ were investigated in Tstructure only while, as was shown [7], H structure can be stable as well even if not existing in the bulk.

According to the literature, all first-row TMI_2 (TM = V, Cr, Mn, Fe, Co, Ni) compounds are antiferromagnets [15-17]. Most of TMHal₂ possess CdI₂-type structure (so-called 1T structure, P-3m1 space group), except of NiHal₂ obeying CdCl₂-type structure (3T structure with ABC stacking of both nickel and halide ions, R-3m:H space group) [18] and CrHal₂, for which both orthorhombic (Cmc21) [19] and pseudo-hexagonal monoclinic (C2/m) [20] structures are reported. Friedt et al. [21] reported the simplest antiferromagnetic structure compatible with the Mössbauer spectroscopy results for VI₂, CoI₂, NiI₂ to be A-type antiferromagnetic phase with spins aligned along the metal to iodine bonds while FeI_2 is proposed to be DF-type antiferromagnet [21,22]. This magnetic structure is similar to that of MnBr₂ [23] but magnetic moments are parallel to c axis and perpendicular to Fe layers. Magnetic unit cell of FeI₂ is 16 times larger than crystallographic unit cell. According to the neutron diffraction data, MnI₂ possesses helical antiferromagnetic ordering with moments ferromagnetically aligned in (307) planes and rotated by $2\pi/16$ in subsequent sixteen (307) planes [24].

The present work is aimed to study the role of strong electron correlations in determination of the main features of electronic and magnetic properties of the first-row transition metal dihalides $TMHal_2$ (TM = 3d metal, Hal = Br, I) using GGA + U calculations. For the sake of comparison, the conventional GGA-PBE approach was used as a reference.

2. Computational methods

All calculations were performed within the framework of density functional theory using PBE exchange-correlation functional [25,26] and projector augmented wave method [27,28], as implemented in Vienna Ab-initio Simulation Package [29–32]. Grimme D3 correction [33] was used to describe van-der-Waals interactions between TMHal₂ layers. In order to account the correlation effects which are usually significant in transition metal compounds, the simplified form of Hubbard U correction proposed by Dudarev et al. [34,35] was implemented. Effective U parameters (U_{eff} = U - J, where U stands for the Coulomb repulsion and J is the exchange parameter) for TM atoms were adopted from Wang et al. [36].

First, unit cell optimization of transition method dihalides (TM = V, Cr, Mn, Fe, Co, Ni; Hal = Br, I) was performed. Then, monolayers were cut from the initial structures along the (001) surface. Two different configurations of TMHal₂ monolayers were considered, namely, H (trigonal prismatic) and T (octahedral) ones (see Fig. 1). In fact, firstlayer ligand atoms in T configuration are rotated by 60° with respect to the second-layer atoms while both first and second ligand layers have the same orientation for H configuration.

The Mönkhorst-Pack [37] scheme was implemented for k-point Brillouin zone sampling. $9 \times 9 \times 1$ k-point mesh was used for NiBr₂, NiI₂ bulk unit cells possessing 3T structure while $9 \times 9 \times 3$ grid was used for bulk calculation of other compounds with 1T structure. A vacuum interval of 20 Å was set normal to the monolayer plane in order to avoid artificial interactions in periodic boundary conditions. *k*-point grid contained $9 \times 9 \times 1$ points for all monolayer structures. Stopping criterion for the geometry optimization was the force acting on atoms less than 0.001 eV/Å. For the sake of comparison, formation energy of different TMHal₂ structures per formula unit was calculated as

$E = E_{ML}/n_1 - E_{UC}/n_2$

 E_{ML} and E_{UC} stand for total energies of the monolayer and corresponding bulk unit cell, n_1 and n_2 stand for the number of formula units per monolayer and bulk unit cell, respectively.

Phonon spectra were calculated as an indicator of stability and the structures with 3 or less small negative modes which have purely computational origin were considered to be stable (see Figs. 1S-12S in SI). In order to verify structural stability of planar 2D TM halide materials against bending due to internal mechanical stress [38], a set of additional calculations of halide 3×3 clusters was performed. Neighboring images were distinguished from each other by 10 Å of vacuum in each direction in order to prevent artificial interactions in periodic boundary conditions. Structures are considered as stable as they do not

Fig. 1. Structures of (a) H and (b) T configurations of TMHal₂ monolayers. TM ions are presented in dark blue, halide ions are presented in purple. Black rhombus demonstrates the top view of monolayer unit cell.

twist and retain their planar geometry during the optimization process (see Fig. 13S).

3. Results and discussion

3.1. Structural parameters

Unit cell parameters and formation energy values for $TMHal_2$ structures are summarized in Table 2. Structural parameters obtained for bulk $TMHal_2$ compounds are in good agreement with experimental values [18,20,39–41]. It's worth noting that PBE + U method gives slightly larger values of the cell vectors than pure PBE does. Anyway, it shows more accurate values of the lengths of metal-ligand bonds [18,20,39–41] in these compounds.

At PBE level of theory, T configuration of monolayer is energetically favorable in all cases, in conformity with the fact that bulk materials

Fig. 3. Dependence of NiI₂ band structure on the value of U_{eff} parameter. At $U_{eff} = 0$ eV PBE + U approach is equivalent to PBE. Increasing of U_{eff} leads to visible increase of spin-down band gap. At $U_{eff} = 6.4$ eV and higher the spin-down band gap stays virtually the same and approximately equal to 1.80 eV. Black and purple lines correspond to spin-up and spin-down states, respectively.

Fig. 4. PBE (left) and PBE + U (right) spin-resolved band structures, TDOS (black lines) and vanadium ion PDOS (red lines) of VBr₂ (top) and VI₂ (bottom).

adopt this structure as well. At GGA + U level of theory, the only exceptions are FeBr₂ and FeI₂ with H configuration favorable with a minor difference of ~0.1 eV per formula unit between H and T configurations. The value of $U_{\rm eff}$ correction strongly affects the stability of

H structure in FeHal₂. A set of additional test calculations was performed to find the U_{eff} value threshold for the inversion of T/H structure stability. All U_{eff} values less than 4.0 eV as well as combinations with non-zero J value (J = 1.0 eV) result in stable T configuration. The

Fig. 5. PBE (left) and PBE + U (right) spin-resolved band structures, TDOS (black lines) and chromium ion PDOS (red lines) of CrBr₂ (top) and CrI₂ (bottom).

Fig. 6. PBE (left) and PBE + U (right) spin-resolved band structures, TDOS (black lines) and manganese ion PDOS (red lines) of MnBr₂ (top) and MnI₂ (bottom).

same effect was previously shown for some TMDs [3,7]. In order to prove our choice of U, additional test electronic structure calculations of FeCl₂ T monolayer were carried out. This structure was previously investigated by Torun et al. [42] using GGA-PBE and hybrid HSE06 functionals and found to be half-metallic with spin-down band gap of

4.4 (PBE) or 6.7 (HSE06) eV. We performed band structure calculation of FeCl₂ using GGA-PBE with the effective Hubbard correction of 4 eV and found the spin-down band gap width (~6.3 eV, see below) to be in a good agreement with HSE06 functional (see Fig. 14S in SI).

Formation energies of favorable monolayer configurations are

Fig. 7. PBE (left) and PBE + U (right) spin-resolved band structure, TDOS (black lines) and cobalt ion PDOS (red lines) of CoBr₂ (top) and CoI₂ (bottom).

considerably small, confirming van-der-Waals character of bonding between adjacent layers in the bulk and assuring of the possibility of monolayers experimental synthesis (Table 2).

3.2. Electronic and magnetic properties of 2D transition metal dihalides

Since Br^- and I^- anions are known to be weak field ligands, dorbitals of TM ions are not expected to split much and so the high-spin state is likely to occur which means that $TMHal_2$ compounds should possess magnetic moment on the metal ions. In agreement with

Fig. 9. PBE (left) and PBE + U (right) spin-resolved band structures, TDOS (black lines) and nickel ion PDOS (red lines) of FeBr₂ (top) and FeI₂ (bottom).

Table 3

Band gaps for energetically favorable $TMHal_2$ monolayers. Direct and indirect gaps are denoted as (d) and (i), respectively.

TMHal ₂ structure	Band gap (PBE + U)	Band gap (PBE)
VBr ₂ T	3.10 (i)	1.10 (i)
CrBr ₂ T	half-metal	half-metal
MnBr ₂ T	3.70 (i)	1.50 (i)
FeBr ₂ T	-	half-metal
FeBr ₂ H	2.00 (i)	-
CoBr ₂ T	2.30 (d)	spin-gapless
NiBr ₂ T	2.50 (i)	0.70 (i)
VI ₂ T	3.00 (i)	1.00 (i)
CrI ₂ T	half-metal	half-metal
MnI ₂ T	2.50 (i)	1.00 (i)
FeI ₂ T	-	1.20 (i)
CoI ₂ T	1.50 (d)	metal
NiI ₂ T	1.80 (i)	1.15 (i)

previous theoretical results [13,14], both PBE and PBE + U methods show large magnetic moments localized on TM ions for all structures under consideration (see Fig. 2).

Then, electronic structures of TMHal₂ monolayers were analyzed. Effective U_{eff} parameter for Ni ion proposed by Wang et al. [36] is noticeably larger than for the other TM ions (see Table 1). In order to check the validity of this value, a series of additional band structure calculations with different U_{eff} was performed for NiI₂ bulk unit cell. Fig. 3 illustrates the change in electronic structure with the increase of U_{eff}.

Ten different values of U_{eff} were tested, namely, 0.0 (corresponding to the conventional PBE); 0.4; 1.4; 2.4; 3.4; 4.4; 5.4; 6.4; 7.4 eV. As U_{eff} increases from 0.0 to 5.4 eV, the spin-down conduction band edge moves up from the Fermi level so NiI₂ changes its nature from spin-gapless semiconductor [43,44] to the ordinary spin-polarized semiconducting material. Spin-down valence band shifts to higher energies as well, almost approaching the Fermi level when U_{eff} = 7.4 eV. Highest occupied spin-up band lies close to the Fermi level without crossing it, spin-up band gap doesn't change as U_{eff} increases. Spin-down band gap

remains virtually the same (1.80 eV) for $U_{eff} = 6.4 \text{ eV}$ and higher. Hence, keeping in mind the absence of experimental data, $U_{eff} = 6.4 \text{ eV}$ [36] was used for further calculations.

Figs. 4–9 show band structures, total (TDOS) and partial (PDOS) densities of states for energetically favorable $TMHal_2$ configurations. It can be clearly seen that Hubbard correction influences electronic properties of structures under investigation drastically.

For both VBr₂ and VI₂ U_{eff} correction enlarges the spin-up band gap without changing their semiconducting nature (~1 eV and ~3 eV, respectively) (see Fig. 4). Oppositely, only spin-down channel of chromium dihalides is affected when implementing Hubbard correction. Both CrBr₂ and CrI₂ demonstrate large spin-down band gap along with half-filled states crossing the Fermi level in spin-up channel revealing their half-metallic nature (Fig. 5). MnBr₂ monolayer is more complex in these terms. Introduction of U_{eff} parameter not only changes the width of spin-down gap but also shifts the whole spin-up channel down in energy by ~3 eV (Fig. 6). This doesn't happen for MnI₂ which is more similar to chromium compounds: spin-down band gap becomes larger while spin-up channel is practically intact.

Introduction of non-zero U_{eff} correction changes the electronic properties of cobalt dihalides drastically (Fig. 7). At PBE level of theory, CoBr₂ has typical spin-gapless band structure with large spin-up band gap (4.10 eV), and CoI₂ is metallic. Introduction of Hubbard correction leads to significant shift of both valence and conduction band edges resulting in semiconducting CoHal₂ band structures.

At PBE + U level of theory the nickel halide spin-down band gaps are almost twice larger than the PBE ones while spin-up electronic subsystems are virtually intact (Fig. 8). Both NiBr₂ and NiI₂ are spin-polarized semiconductors.

Iron dihalides are kind of exception since including of U_{eff} correction leads to the inversion of energetically favorable configuration. While T-configuration (PBE level of theory) demonstrates half-metallic behavior for both FeBr₂ and FeI₂, the H-configuration monolayers (PBE + U method) are spin-polarized semiconductors (Fig. 9).

For all semiconducting compounds, except of MnBr₂, the top of the valence band reaches the Fermi level while MnBr₂ demonstrates conduction band touching the Fermi level. This opens a possibility to tune their properties by inducing point defects or doping and easily obtain half-metallic materials instead of semiconducting ones.

The values and characters of the $TMHal_2$ band gaps are summarized in Table 3. Most of TM dihalides are indirect gap semiconductors. For them, introduction of U_{eff} correction enlarges the band gap without changing its indirect nature. Oppositely, cobalt halides monolayers demonstrate direct band gaps at PBE + U level of theory instead of metallic/spin-gapless band structure obtained by using PBE method.

Atomic charges of transition metal ions in $TMHal_2$ 2D monolayers are presented in Fig. 10. Generally, the TM atomic charges decrease from V to Ni correlating with the decrease of the ionic size. Chromium dihalides are the exceptions of this trend which can be attributed to the high degree of structural deformation in comparison with their bulk counterparts which have pseudo-hexagonal monoclinic symmetry with distorted octahedral surrounding of Cr while the optimized 2D structures have six equidistant halide atoms around each chromium ion, similarly to the other structures having triangular symmetry of the bulk counterparts.

TM atomic charges in TMBr₂ are higher than in TMI₂, in agreement with bromine higher electronegativity. In general, PBE + U shows higher charges on TM ions, except of Cr. The difference between PBE and PBE + U results increases from V to Ni and from Br to I. However, the common trend can be clearly seen confirming the validity of PBE + U approach.

4. Conclusion

According to the results of PBE calculations, most of TMHal₂ monolayers are semiconductors, except of metallic CoI₂, spin-gapless

CoBr₂ and CrHal₂ which are half-metals. In general, introduction of Hubbard correction leads to the increase of the band gap. According to the results of PBE + U calculations, most of TMHal₂ monolayers are spin-polarized semiconductors, though there's an option of altering their properties to half-metallic. Chromium dihalides monolayers were found to be intrinsic half-metals. Inclusion of Hubbard U_{eff} correction enlarges the band gap, predominantly in one spin channel and may lead to the completely different electronic properties in comparison with pristine PBE. This effect is especially noticeable for Co-base compounds. In some cases, Hubbard correction can even lead to the inversion of favorable monolayer configuration, as was demonstrated for iron dihalides. Nevertheless, both methods give the same values of magnetic moments on metal atoms and the same trends for their partial charge dependence.
